
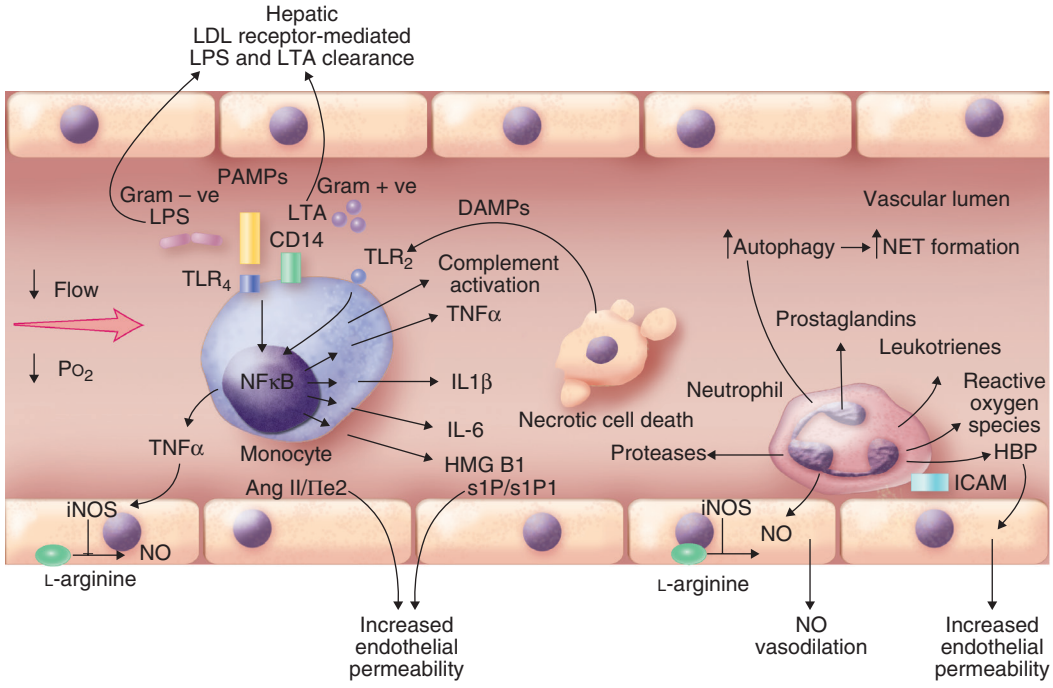
E-FIGURE 94-2. **Clearance of endotoxin by the liver via the LDL receptor pathway.** Schematic view of hepatocytes within the liver. Free proprotein convertase subtilisin/kexin type 9 (PCSK9) in plasma binds to an extracellular portion near the N terminus of the LDL receptor (LDLR) and triggers endosomal internalization. The C-terminus portion of PCSK9, now complexed to LDLR, mediates PCSK9 and LDLR degradation. The net result of increased PCSK9 activity is lower levels of membrane-associated LDLR. Bacterial lipids, such as endotoxin and lipoteichoic acid, are carried within LDL and other lipoproteins. Decreased PCSK9 increases clearance of LDL and associated pathogen lipids, thereby reducing the harmful effects of the pathogen lipids.



E-FIGURE 94-3. **Inflammatory responses to sepsis.** Gram-positive and gram-negative bacteria, viruses, and fungi have unique cell wall molecules called pathogen-associated molecular patterns (PAMPs) that bind to pattern recognition receptors (called toll-like receptors [TLRs]) on the surface of immune cells as well as C-type lectin receptors, retinoic acid inducible gene 1–like receptors, and nucleotide-binding oligomerization domain–like receptors. Nucleotide-binding oligomerization domain–like receptors alter protein complexes in the inflammasome. The lipopolysaccharide (LPS) of gram-negative bacilli binds to the LPS-binding protein–CD14 complex. The lipoteichoic acid (LTA) of gram-positive bacteria and the LPS of gram-negative bacteria bind to TLR-2 and TLR-4, respectively. TLR-2 and TLR-4 binding activates intracellular signal transduction pathways that lead to the activation of the cytosolic transcription factor nuclear factor κB (NF-κB). Activated NF-κB moves from the cytoplasm to the nucleus, binds to transcription start sites, and increases the transcription of pro-inflammatory cytokines such as tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), and interleukin-6 (IL-6). Increased necrotic cell death releases damage-associated molecular patterns (DAMPs or alarmins) that bind to TLRs and thus feed back to further amplify the pro-inflammatory response. TNF-α, IL-1β, and IL-6 are pro-inflammatory cytokines that activate the adaptive immune response but also cause both direct and indirect host injury (e.g., by complement activation). LPS and LTA activation of inflammation is offset by hepatic low-density-lipoprotein receptor (LDLR)–mediated LPS and LTA clearance. Sepsis increases the activity of inducible nitric oxide synthase (iNOS), which increases the synthesis of nitric oxide (NO), a potent vasodilator. Cytokines activate endothelial cells by upregulating adhesion receptors such as intercellular adhesion molecule (ICAM), and they injure endothelial cells by the activation and binding of neutrophils, monocytes, macrophages, and platelets to endothelial cells. These effector cells release mediators such as proteases, reactive oxygen species, prostaglandins, and leukotrienes. Cytokines also activate the coagulation cascade. Autophagy increases in neutrophils, thereby leading to increased neutrophil extracellular trap (NET) formation. Dysregulated autophagy in sepsis impairs NET formation and is associated with decreased survival. Endothelial permeability is increased by injurious agents such as heparin-binding protein (HBP) that is released by neutrophils, angiopoietin 2/Tie 2 receptor interaction, and sphingosine 1-phosphate (S1P) ligation to its G protein–coupled receptor S1P1.

inflammasome activation of immune cells (see E-Fig. 94-3), and is a pro-survival mechanism of cardiomyocytes. Dysregulated autophagy is associated with decreased survival in septic models. Autophagy research suggests that modulation of autophagy in sepsis may prove beneficial. The inflammatory response to septic shock varies according to the organism load, host genotype, underlying conditions, and prior immunosuppressing drugs.

Endothelial Injury

In septic shock, widespread endothelial injury is common and leads to increased endothelial permeability with loss of protein and fluid to the interstitial space. Endothelial permeability is a final common pathway for widespread tissue injury. Cytokines and other inflammatory mediators induce intercellular endothelial cell gaps by disrupting intercellular junctions, by changing cytoskeletal structure, or by direct damage to endothelial cells. Several pathways of altered endothelial permeability have been implicated in sepsis, including protease-activated receptor 1 (PAR-1) and disruption of the intercellular VE-cadherin, β-catenin, and p120-catenin complex. PAR-1 binding by activated protein C and low-dose thrombin is cytoprotective, whereas PAR-1 stimulation by high-dose thrombin increases endothelial permeability. Binding of Slit to Robo4 maintains the integrity of the intercellular VE-cadherin, β-catenin, and p120-catenin complexes and thus maintains healthy endothelial permeability. Mediators of increased permeability in sepsis include heparin-binding protein, soluble thrombomodulin, angiopoietin-2, sphingosine-1 phosphate, and natriuretic peptides.

Adaptive Immunity Adds Specificity and Amplifies the Immune Response

Microorganisms stimulate specific humoral and cell-mediated adaptive immune responses that amplify innate immunity. B cells release immunoglobulins that bind to microorganisms and thereby facilitate delivery of microorganisms to natural killer cells and neutrophils. In sepsis, type 1 helper T (T_H1) cells generally secrete pro-inflammatory cytokines (TNF-α, IL-1β), and type 2 helper T (T_H2) cells secrete anti-inflammatory cytokines (IL-4, IL-10).

Coagulation Response to Infection

Septic shock activates the coagulation system, thereby causing sepsis-associated coagulopathy (E-Fig. 94-4), and ultimately converts fibrinogen to fibrin, which binds to platelets to form microvascular thrombi. A marked or sustained procoagulant response to septic shock can lead to disseminated intravascular coagulation (DIC; Chapter 161) and widespread tissue injury, including loss of digits and limbs. The three main features of sepsis-associated coagulopathy are increased procoagulant activity and decreased anticoagulant and fibrinolytic activity. Microvascular thrombi amplify endothelial injury by the release of inflammatory mediators and by tissue hypoxia because of obstruction to blood flow.

Normally, natural anticoagulants (protein C, protein S, antithrombin, and tissue factor pathway inhibitor) dampen coagulation, enhance fibrinolysis, and remove microthrombi. Thrombin-α binds to thrombomodulin, which activates protein C when protein C is bound to the endothelial protein C receptor (EPCR). Activated protein C dampens the procoagulant phenotype because it inactivates factors Va and VIIIa and inhibits the synthesis of plasminogen activator inhibitor 1 (PAI-1). Activated protein C also decreases apoptosis, leukocyte activation and adhesion, and production of cytokines. Endothelial thrombomodulin expression is decreased in meningococcemia (Chapter 274), thereby explaining in part the profound DIC characteristic of meningococcemic shock.

Septic shock decreases the levels of the natural anticoagulants protein C, protein S, antithrombin, and tissue factor pathway inhibitor. Furthermore, lipopolysaccharide and TNF-α decrease the expression of thrombomodulin and EPCR, thereby further limiting the activation of protein C. Lipopolysaccharide and TNF-α also increase levels of PAI-1, inhibiting fibrinolysis. The coagulation system is linked to the inflammatory response by protease activated receptors (PARs), especially PAR-1.

Tissue Hypoxia in Septic Shock

Tissue hypoxia independently activates inflammation (by activation of NF-κB and cytokines, synthesis of nitric oxide, and activation of HMGB-1); induces coagulation (through tissue factor and PAI-1); and activates neutrophils, monocytes, and platelets. Hypoxia disinhibits hypoxia-inducible factor-1α (HIF-1α), which upregulates erythropoietin, and vascular endothelial growth factor (VEGF). Erythropoietin is protective to brain and other tissues. VEGF inhibits fibrinolysis and increases inducible nitric oxide synthase, thereby increasing nitric oxide–induced vasodilation. Nitric oxide's other injurious effects include inhibiting the beneficial actions of HIF-1α (e.g., upregulating synthesis of erythropoietin) during hypoxia. Tissue hypoxia also causes release of damage-associated molecular patterns (alarmins), which are ligands for the pattern recognition receptors described earlier, thereby increasing the inflammation in septic shock.

Endocrine Responses Relevant to Cardiovascular Support

Complex interactions of several endocrine systems modulate vascular tone, heart rate, and other noncardiovascular functions such as immune function. The main axes stimulated to increase hormone production are the adrenal medullary release of norepinephrine and epinephrine (Chapter 209), hypothalamic-posterior pituitary release of vasopressin (Chapter 204), the hypothalamic-anterior pituitary-adrenal cortex release of corticosteroids (such as cortisone) (Chapter 208), and the renin-angiotensin-aldosterone (RAAS) release of angiotensin II (E-Fig. 94-5). Norepinephrine binds to α1 receptors, vasopressin binds to V1a receptors, and angiotensin II similarly binds to angiotensin II receptors on smooth muscle to stimulate calcium-mediated vasoconstriction. Cortisone modulates α1 receptor density. Deficiencies in each of these hormone levels and the downregulation of relevant receptors (such as V1a) in part explain the need for vasopressor(s)—such as first-line norepinephrine, and second-line epinephrine, vasopressin, and possibly angiotensin II—to increase vascular tone by producing vasoconstriction in patients who do not respond to volume resuscitation.

Immunosuppression and Apoptosis of Immune and Epithelial Cells

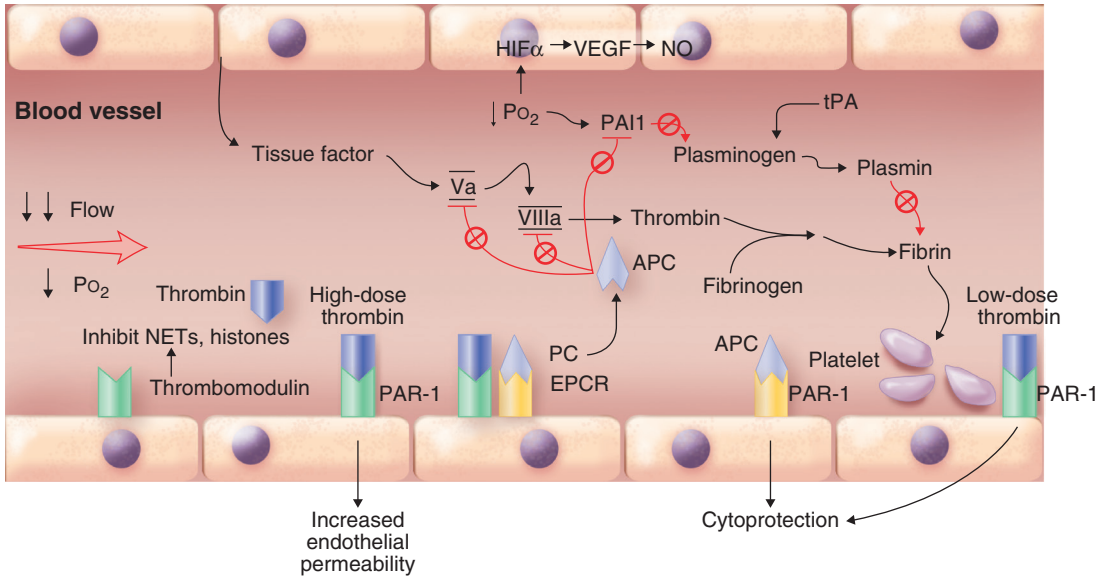
Septic shock can initiate an immunosuppressed state that can exceed the pro-inflammatory response starting soon after the onset of septic shock and can be fatal. Patients move through the balance of pro- versus anti-inflammatory/immunosuppressed states at different rates, likely accounting for the wide variability in the clinical progression and recovery from septic shock. Immunodepression occurs in the humoral, cellular, and neural regulation of immunity. Immunosuppression is suggested by anergy, lymphopenia, a decreased CD-4 level, hypothermia, and nosocomial infection (E-Fig. 94-6). Multiple organ dysfunction may be an immunodepressed phenotype because of the apoptosis of immune (B and T cells as well as dendritic cells), epithelial, and endothelial cells. Activated $CD4^+$ T cells evolve into either a T_H1 pro-inflammatory (TNF-α, IL-1β) or a T_H2 anti-inflammatory (IL-4, IL-10) phenotype. Sepsis leads to migration from a T_H1 to a T_H2 phenotype; for example, persistent elevation of IL-10 is associated with an increased risk of death. Immunosuppression also develops because of apoptosis of lymphocytes. Pro-inflammatory cytokines, activated B and T cells, and glucocorticoids induce lymphocyte apoptosis, whereas TNF-α and endotoxin induce apoptosis of lung and intestinal epithelial cells. Other late features of septic shock include expansion of regulatory T cells and myeloid suppressor cells, decreasing inflammation, but impaired phagocytosis. The vagus nerve activates the splenic nerve, thereby causing CD4+ T cells to release acetylcholine, which further attenuates inflammation.

Septic patients can be divided into subgroups based on transcriptomic signatures in blood and the key differences in gene expression related to immunosuppression.[4] These subgroups may respond differently to treatment such as corticosteroids, thereby paving the way for personalized medicine approaches in septic shock.

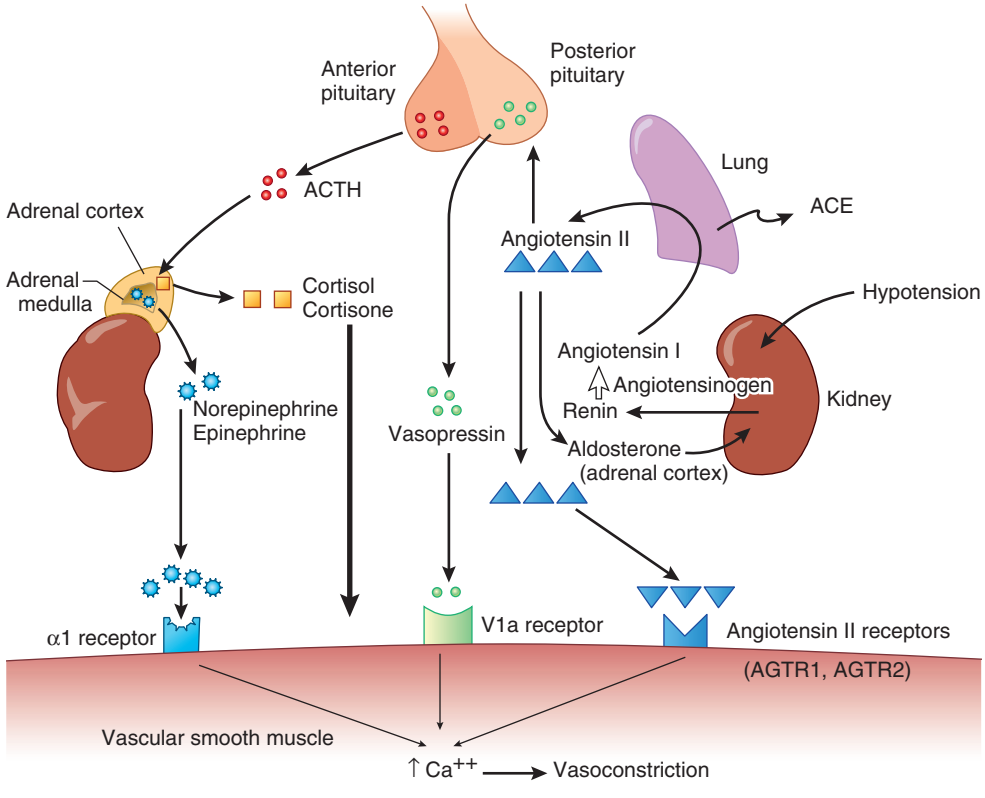
Death from infectious disease appears to be highly heritable. Sepsis is a prime example of a polygenic disease related to the interaction of multiple genes and an environmental insult (infection). Single-nucleotide polymorphisms of cytokines (TNF-α, IL-6, IL-10), coagulation factors (protein C, fibrinogen-β), the catecholamine pathway (β-adrenergic receptor), and innate immunity genes (CD14, TLR-1, TLR-2) have been variably associated with an increased risk of death from sepsis. To date, none of these findings have evolved into actionable diagnostic or prognostic biomarkers for clinical use.

Cardiovascular Dysfunction

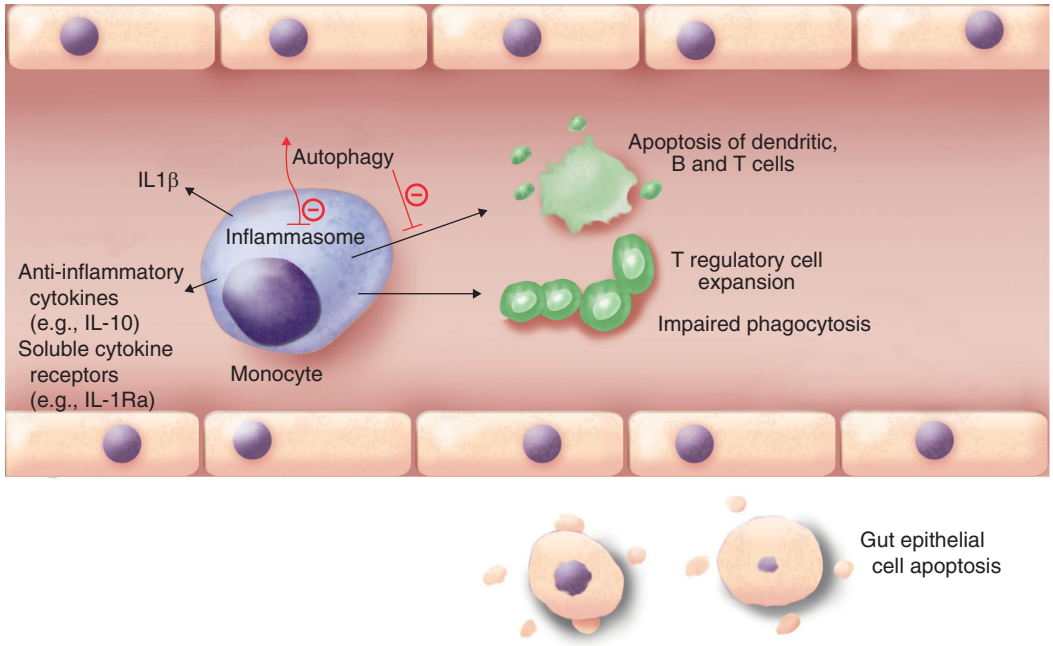
The main features of cardiovascular dysfunction in septic shock are vasodilation, hypovolemia, decreased ventricular contractility, and increased vascular permeability. Inadequate tissue perfusion and tissue hypoxia are the cardinal features of all types of shock. Peripheral levels of catecholamines are dramatically increased in septic shock, but peripheral vasodilation indicates decreased responsiveness to these endogenous vasoconstrictors. Vasodilation in sepsis is mediated mainly by increased synthesis of nitric oxide and prostacyclin. Nitric oxide is increased by a calcium-independent nitric oxide synthase induced by



E-FIGURE 94-4. **Procoagulant response in sepsis.** Sepsis initiates coagulation by activating the endothelium to increase tissue factor. Protease-activated receptors (PARs), especially PAR-1, link the inflammatory and coagulation responses to sepsis. Activation of factors Va and VIIIa leads to the formation of thrombin-α, which converts fibrinogen to fibrin. Fibrin binds to platelets that adhere to endothelial cells, forming microvascular thrombi. Microvascular thrombi amplify injury by the release of mediators and by microvascular obstruction, which causes distal ischemia and tissue hypoxia. Normally, natural anticoagulants—protein C (PC), protein S (PS), antithrombin, and tissue factor pathway inhibitor (TFPI)—dampen coagulation, enhance fibrinolysis, and remove microthrombi. Thrombin-α binds to thrombomodulin on endothelial cells and thus activates the binding of PC to endothelial PC receptor (EPCR). PC forms a complex with its cofactor PS. PC binding to EPCR increases the activation of PC to activated PC (APC). APC proteolytically inactivates factors Va and VIIIa and decreases the synthesis of plasminogen activator inhibitor 1 (PAI-1). Sepsis decreases levels of PC, PS, antithrombin, and TFPI. Lipopolysaccharide and tumor necrosis factor-α (TNF-α) decrease thrombomodulin and EPCR, thus decreasing the activation of PC. PAR-1 binding by activated protein C and low-dose thrombin is cytoprotective, whereas PAR-1 stimulation by high-dose thrombin increases endothelial permeability. Lipopolysaccharide and TNF-α also inhibit PAI-1, so fibrinolysis is inhibited. HIFα = hypoxia-inducible factor-α; NO = nitric oxide; tPA = tissue plasminogen activator; VEGF = vascular endothelial growth factor.



E-FIGURE 94-5. **Endocrine response and therapies in septic shock.** The complex interplay of several key endocrine axes in septic shock includes (1) release of norepinephrine and epinephrine from the adrenal medulla; (2) release of adrenocorticotropic hormone (ACTH) from the anterior pituitary, then stimulating synthesis and release of cortisone and cortisol from the adrenal cortex; (3) release of vasopressin from the posterior pituitary; and (4) release of renin (in response to hypotension) from the kidney. Renin is converted to angiotensin I by angiotensinogen (that was released from the liver), and then angiotensin I is converted to angiotensin II by angiotensin-converting enzyme (ACE) in the lung. Angiotensin II increases aldosterone synthesis and release from the adrenal cortex, and aldosterone increases sodium retention in the kidney. Angiotensin II also increases release of vasopressin. Norepinephrine and epinephrine bind to alpha-1 adrenergic receptors, vasopressin binds to V1a receptors, and angiotensin II binds to angiotensin II receptors (AGTR1 and AGTR2), all on vascular smooth muscle. After ligand binding, intracellular signal transduction increases intracellular calcium, thereby causing vascular smooth muscle contraction and vasoconstriction. Corticosteroids have complex cardiovascular effects that are incompletely understood but include modulation of α-1 receptor density and other actions that quickly increase responsiveness to catecholamines, such as norepinephrine. Thus, much of the management of septic shock—such as infusions of norepinephrine, vasopressin, and possibly angiotensin II, as well as administration of hydrocortisone, have foundations in the endocrine axes and pathophysiologic effects of septic shock on endocrine function.



E-FIGURE 94-6. Immunodepression in sepsis. Monocytes release anti-inflammatory cytokines, such as IL-10, and anti-inflammatory soluble cytokine receptors, such as IL-1Ra. Monocytes also induce apoptosis of dendritic, B, and T cells and also induce T regulatory cell expansion as well as impaired phagocytosis. Induction of autophagy is critical for survival and differentiation of monocytes, and it also inhibits apoptosis of monocytes and other cells. Monocytes and macrophages also use autophagy to inhibit the activation of the inflammasome and so limit mature IL-1β synthesis and release. IL = interleukin; IL-1Ra = interleukin 1 receptor antagonist.

endotoxin interaction with vascular endothelial cells. Prostacyclin is released by endothelial cells in response to both endotoxin and inflammatory cytokines. Adrenomedullin, which is a pleiotropic vasodilating hormone and cardiac depressant, is increased in septic shock. Early in septic shock, most patients have sinus tachycardia and, by definition, a need for vasopressor(s) because of decreased blood pressure (<90 mm Hg systolic, a decrease of ≥40 mm Hg from baseline systolic pressure, or mean arterial pressure <65 mm Hg; see Table 94-1). Septic shock is the classic form of distributive shock (Chapter 92), characterized by increased pulse pressure (bounding pulses), decreased systemic vascular resistance (warm, flushed skin), and functional hypovolemia (low jugular venous pressure). Distributive shock means that the distribution of systemic blood flow is abnormal, with areas of low flow (and low venous oxygen saturation) and high flow (and high venous oxygen saturation) present. Nevertheless, about one third of patients with septic shock initially present with findings more typical of hypovolemic shock (low central venous pressure, low central venous oxygen saturation, and cold, poorly perfused limbs) because the clinical features depend on the stage and severity of septic shock as well as on the degree of fluid resuscitation that has occurred. After fluid resuscitation, patients typically develop the characteristic clinical and hemodynamic features of classic distributive shock.

Vascular volume and ventricular preload are commonly decreased in early septic shock for several reasons. First, patients may be volume depleted because of decreased fluid intake and because of increased fluid losses due to fever, vomiting, and diarrhea if gastrointestinal disease is present. Second, fluid loss from the intravascular to the interstitial space (capillary leak) is caused by mediators that induce widespread endothelial injury, which increases capillary permeability. Increased capillary permeability leads to loss of protein-rich edema fluid into the interstitial space. The increased vascular permeability exacerbates transmural vascular leak at any given transmural hydrostatic pressure, thereby creating a vicious cycle. Sicker patients have greater increases in endothelial permeability, yet sicker patients have greater third-space fluid losses, so they need more fluid input. If, however, fluid input increases transmural hydrostatic pressure even modestly, then sicker patients will have greater fluid leakage into tissues, with increasing organ edema, organ dysfunction, and mortality.

In the lung, increased capillary permeability is a key component of ARDS (Chapter 90). Ventricular preload is also decreased in septic shock because of venodilation induced by mediators such as nitric oxide. Venodilation increases venous capacitance and relative volume depletion, thereby compounding absolute volume depletion. Ventricular afterload is decreased because of excessive release of potent vasodilators such as nitric oxide, prostaglandin I_2, adenosine diphosphate, and other vasodilators.

In addition to abnormal vasodilation, patients have concurrent microvascular vasoconstriction. Microvascular vasoconstriction may not be apparent clinically but can cause tissue hypoxia, detected by increased arterial lactate concentrations. Microvascular vasoconstriction is caused by increased norepinephrine, thromboxanes, and other local vasoconstrictors. Microvascular vasoconstriction-induced focal hypoxia is exacerbated by microvascular obstruction by platelets and leukocytes.

The abnormal mismatch of oxygen delivery to oxygen demand disturbs the global relationship of oxygen delivery to oxygen consumption. Normally, oxygen consumption is independent of oxygen delivery over a wide range. When oxygen delivery decreases to less than the critical oxygen delivery level, oxygen consumption decreases and leads to a state in which oxygen consumption depends on oxygen delivery. At levels lower than the critical oxygen delivery level, blood lactate increases as a result of tissue hypoxia, explaining in part why an elevated serum lactate level is a component of the diagnosis of septic shock. The clinical implication is that oxygen delivery should be increased (e.g., by increasing cardiac output by volume resuscitation, infusion of dobutamine, or transfusion of erythrocytes) to more than the critical level.

Cardiovascular function is further compromised in septic shock because of decreased ventricular contractility.[5] Within minutes of recognizing bacteria, cardiomyocytes secrete pro-inflammatory cytokines and chemokines that recruit inflammatory cells. Cardiomyocytes concurrently express cell-surface-adhesion molecule ICAM-1, which interacts with actin filaments within the cell to reduce contractile efficiency. Decreased ventricular contractility may be difficult to detect clinically and may be diagnosed only by hemodynamic or echocardiographic assessment. Numerous circulating mediators of sepsis, including endotoxin, cytokines (e.g., IL-6, TNF-α), and nitric oxide (locally released into the coronary circulation), decrease contractility. Endotoxin signals through TLRs to upregulate the expression of proteins such as two small calcium-regulated molecules (S110A8 and S100A9) to cause a receptor for advanced glycation end products (RAGE)–dependent decrease in calcium flux, thereby decreasing the ejection fraction. Coronary ischemia resulting from microvascular obstruction is another mechanism of decreased contractility.

Early in septic shock, patients who ultimately survive have increased left ventricular end-diastolic volume to help maintain cardiac output despite decreased contractility. In contrast, nonsurvivors do not increase their left ventricular end-diastolic volume, so cardiac output is compromised. In some patients with septic shock, concurrent ARDS causes secondary pulmonary hypertension, which increases right ventricular afterload and shifts the interventricular septum from right to left. This septal shift decreases left ventricular end-diastolic volume, thereby further limiting cardiac output.

CLINICAL MANIFESTATIONS

Patients in septic shock have a systolic pressure of 100 mm Hg or less, often accompanied by an elevated respiratory rate (>22/minute) or altered mental status. About 80% of patients are febrile, but patients can be normothermic or even hypothermic (in about 20% of cases). On initial presentation, the source of infection may be obvious, especially if patients have previous evidence of a specific site of infection such as pneumonia or a surgical site infection, or can be occult.

The cardiovascular dysfunction in septic shock is characterized by decreased preload (because of decreased intake, fluid losses, third spacing resulting from increased permeability, and venodilation), decreased afterload, and often decreased ventricular contractility. Decreased ventricular volume is detected clinically by low jugular venous pressure and hemodynamically by decreased central venous pressure. Left ventricular resistance, or afterload, is also commonly decreased and is detected clinically by warm, flushed skin and hemodynamically by decreased systemic vascular resistance.

DIAGNOSIS

The initial assessment of a critically ill patient must focus on the airway (need for intubation), breathing (respiratory rate, respiratory distress, pulse oximetry), circulation (heart rate, blood pressure, jugular venous pressure, skin perfusion), and the rapid initiation of warranted resuscitation (Fig. 94-1).[6] Arterial blood gases and lactate levels are useful especially since an elevated lactate level is a component of the clinical diagnosis of septic shock.

A secondary survey is designed to determine the source of infection and the status of organ function. Pneumonia (Chapter 85) is suggested by cough, sputum, and respiratory distress; empyema (Chapter 86) is suggested by pleuritic chest pain. Signs of peritonitis (Chapter 128), an abdominal mass (Chapter 118), and tenderness (Chapter 141) suggest abdominal sepsis (Chapter 118). Pyelonephritis (Chapter 263) is likely in patients with dysuria and costovertebral angle tenderness. Integumentary assessment for erythema (cellulitis), erythema at the vascular access site (line sepsis), tenderness (necrotizing fasciitis; Chapter 271), crepitus (anaerobic myonecrosis), and petechiae and purpura (meningococcemia; Chapter 274) can be illuminating. Headache, stiff neck, and signs of meningismus raise the suspicion of meningitis (Chapter 381). Focal neurologic signs suggest brain abscess (Chapter 382).

Laboratory investigations that are helpful to identify the source of infection include appropriate cultures and Gram stains (blood, sputum, urine, fluids, and cerebrospinal fluid). Blood cultures are positive in about 30 to 40% of patients with septic shock, but they are positive one-third less often if antibiotics were administered before the cultures were drawn.[7] In patients with negative cultures, RNA gene-targeted metagenomic sequencing can find a likely pathogenic organism in about 40% of cases.[8] The chest radiograph aids in the diagnosis of pneumonia, empyema, and the acute respiratory distress syndrome.

Direct visualization of the heart by transthoracic bedside echocardiography can immediately estimate the left ventricular ejection fraction. It can also be used to assess intravascular volume status (diagnosed by collapse of the inferior vena cava) and valvular dysfunction. Echocardiographic features of decreased ventricular contractility include decreased right and left ventricular ejection fractions and increased end-diastolic and end-systolic volumes. Early in septic shock, the left ventricular ejection fraction is decreased, and it remains low in nonsurvivors. In survivors, the left ventricular ejection fraction usually returns to normal during 5 to 10 days.

In early septic shock, central venous pressure is usually low and increases in response to volume resuscitation. Central venous oxygen saturation, cardiac output, and ventricular filling pressures may be determined. Central venous pressure measurement is recommended in patients who require vasopressors because their hypotension is not responsive to fluids alone. Pulmonary artery pressure is usually normal but may be increased because septic shock can cause pulmonary hypertension. Pulmonary artery occlusion (or wedge) pressure is

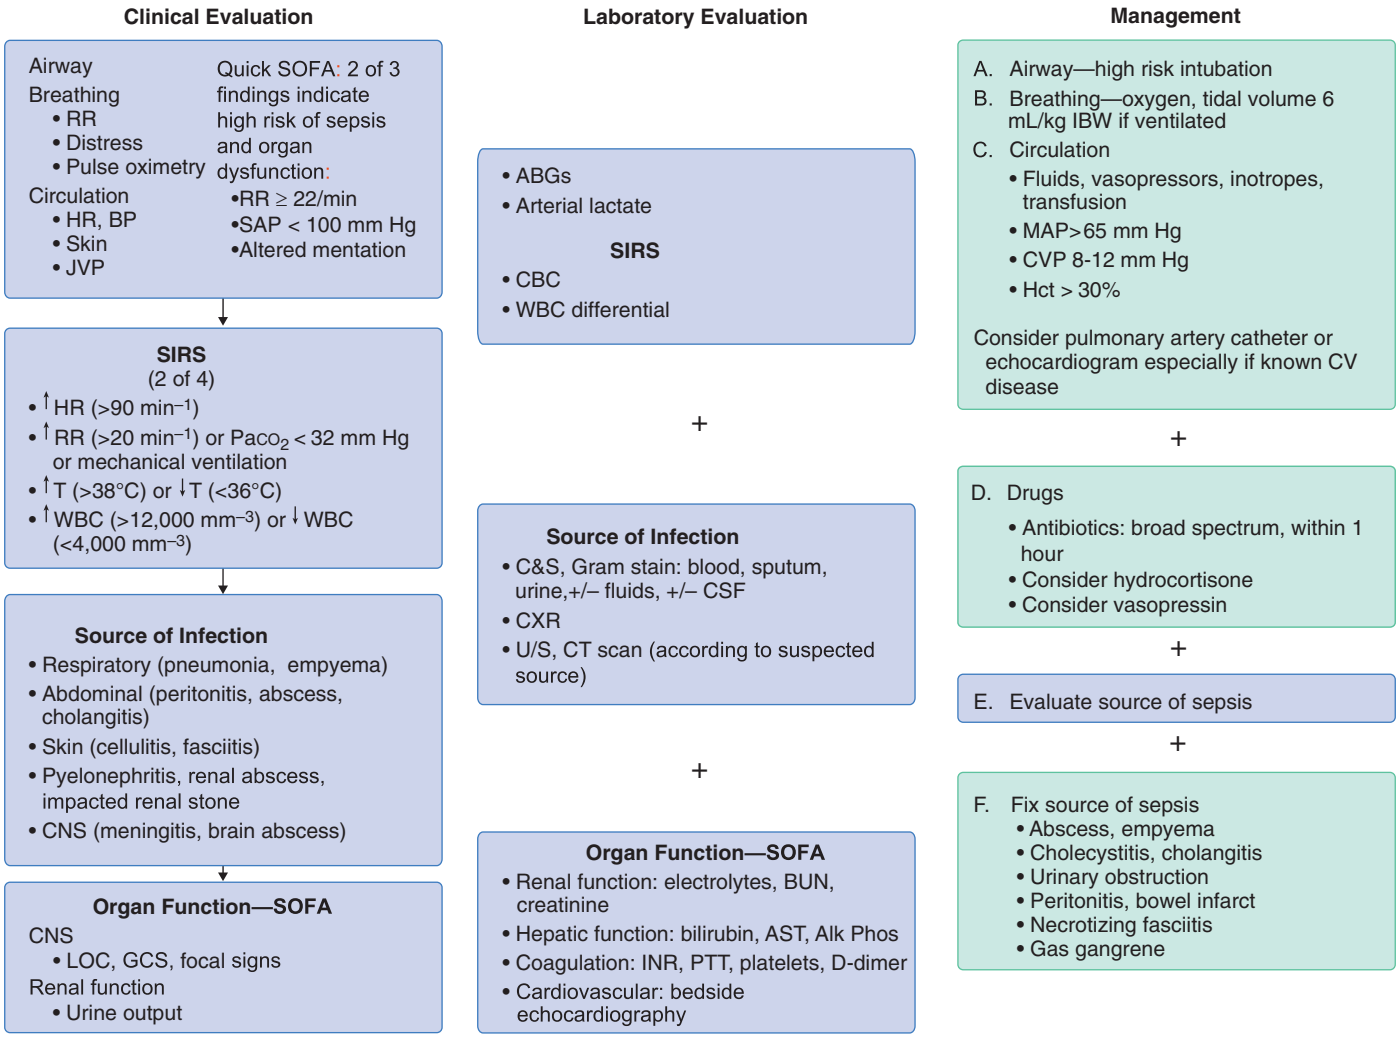


FIGURE 94-1. Algorithm for the clinical and laboratory evaluation and management of septic shock. ABGs = arterial blood gases; Alk Phos = alkaline phosphatase; AST = aspartate aminotransferase; BP = blood pressure; BUN = blood urea nitrogen; C&S = culture and sensitivity; CBC = complete blood count; CNS = central nervous system; CSF = cerebrospinal fluid; CT = computed tomography; CV = cardiovascular; CVP = central venous pressure; CXR = chest radiograph; GCS = Glasgow Coma Scale; Hct = hematocrit; HR = heart rate; IBW = ideal body weight; INR = international normalized ratio; JVP = jugular venous pressure; LOC = level of consciousness; MAP = mean arterial pressure; $Paco_2$ = partial pressure of carbon dioxide; PTT = partial thromboplastin time; RR = respiratory rate; SAS = systolic arterial pressure; $Scvo_2$ = central venous oxygen saturation; SIRS = systemic inflammatory response syndrome; SOFA = Sequential Organ Failure Assessment; T = temperature; U/S = ultrasound; WBC = white blood cell count.

usually low before resuscitation, but it may be normal or increased if the patient has underlying preexisting heart disease (e.g., heart failure, prior myocardial infarction) or if left ventricular contractility is decreased by sepsis. Cardiac output may be low or normal before fluid resuscitation and typically increases to higher than normal after fluid resuscitation. If fluid resuscitation increases central venous pressure and pulmonary artery occlusion pressure but cardiac output does not increase, left ventricular dysfunction is presumably present.

Vital signs and the leukocyte count quickly establish whether the patient has the systemic inflammatory response syndrome (SIRS). Abdominal ultrasound and computed tomography are indicated if abdominal sepsis is suspected. Renal, hepatic, and coagulation function tests are helpful to evaluate acute kidney injury, hepatic dysfunction, and sepsis-associated coagulopathy, respectively. After determining the source of sepsis, the clinician must address source control by draining abscesses and empyemas; using image-directed procedures or open surgery to correct urinary tract obstruction; and surgically managing peritonitis, bowel infarction, cholecystitis, cholangitis, necrotizing fasciitis, and gas gangrene.

Differential Diagnosis

The major differential diagnoses of septic shock are acute pancreatitis (Chapter 130), the acute respiratory distress syndrome (Chapter 90), aspiration pneumonitis (Chapter 82), multiple trauma (Chapter 97), cytokine storm,[9] and recent major surgery without infection (Chapter 401). Other causes of distributive shock to consider are anaphylactic shock (suggested by angioedema and hives; Chapter 407), spinal shock (recent trauma and paraplegia; Chapter 368), acute adrenal insufficiency ("tanned skin," hyperkalemia, metabolic alkalosis; Chapter 208), and acute or acute-on-chronic hepatic failure (jaundice, ascites, encephalopathy; Chapter 139).

The differential diagnosis of septic shock must include the other causes of shock: hypovolemic, cardiogenic, and obstructive shock (Chapters 92 and 93). Patients with hypovolemic shock (e.g., from internal or external fluid losses or hemorrhage) present with a suggestive history and signs of hypovolemia (low jugular venous pressure) and skin hypoperfusion (cool and clammy skin, peripheral cyanosis, slow capillary refill). Cardiogenic shock (e.g., owing to myocardial infarction, heart failure, or post–cardiovascular surgery) is suggested by the history, signs of increased filling pressure (increased jugular venous pressure, crackles, S_3, pulmonary edema, cardiomegaly), and skin hypoperfusion (Chapter 93). Some patients who have acute myocardial infarction and cardiogenic shock have features of SIRS, with excessive vasodilation in the absence of infection. Obstructive shock (e.g., pulmonary thromboembolism [Chapter 68], cardiac tamponade [Chapter 62], pneumothorax [Chapter 86]) manifests similarly to cardiogenic shock.

TREATMENT

Respiratory Therapy

All patients in septic shock require oxygen initially, and many require mechanical ventilation because acute respiratory distress syndrome (ARDS) is the most common complication of septic shock.[10] Endotracheal intubation of the patient in septic shock can be complicated by worsening hypotension, but a 500 mL intravenous bolus of normal saline prior to intubation does not improve

outcomes in critically ill patients undergoing intubation.[A1] Lung-protective ventilation (mechanical ventilation that minimizes lung injury by using a combination of strategies, including a set tidal volume, such as 6 to 8 mL/kg of predicted body weight [when using volume-cycled ventilatory assist]) decreases mortality from ARDS (Chapter 91).

Patients on mechanical ventilation need adequate, but not excessive, sedation because excessive sedation worsens hemodynamic instability, prolongs the need for mechanical ventilation, and increases the risk for development of nosocomial pneumonia. Sedation should be titrated by objective assessment. Daily interruption of sedation decreases the duration of mechanical ventilation and intensive care. The use of dexmedetomidine to induce sedation does not improve outcomes, including delirium, compared with propofol.[A2] Weaning from mechanical ventilation is often associated with fluid overload from prior fluid resuscitation and from the reduction in intrathoracic pressure. Patients whose weaning is guided by brain natriuretic peptide levels are weaned more quickly and have more ventilator-free days because they receive more aggressive diuretic therapy.

Circulatory Therapy

Early therapy is the cornerstone of emergency management, but such therapy need not achieve specific central hemodynamic or oxygen-delivery targets, or require the placement of a central venous catheter or the administration of inotropic agents or blood transfusions.[A3] Standard therapies aim to increase perfusion and tissue oxygen delivery by increasing profoundly low blood pressure, increasing inadequate cardiac output, and increasing low arterial oxygen saturation.

The overall goal is to achieve adequate mean arterial pressure (>65 mm Hg) and other indices of perfusion such as urine output (>0.5 mL/kg/hour), blood lactate levels (<2 mmol/L), mental status, and skin perfusion. To assess the adequacy of early resuscitation of septic shock and to guide ongoing therapy, a central venous oxygen saturation goal greater than 70% or a lactate clearance of at least 10% is equivalent.[11]

A mean arterial blood pressure target of 65 to 70 mm Hg generally is as effective as a target of 80 to 85 mm Hg[A4] or compared with usual care.[A5] In patients who have ARDS, no difference in outcomes is seen with management using a pulmonary artery catheter versus a central venous catheter, so measurement and monitoring of central venous pressure (CVP) is recommended in patients who require vasopressor infusion. Patients whose ARDS is managed after 24 to 48 hours with a conservative fluid strategy (compared with a liberal fluid strategy) have shorter durations of mechanical ventilatory assist and ICU stay.

Fluids must be administered in an adequate but not excessive volume. Restrictive and liberal fluid strategies result in similar mortality rates for patients in septic shock,[A6,A7] but the restrictive fluid approach requires strict protocols for identifying and treating hypovolemia to avoid more prevalent and longer duration vasopressor support. Fluids (30 mL/kg of intravenous crystalloid, either 0.9% saline or a balanced solution such as lactated Ringer solution) should be given over the first 3 hours followed by additional fluids to achieve and maintain central venous pressure at 8 to 12 mm Hg and adequate tissue perfusion (e.g., mentation, urine output). In critically ill adults, balanced crystalloids are often used instead of sodium chloride because of lower rates of acute kidney injury, less need for renal replacement therapy, and fewer deaths,[A8] but a recent double-blind trial comparing a balanced solution with saline found no difference in outcomes in a diverse group of ICU patients, including the subgroup who had sepsis.[A9] There are no convincing data indicating that albumin is better than crystalloid solutions.[A10] Hetastarch should not be used in septic shock. Excess fluid resuscitation is associated with increased mortality from septic shock, and an increased CVP may indicate fluid overload and a higher risk of developing pulmonary edema. Heart failure with a decreased ejection fraction is common in patients with sepsis,[12] and lesser amounts of fluid administration (i.e., below guideline recommended volumes) are safer and associated with no difference in risk-adjusted mortality compared with patients with normal ejection fractions.[13]

Vasopressors (e.g., first-line: norepinephrine, 1 to 50 μg/minute; alternative: epinephrine, 1 to 30 μg/minute) should be added if the mean arterial pressure is less than 65 mm Hg despite adequate fluid resuscitation,[14] and earlier administration concomitant with fluid resuscitation appears to improve the early control of septic shock but not clearly reduce septic shock mortality.[A11] Norepinephrine is slightly, but not significantly, better than dopamine for reducing mortality when used as the first-line vasopressor for patients with septic shock; however, norepinephrine is associated with a lower rate of arrhythmias, especially atrial fibrillation. Norepinephrine and vasopressin are similar for preventing acute kidney failure in patients with septic shock.[A12] These accumulated data suggest that norepinephrine is the preferred first-line vasopressor in septic shock.

Although vasopressin deficiency and downregulation of vasopressin receptors are common findings in septic shock, a low-dose vasopressin infusion added to norepinephrine is not significantly better than a norepinephrine infusion alone in septic shock. Vasopressin (up to 0.03 U/min) may be added in patients not responding adequately to norepinephrine to increase mean arterial pressure and to decrease norepinephrine dose, but selepressin (a vasopressin agonist) has no incremental value when added to norepinephrine.[A13] Whether vasopressin infusion may be beneficial in patients with less severe shock is uncertain.

Angiotensin II infusion (20 ng/kg/minute initially, adjusted upward to a maximum of 200 ng/kg/minute) can decrease early norepinephrine requirements and improve the cardiovascular component of the SOFA score. However, it does not significantly reduce mortality. Levosimendan, which is an inotropic agent and mild vasodilator with anti-inflammatory properties, is not of added benefit in patients with septic shock.

Some patients, especially younger patients, have excessive tachycardia that limits diastolic filling time. Short-acting intravenous β-blockers (e.g., esmolol started at about 0.2 μg/kg/minute and titrated to a targeted heart rate of 80 to 90 beats per minute) have shown encouraging results,[A14] but more evidence is required before recommending this approach for routine clinical use.

In some patients in septic shock, the cardiac index is inadequate, as reflected by a low mixed venous oxygen saturation despite a high central venous pressure (>12 mm Hg) because of underlying cardiovascular dysfunction or because of acute left ventricular dysfunction resulting from sepsis. In such patients, clinicians can consider use of an inotropic agent (e.g., dobutamine, initially 2 to 5 μg/kg/minute and increasing to 20 μg/kg/minute) to increase left ventricular contractility and raise cardiac output. In patients with septic shock, however, the combination of norepinephrine plus dobutamine results in a mortality similar to that with epinephrine alone, with no differences in organ dysfunction.

Fever is common in septic shock and may have beneficial effects for resisting infection but also increases oxygen demand. Reducing fever can decrease the need for vasopressors and possibly the risk of septic encephalopathy. External cooling for 48 hours to maintain core body temperature between 36.5°C and 37°C is safe and can decrease the need for vasopressors and 14-day mortality rates. Cooling to reduce fever to normothermia is especially promising for febrile septic shock patients who are receiving high doses of vasopressors or inotropic agents, or who have marked tachycardia.

Transfusion of Red Blood Cells

Anemia is common in septic shock, but red cell transfusion can increase risk of nosocomial infection and other complications, so the appropriate hemoglobin level for resuscitation has been controversial. A transfusion threshold of a hemoglobin level of 7 g/dL is equivalent to a threshold of 9 to 10 g/dL in terms of the need for life support, or death, and such a goal can decrease the need for transfusion.[A15] The freshest available, compatible red blood cells are no better than standard-issue red blood cells for patients with septic shock.[A16]

Drugs

Antibiotics

Early antibiotic administration, ideally within 1 hour, is highly recommended and allows the duration of antibiotic administration to be shortened without increasing resistance or the subsequent need for additional antibiotics.[15] Meropenem alone is equivalent to the combination of meropenem and moxifloxacin in terms of mortality rates and organ dysfunction. Adding empirical fluconazole treatment does not result in better outcomes in critically ill, non-neutropenic patients. Continuous infusion of beta-lactam antibiotics results in higher clinical cure rates 14 days after cessation of antibiotics, better pharmacokinetic/pharmacodynamic target attainment, and more ventilator-free days compared with an intermittent bolus of antibiotics but does not improve 30-day survival.[A17]

The infected site and infecting organisms of septic shock are often not known initially, and clinicians often must select an empirical antibiotic regimen before knowing culture results. After appropriate culture specimens are obtained, intravenous broad-spectrum antibiotics as guided by an infectious disease consultation should be administered within 1 hour (while considering host factors such as immune and allergic status) complemented by control of the infectious source based on an anatomic diagnosis, which may require radiologic investigations (Chapters 259 and 260; see Fig. 94-1). Emergency, empirical antibiotic therapy (Table 94-2) should be guided by the greater frequency of gram-positive bacteria, the possibility of resistant organisms, and the local bacteriologic features. In a meta-analysis, the efficacies of empirical antibiotic monotherapies and combination antibiotic therapy appear to be equivalent for the treatment of sepsis.[A18]

Broad-spectrum antibiotics should be used for as short a time as possible. If a causative organism is identified, the antibiotic regimen should be quickly narrowed within 3 to 5 days to decrease the emergence of resistant organisms. The duration of antibiotics should be guided by the cause of septic shock, reviewed regularly, but patients generally require 7 to 10 days of therapy. Compared with usual care, procalcitonin-guided use of antibiotics (e.g., a ≥80% reduction in the procalcitonin level or a level ≤0.5 μg/L on day 5 or later) in critically ill patients can decrease the duration of antibiotic therapy and hospitalization, but its effect on more important outcomes is less clear.[A19,A20]

Corticosteroids

Corticosteroids administered before antibiotics can decrease the neurologic sequelae of bacterial (especially pneumococcal) meningitis (Chapter 381). Although corticosteroids are not effective for preventing septic shock in patients who have sepsis but are not in shock, the combination of 50 mg intravenous hydrocortisone every 6 hours (200 mg daily) plus 50 μg fludrocortisone (orally

via a nasogastric tube) once daily for 7 days can improve 90-day all-cause mortality in patients with septic shock.[A21] By comparison, hydrocortisone (200 mg intravenously daily) treatment alone is associated with a shorter duration of shock but no reduction in 90-day mortality,[A22] and no benefit from the combination of hydrocortisone, vitamin C, and thiamine has been seen in randomized clinical trials.[A23,A24] Current sepsis guidelines suggest that corticosteroids not be used if fluid resuscitation and vasopressors can restore hemodynamic stability, but low-dose corticosteroids (200 mg hydrocortisone per day) or the combination of hydrocortisone plus fludrocortisone may be added if hemodynamic stability cannot be achieved. The one exception is COVID-19 (Chapter 337), for which corticosteroids (e.g., dexamethasone 6 mg intravenously once daily) decrease the need for ventilation and mortality by about 30% in patients who require oxygen.[A25] Enthusiasm for steroid therapy must be tempered by the risk of complications such as superinfection, neuromyopathy, hyperglycemia, immune suppression, and impaired wound healing.

Hyperglycemia and Intensive Insulin Therapy

Hyperglycemia and insulin resistance are common in septic shock, but intensive insulin therapy to control blood glucose levels tightly is not beneficial in patients in medical ICUs because of significantly higher rates of hypoglycemia and perhaps increased mortality. Aggressive insulin therapy to address the hyperglycemia that often accompanies corticosteroid treatment is no better than usual glucose control.

Renal Dysfunction and Dialysis

Acute kidney injury is an important complication of septic shock because of its associated morbidity, mortality, and resource use (Fig. 94-2). In critically ill patients who have acute kidney injury, hemodialysis six times per week is no better than conventional hemodialysis, and intensive renal replacement therapy is no better than standard therapy overall or in patients who have sepsis.

Continuous renal replacement therapy may be preferable to intermittent hemodialysis in patients with septic shock who remain hemodynamically unstable. The use of regional citrate for anticoagulation increases the filter's life span during renal replacement therapy and reduces the risk of bleeding.[A26]

The timing for initiation of renal replacement therapy in the critically ill remains uncertain. The largest trials have not shown any benefit in mortality when renal replacement therapy is started earlier than with standard criteria.[A27] Venoarterial extracorporeal membrane oxygenation may be beneficial for patients with sepsis-induced cardiogenic shock (Chapter 93).

Low-dose dopamine (2 to 4 μg/kg/minute) does not decrease the need for renal support, does not improve outcomes, and is not recommended. Lactic acidosis is a common complication of septic shock, but administration of sodium bicarbonate for lactic acidosis does not improve hemodynamics or the response to vasopressors.

Other Therapies

Deep venous thrombosis prophylaxis with low-molecular-weight heparin (LMWH) may be superior to low-dose unfractionated heparin because it may decrease the risk of pulmonary emboli in the critically ill. LMWH is recommended for patients who do not have active bleeding, coagulopathy, or a contraindication to heparin (see Fig. 94-2). Stress ulcer prophylaxis with proton pump inhibitors or H_2-receptor antagonists decreases the risk of gastrointestinal hemorrhage.

Adding vitamin C and thiamine does not add benefit to corticosteroids alone,[A28] and, as noted earlier, the three-drug combination may be no better than placebo. Enteral nutrition is generally safer and more effective than total parenteral nutrition (Chapter 198), but total parenteral nutrition is sometimes required in patients with abdominal sepsis, surgery, or trauma. Initial trophic feeding, which provides about 25% of normal calorie requirements, is comparable to full enteral feeding after stabilization of patients in septic shock. The use of sedation, neuromuscular blocking agents, and corticosteroids should be minimized because they can exacerbate septic encephalopathy and the polyneuropathy or myopathy of sepsis. Neutropenic patients may benefit from granulocyte colony-stimulating factor (Chapter 153). The risk of nosocomial infection is decreased by narrow-spectrum antibiotics, early weaning from ventilation, and periodic removal and replacement of catheters (Chapter 261).

TABLE 94-2 POTENTIAL ANTIBIOTIC REGIMENS FOR PATIENTS WITH SEPTIC SHOCK*

SOURCE OF SEPSIS	INITIAL ANTIBIOTIC REGIMEN	ALTERNATIVE ANTIBIOTIC REGIMEN
Community-acquired pneumonia	Third-generation cephalosporin (e.g., cefotaxime 2 g IV q6h; ceftriaxone 2 g IV q12h; ceftizoxime 2 g IV q8h) *plus* fluoroquinolone (e.g., ciprofloxacin 400 mg IV q12h, levofloxacin 750 mg IV q24h, moxifloxacin 400 mg IV q24h) *or* macrolide (azithromycin 500 mg IV q24h)	Piperacillin-tazobactam (3.375 g IV q6h) *plus* fluoroquinolone (e.g., ciprofloxacin 400 mg IV q12h, levofloxacin 750 mg IV q24h, moxifloxacin 400 mg IV q24h) *or* macrolide (azithromycin 500 mg IV q24h)
Hospital-acquired pneumonia	Vancomycin (15 mg/kg IV q 8-12h, if increased risk of MRSA) *or* linezolid (600 mg IV q12h, if increased risk of MRSA) *plus* carbapenem (e.g., imipenem 0.5 g IV q6h *or* meropenem 1 g IV q8h) *plus* fluoroquinolone (e.g., ciprofloxacin 400 mg IV q12h, levofloxacin 750 mg IV q24h)	Fluoroquinolone (e.g., ciprofloxacin 400 mg IV q12h, levofloxacin 750 mg IV q24h) *plus* vancomycin (1.5 g IV q12h) *plus* piperacillin-tazobactam (3.375 g IV q6h) *or* ceftazidime (2 g IV q8h) *or* aztreonam (2 g IV q8h)
Spontaneous bacterial peritonitis	Ceftriaxone (1 g IV q12h)	Moxifloxacin (400 mg IV q24h)
Gastrointestinal perforation	Piperacillin-tazobactam (3.375 g IV q6h) *or* carbapenem (e.g., imipenem 0.5 g IV q6h, meropenem 1 g IV q8h)	Cefepime (1 g IV q8h) *plus* metronidazole (500 mg IV q8h) *or* Metronidazole (500 mg IV q8h) *plus* fluoroquinolone (e.g., ciprofloxacin 400 mg IV q12h)
Urinary tract	Third-generation cephalosporin (e.g., cefotaxime 2 g IV q6h, ceftriaxone 2 g IV q12h, or ceftizoxime 2 g IV q8h)	Ampicillin (2 g IV q4h) *plus* gentamicin (1.5 mg/kg IV q8h) *or* ertapenem (1 g IV q24h, if ESBL)
Necrotizing fasciitis	Vancomycin (15 mg/kg IV q8-12h) *plus* piperacillin-tazobactam (3.375 g IV q6h) *plus* clindamycin (600 mg IV q8h)	Vancomycin (15 mg/kg IV q8-12h) *plus* ciprofloxacin (400 mg IV q12h) *plus* clindamycin (600 mg IV q8h)
Primary bacteremia (normal host)	Piperacillin-tazobactam (3.375 g IV q6h) *plus* vancomycin (1.5 g IV q12h)	Carbapenem (e.g., imipenem 0.5 g IV q6h, meropenem 1 g IV q8h) *plus* vancomycin (1.5 g IV q12h)
Primary bacteremia (intravenous drug user)	Vancomycin (1.5 g IV q12h) *plus* fluoroquinolone (e.g., ciprofloxacin 400 mg IV q12h)	Piperacillin-tazobactam (3.375 g IV q6h) *plus* vancomycin (1.5 g IV q12h)

TABLE 94-2 POTENTIAL ANTIBIOTIC REGIMENS FOR PATIENTS WITH SEPTIC SHOCK*—cont'd

SOURCE OF SEPSIS	INITIAL ANTIBIOTIC REGIMEN	ALTERNATIVE ANTIBIOTIC REGIMEN
Catheter-related bloodstream infection (CR-BSI)	Vancomycin (1.5 g IV q12h) +/− cefepime (2 g IV q8h)	Vancomycin (1.5 g IV q12h) +/− carbapenem (e.g., imipenem 0.5 g IV q6h, meropenem 1 g IV q8h)
If gram-positive cocci in clusters ≥2 blood cultures	Vancomycin (1.5 g IV q12h)	Piperacillin-tazobactam (3.375 g IV q6h) *or* ceftazidime (2 g IV q8h) *or* aztreonam (2 g IV q8h)
Febrile neutropenia	Cefepime (2 g IV q8h) *plus* vancomycin (1.5 g IV q12h)	Aztreonam (2 g IV q8h) *plus* gentamicin (1.5 mg/kg q8h) *or* Cefepime (2 g IV q8h) *plus* gentamicin (1.5 mg/kg q8h) *or* Piperacillin-tazobactam (3.375 g IV q6h) *plus* gentamicin (1.5 mg/kg q8h) *or* Carbapenem (e.g., imipenem 0.5 g IV q6h, meropenem 1 g IV q8h) *plus* gentamicin (1.5 mg/kg q8h) If beta-lactam allergy: Vancomycin (1.5 g IV q12h) *plus* gentamicin (1.5 mg/kg q8h) *plus* ciprofloxacin (400 mg IV q12h)
Bacterial meningitis	Ceftriaxone (2 g IV q12h) *plus* ampicillin (3 g IV q6h) *plus* vancomycin (1.5 g IV q12h) *plus* dexamethasone (0.15 mg/kg IV q6h for 2-4 days)	Gram-positive cocci: vancomycin (1.5 g IV q12h) *plus* ceftriaxone (2 g IV q12h) Gram-negative diplococci: cefotaxime (2 g IV q4-6h) *or* ceftriaxone (2 g IV q12h) Gram-positive bacilli: ampicillin (3 g IV q6h) *plus* gentamicin (1.5 mg/kg IV q8h) Gram-negative bacilli: ceftazidime (2 g IV q8h) *plus* gentamicin (1.5 mg/kg IV q8h) *or* cefepime (1 g IV q8h) All above *plus* dexamethasone (0.15 mg/kg IV q6h for 2-4 days)
Cellulitis†	Severe: Vancomycin (1.5 g IV q12h) *plus* piperacillin-tazobactam (3.375 g IV q6h)	Moderate: Cefazolin (1-2 g IV q8h) *or* ceftriaxone (2 g IV q12h) *or* clindamycin (600 mg IV q8h)

*Most antibiotic doses must be adjusted if there is hepatic or renal dysfunction. Some antibiotics require adjustment based on levels (e.g., gentamicin). In selecting a drug, carefully consider the patient's history of antibiotic (especially penicillin) allergy.
†Assess for necrotizing fasciitis and consider surgical consultation; raise extremity.
ESBL = gram-negative organisms including those that produce extended spectrum β-lactamases (ESBL); IV = intravenous; MRSA = methicillin-resistant *S. aureus*.

PREVENTION

Measures to prevent sepsis include caregiver handwashing before and after patient contact, elevation of the head of the bed to help prevent aspiration, sterile techniques for the insertion of catheters, and possibly the use of antibiotic-impregnated catheters. New catheter insertion sites for catheter changes, isolation of patients who have resistant organisms, and isolation of significantly immunocompromised patients may also prevent infection.

Preventing the progression from sepsis to septic shock requires early diagnosis and aggressive resuscitation.[16] Early intravenous antibiotics (within 1 hour),[17] fluid resuscitation, and lung-protective ventilation are critical therapies in early septic shock (Table 94-3). In patients with severe community-acquired pneumonia (Chapter 85), hydrocortisone (200 mg intravenously daily for 4 to 8 days) can reduce the need for vasopressors.[A29]

PROGNOSIS

The survival and quality of life after hospital discharge after septic shock remain poorer than expected for at least the next 10 years. For example, the 28-day mortality of septic shock is about 20% in academic centers, where early initiation of appropriate therapies, especially antibiotics, is routine.[18] Deaths in the first 72 hours are usually due to refractory septic shock despite increasing life support. Later deaths (after day 3) are usually due to multiple organ dysfunction, nosocomial infection, or both. The number of dysfunctional organs is a marker of poor prognosis, especially in patients who do not improve or have progressive organ dysfunction. Other markers of poor prognosis include delays in achieving adequate resuscitation and antibiotics, increased age, underlying chronic comorbidities, more severe critical illness, increased arterial lactate, and the need for high doses of vasopressors. Patients who have an episode of acute kidney injury during septic shock also have a significantly decreased long-term survival than patients without it.

The increasing numbers of septic shock survivors highlight the importance of long-term sequelae, such as depression, cognitive dysfunction, and post-traumatic stress disorder. Septic shock survivors have about a 35% risk of hospital readmission within 6 months, higher than that of patients who are discharged after an acute myocardial infarction, heart failure, or chronic obstructive pulmonary disease.

Quality of life is frequently impaired in survivors of septic shock. For example, survivors of septic shock accompanied by ARDS (Chapter 90) can have neuromuscular dysfunction (weakness) and dyspnea on exertion or other persistent organ dysfunction. Unfortunately, a trial of more intensive postdischarge therapy compared with usual care found no difference in mental health–related quality of life.[A30]

B. Breathing—Oxygen, with a tidal volume 6 mL/kg IBW if ventilated. Wean according to ARDSNet protocol (Chapters 90 and 91)

C. Circulation
- Fluids, vasopressors, inotropes, transfusion; goals include:
  - MAP >65 mm Hg
  - CVP 8-12 mm Hg
  - Hgb 7.0-9.0 g/L

Consider pulmonary artery catheter or echocardiogram especially if known cardiovascular disease; goals include:
- Wedge pressure 8-15 mm Hg
- Cardiac index: normal or increased

D. Drugs:
- Antibiotics: Narrow spectrum to cause of infection

Consider:
- Hydrocortisone (see text): hydrocortisone 50 mg intravenously every 6 hours daily for 7 days
- Vasopressin 0.01–0.03 units/minute intravenously

Other Organ Support
- Renal function: Continuous renal replacement
- DVT prophylaxis: (e.g., low molecular weight heparin [e.g., dalteparin 5000 IU subcutaneously daily])
- Stress ulcer prophylaxis: PPI (e.g., pantoprazole 40 to 80 mg intravenously once or twice daily) or H_2-receptor antagonist (e.g., ranitidine 50 mg intravenously every 8 hours)
- Nutrition: Enteral preferred
- Sedation: Intermittent with daily awakening

FIGURE 94-2. Ongoing critical care support and management in septic shock. ARDSNet = The US National Institute of Health Acute Respiratory Distress Syndrome; CVP = central venous pressure; DVT = deep venous thrombosis; Hgb = hemoglobin; IBW = ideal body weight; MAP = mean arterial pressure; NG = nasogastric; PPI = proton pump inhibitor; $Scvo_2$ = central venous oxygen saturation.

TABLE 94-3 HEMODYNAMIC VARIABLES, ABBREVIATIONS, AND NORMAL VALUES

Arterial pressure: systolic pressure (SAP) (>100 mm Hg), diastolic pressure, pulse pressure, mean arterial pressure (MAP) (>65 mm Hg)
Central venous pressure (CVP): normal, 6-12 mm Hg
Pulmonary artery pressure (PAP): normal, 25/15 mm Hg
Pulmonary vascular resistance (PVR): normal, 150-250 dynes*sec/cm^5

$$\left(= \frac{\text{PAP} - \text{PAOP}}{\text{CO}} \times 80\right)$$

Pulmonary artery occlusion pressure (PAOP) or pulmonary artery wedge pressure (PAWP): normal, 8-15 mm Hg
Systemic vascular resistance (SVR): normal, 900-1400 dynes*sec/cm^5

$$\left(= \frac{\text{PAP} - \text{CVP}}{\text{CO}} \times 80\right)$$

Cardiac output (CO): normal, 5 L/min
Left ventricular stroke work index (LVSWI): normal, (60-100 grams × meters/beats) = (SV × [MAP − PAWP] × 0.0136)
Oxygen delivery (Do_2): normal, 1 L/min (= CO × [Hb × 1.38 × Sao_2] + [0.003 × Po_2])
Oxygen consumption ($\dot{V}o_2$): normal, 250 mL/min (= CO × Hb × 1.38 × [Sao_2 − Svo_2] + [0.003 × (Pao_2 − Pvo_2)])
Oxygen extraction ratio: normal, 0.23-0.32 (= $\dot{V}o_2/Do_2$)
Hemodynamic variables are often normalized to account for different body mass by dividing by body surface area (BSA)
Pulmonary vascular resistance index (PVRI): normal (= PVR/BSA)
Systemic vascular resistance index (SVRI): normal (= SVR/BSA)
Cardiac index (CI): normal, 2.5-4.2 L/min/m^2 (= CO/BSA)
Left ventricular stroke work index (LVSWI): normal (= LVSW/BSA)
Oxygen delivery index (Do_2I): normal, 460-650 mL/min/m^2 (= Do_2/BSA)
Oxygen consumption index ($\dot{V}o_2I$): normal, 95-170 mL/min/m^2 (= $\dot{V}o_2$/BSA)
Hb = hemoglobin concentration in grams/liter: Normal value is 12 to 15 mg/dL in females and about 10% higher in males.

95 DISORDERS DUE TO HEAT AND COLD

MICHAEL N. SAWKA AND FRANCIS G. O'CONNOR

TEMPERATURE REGULATION

Body temperature is regulated through two parallel processes that modify body heat balance: behavioral (clothing, shelter, physical activity) and physiologic (skin blood flow, sweating, shivering). Both peripheral (skin) and central (core) thermal receptors provide afferent input to a central nervous system integrator (hypothalamic thermoregulatory center), and any deviation between the controlled variable (body temperature) and a theoretical reference variable ("set point" temperature) results in a heat loss or conservation response.

Humans normally regulate body (core) temperature at about 37° C (98.6° F), and fluctuations within the narrow range of 35° to 41° C (95° to 105.8° F) can be tolerated by healthy acclimatized persons; core temperatures outside this range can induce morbidity and mortality. By one estimate, about 8% of worldwide mortality can be attributed to high or low ambient environmental temperatures, with cold-attributable mortality exceeding heat-attributable mortality by a wide margin worldwide.[1]

There is no single core temperature because it varies at different deep body sites, during rest and physical exercise, and with different measurement techniques.[2] Arterial blood temperature, which provides the best invasive measurement of core temperature, is slightly lower than brain temperature. The most accurate noninvasive index of core temperature is esophageal temperature, followed in order of preference by rectal, gastrointestinal tract (telemetry pill), and oral temperature. Ear (tympanic and auditory meatus) or scanned temporal artery temperature should not be relied on for clinical judgment. Rectal temperatures are most commonly recommended because they are easy to measure and are not biased by environmental conditions.

HEAT ILLNESS

DEFINITION

Minor heat-related illnesses include miliaria rubra, heat syncope, and heat cramps. Serious heat illness represents a spectrum from heat exhaustion to heat injury and heatstroke.

EPIDEMIOLOGY

Heat illness, which is increasing because of global warming, accounts for considerable morbidity and mortality in the world today.[3] Serious heat illness is associated with a variety of individual factors, health conditions, drugs, and environmental factors (Table 95-1). Exertional heat illness is among the leading causes of death in young athletes, and its incidence appears to be increasing in the United States, particularly in vulnerable (e.g., homeless) populations.[4] Classic heat illness caused by high environmental temperatures remains a problem, especially in homebound elderly persons without air conditioning.[5] Anticholinergic and sympathomimetic poisoning (Chapter 96) can induce hyperthermia. Malignant hyperthermia (Chapter 400) is a rare disorder occurring in genetically predisposed individuals. Rapid and massive skeletal muscle contraction from exposure to certain volatile anesthetic agents (most commonly halothane, sevoflurane, desflurane, isoflurane, or enflurane) or depolarizing muscle agent relaxants (e.g., succinylcholine) can trigger core temperature elevations well above 43° C (110° F). However, some speculate that heat disorders with extreme exercise may represent a similar syndrome. Neuroleptic malignant syndrome (Chapter 402) is an idiosyncratic hyperthermic reaction caused by skeletal muscle rigidity from treatment with neuroleptic medications (e.g., antipsychotics, antidepressants, antiemetics, and L-dopa. Both malignant hyperthermia and neuroleptic malignant syndrome are potentially fatal without prompt recognition and early intervention.

Heat illness can also occur in low-risk individuals who have taken appropriate precautions relative to situations to which they have been exposed in the past. Historically, such unexpected cases were attributed to dehydration (which impairs thermoregulation and increases hyperthermia and cardiovascular strain), but it is now suspected that a previous heat exposure or a concurrent event (e.g., sickness or injury) might make these individuals more susceptible to serious heat illness. One theory is that previous heat injury or illness primes the acute phase response and augments the hyperthermia of exercise, inducing unexpected serious heat illness. Another theory is that previous infection produces proinflammatory cytokines that deactivate the cells' ability to protect against heat shock.

TABLE 95-1 FACTORS PREDISPOSING TO SERIOUS HEAT ILLNESS

INDIVIDUAL FACTORS
Lack of acclimatization
Low physical fitness
Excessive body weight
Dehydration
Advanced age
Young age
Toll-like receptor-4 polymorphisms
HEALTH CONDITIONS
Inflammation and fever
Viral or bacterial infection
Cardiovascular disease
Diabetes mellitus
Gastroenteritis
Rash, sunburn, and previous burns to large areas of skin
Seizures
Thyroid storm
Neuroleptic malignant syndrome
Malignant hyperthermia
Sickle cell trait
Cystic fibrosis
DRUGS
Anticholinergic properties (atropine)
Antiepileptic (topiramate)
Antihistamines
Anti-Parkinsonian medications
Glutethimide
Phenothiazines
Tricyclic antidepressants
Amphetamines, cocaine, ecstasy [3,4-methylenedioxy-methamphetamine (MDMA)]
Ergogenic stimulants (e.g., ephedrine, ephedra)
Lithium
Diuretics
β-Blockers
Ethanol
Nonsteroidal anti-inflammatory drugs
ENVIRONMENTAL FACTORS
High temperature
High humidity
Little air motion
Lack of shade
Heat wave
Physical exercise
Heavy clothing
Prior compromised heat exposures

PATHOBIOLOGY

Body temperature can increase from a number of mechanisms: exposure to environmental heat (impeded heat dissipation), physical exercise (increased heat production), fever from systemic illness (elevated set point with subsequent activation of shivering), and medications (neuroleptic malignant syndrome and malignant hyperthermia). In addition, febrile persons have accentuated elevations in core temperature when they are exposed to high ambient temperature, physical exercise, or both. Environmental temperature and humidity, medications, and exercise heat stress in turn challenge the cardiovascular system to provide high blood flow to the skin, where blood pools in warm, compliant vessels such as those found in the extremities. When blood flow is diverted to the skin, reduced perfusion of the intestines and other viscera can result in ischemia, endotoxemia, and oxidative stress. Several common mutations in toll-like receptor 4 are associated with endotoxin hypo-responsiveness. In addition, excessively high tissue temperatures (heat shock: >41° C [105.8° F]) can produce direct tissue injury; the magnitude and duration of the heat shock influence whether cells respond by adaptation (acquired thermal tolerance), injury, or death (apoptotic or necrotic). Heat shock, ischemia, and systemic inflammatory responses can result in cellular dysfunction, disseminated intravascular coagulation, and multiorgan dysfunction syndrome (E-Fig. 95-1). Furthermore, reduced cerebral blood flow, combined with abnormal local metabolism and coagulopathy, can lead to dysfunction of the central nervous system.

ABSTRACT

Humans normally regulate body (core) temperature at about 37° C (98.6° F), and fluctuations within the narrow range of 35° to 41° C can be tolerated by healthy acclimatized persons. Rectal, esophageal, and oral measures of core temperature can be used for clinical judgment but not ear or scanned temporal artery temperature. Serious heat illness includes heat exhaustion, heat injury, and heatstroke. Heat illness accounts for substantial morbidity and mortality in the world and appears to be increasing in the United States. With global climate change, the resultant warming has led to severe heat waves that put vulnerable populations at particular risk. Management of serious heat illness should stress early and aggressive whole-body cooling (e.g., cool/cold water immersion or skin soaking with accelerated evaporation), rehydration, and monitoring. Cold injuries are classified as hypothermia (mild, moderate, and profound) and peripheral cold injuries (nonfreezing and freezing), which often occur simultaneously. Moderate (core temperature < 32° C) and profound (core temperature < 26° C) cold require active rewarming with common complications including ventricular fibrillation. Frostbitten tissues should be protected from trauma and not thawed until confident that warmth can be maintained because refreezing causes additional injury. Gentle rewarming in a water-bath (38° to 43° C) with ibuprofen administration is recommended. Imaging can help predict likelihood of tissue viability, and surgical consultation is recommended. Therapeutic hyperthermia and hypothermia are experimental.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Minor heat illness is common and can be recognized by its clinical features. Miliaria rubra (heat rash) results from the occlusion of eccrine sweat gland ducts and can be complicated by secondary staphylococcal infection. Heat syncope (fainting) is caused by temporary circulatory insufficiency as a result of blood pooling in the peripheral veins, especially the cutaneous and lower extremity veins. Skeletal muscle cramps most commonly occur during and after intense exercise and are probably related to dehydration, loss of sodium or potassium, and neurogenic fatigue rather than to overheating itself.

Serious heat illness includes heat exhaustion, heat injury, and heatstroke, with some individuals progressing along this spectrum. Patients who exhibit symptoms (e.g., dizziness, unsteady gait, ataxia, headache, confusion, weakness, fatigue, nausea, vomiting, diarrhea) should have an immediate assessment of their mental status, core (rectal) temperature, and other vital signs. The most common heat-related causes of hospital admission are fluid and electrolyte disorders (Chapters 102 and 103), acute kidney injury (Chapter 106), urinary tract infection (Chapter 263), and heatstroke. Until proven otherwise, heatstroke should be the initial working diagnosis in anyone who is a heat casualty and has an altered mental status.

Heat exhaustion is defined as a syndrome of hyperthermia (temperature at time of event usually ≤40° C or 104° F) and debilitation that occurs during or immediately after exertion in the heat, accompanied by no more than minor central nervous system dysfunction (headache, dizziness, mild confusion), which resolves rapidly with intervention. It is primarily a cardiovascular event (insufficient cardiac output) frequently accompanied by sweaty hot skin, dehydration, and collapse.

Heat injury is a moderate to severe illness characterized by evidence of damage to end organs (e.g., liver, renal, gut) and tissues (e.g., rhabdomyolysis) without sufficient neurologic symptoms to be diagnosed as heatstroke. It is usually associated with body temperatures above 40° C (104° F).

Heatstroke is a severe illness characterized by profound mental status changes with high body temperatures usually, but not always, higher than 40.5° C (104.9° F).[6] However, patients with a core temperature higher than 40.5° C do not universally have a heat injury or heatstroke, and core temperatures this high can be seen transiently after stressful exercise in the heat. To establish the diagnosis of heatstroke, the entire clinical picture, including mental status and laboratory results, must be considered. Heatstroke is often categorized as classic or exertional; classic heatstroke is observed primarily in otherwise sick and compromised individuals, and exertional heatstroke is observed during or after vigorous exercise (Table 95-2).

Severe heatstroke evolves clinically through three distinct phases, more commonly seen in exertional heatstroke than in classic heatstroke: a hyperthermic-neurologic acute phase, a hematologic-enzymatic phase, and a late renal-hepatic phase. In the hyperthermic-neurologic acute phase, the marked elevation in tissue and organ temperatures is associated with gastrointestinal and central nervous system dysfunction. In the hematologic-enzymatic phase, manifestations range from mild activation of coagulation and fibrinolysis to severe disseminated intravascular coagulation with elevated aminotransferase and creatine kinase levels. The late renal-hepatic phase is characterized by diffuse end-organ failure. In fulminant heatstroke, patients have the full spectrum of abnormalities associated with the systemic inflammatory response syndrome (Chapter 94).

TREATMENT AND PREVENTION

Heat illness can be prevented by heat acclimatization and acquired thermal tolerance, maintenance of adequate hydration, and avoidance of overwhelming heat exposure.[7] Adequate fluid intake is critical, and oral rehydration solutions should contain sodium and other electrolytes to restore both intracellular and extracellular fluid.

Management of serious heat illness, which should begin in the field setting, includes cooling, rehydration, and monitoring (Table 95-3).[8] The first priority should be immediately to initiate whole-body cooling and to continue cooling until the core temperature falls below 38.8° C (102° F). Body cooling lowers skin temperatures, thereby facilitating conduction and convection from the core to the shell, and reduces cardiovascular stress by causing arterial and venous constriction that redirects blood back to the heart. Immersion or soaking of the skin in cool or ice water with skin massage is the most effective method,[9] but other effective methods include soaking of the skin followed by accelerated evaporation with fans or the use of ice sheets and ice packs. These noninvasive treatments can be supplemented with the infusion of chilled (≈4° C) normal saline. Cooling can induce shivering, which is usually not sufficient to increase body temperature, so shivering need not be treated.

Hospital care of exertional heat stroke, while largely supportive, can rapidly escalate to the complex management of fulminant multiorgan failure.[10] The highest priority for patient care remains urgent cooling, including cold intravascular fluid. Cooling is usually discontinued at a core temperature of 38° to 39° C to avoid overcooling, but this practice is not based on data from controlled trials.[11]

Patients who are unconscious are at risk of poor airway control and may require endotracheal intubation to prevent aspiration. Fluid and electrolyte deficits should be corrected; restoration of plasma volume with isotonic fluids (e.g., normal saline) sufficient to sustain adequate perfusion, as judged by carefully monitored urine output, is also a priority. Rapid overcorrection of serum electrolytes (e.g., sodium) should be avoided. If rhabdomyolysis (Chapter 99) and myoglobinuria are present, maintaining urine flow helps minimize renal injury.

TABLE 95-2 COMPARISON OF CLASSIC AND EXERTIONAL HEATSTROKE

PATIENT CHARACTERISTICS	CLASSIC	EXERTIONAL
Age	Young children or elderly	15-55 years
Health	Chronic illness	Usually healthy
Fever	Unusual	Common
Prevailing weather	Frequent in heat waves	Variable
Activity	Sedentary	Strenuous exercise
Drug use	Diuretics, antidepressants, anticholinergics, phenothiazines	Ergogenic stimulants or cocaine
Sweating	Often absent	Common
Acid-base disturbances	Respiratory alkalosis	Lactic acidosis
Acute renal failure	Uncommon	Common (≈15%)
Rhabdomyolysis	Uncommon	Common (≈25%)
CK	Mildly elevated	Markedly elevated (500-1000 U/L)
ALT, AST	Mildly elevated	Markedly elevated
Hyperkalemia	Uncommon	Common
Hypocalcemia	Uncommon	Common
DIC	Mild	Marked
Hypoglycemia	Uncommon	Common

ALT = alanine aminotransferase; AST = aspartate aminotransferase; CK = creatine kinase; DIC = disseminated intravascular coagulation.

TABLE 95-3 MANAGEMENT OF HEAT ILLNESS

HEAT EXHAUSTION
Rest and shade
Loosen and remove clothing
Supine position and elevate legs
Actively cool skin
Fluids by mouth
Monitor core temperature
Monitor mental status
HYPERTHERMIA
Protect the airway
Insert at least two large-bore intravenous lines
Monitor core temperature; options include rectal, pulmonary artery, esophageal probe
Actively cool the skin until core temperature reaches <39° C (<102.2° F)
Ice baths or cool water (≈22° C [71.6° F]) immersion
Wetting with water (avoid alcohol rubs)
Continuous fanning
Exposure to cool environment
Axillary or perineal ice packs and ice sheets
Infusion of room-temperature saline
Gastric or colonic iced saline lavage
Peritoneal lavage with iced normal saline
Monitor electrocardiogram for arrhythmia
Obtain serial diagnostic studies*

*Electrocardiogram, chest radiograph, complete blood count with differential, platelet count, urinalysis, aminotransferases, alkaline phosphatase, bilirubin, creatine kinase, blood urea nitrogen, creatinine, phosphate, calcium, glucose, electrolytes, uric acid, prothrombin time and partial thromboplastin time, D-dimer, fibrinogen, arterial blood gases, toxicology screen.

The hematologic-enzymatic and renal-hepatic phases should be anticipated, because they may require appropriate subspecialty care. Patients should be carefully monitored to detect possible metabolic abnormalities (e.g., hyperkalemia; Chapter 103), renal or hepatic failure (Chapters 116 and 140), disseminated intravascular coagulation (Chapter 161), cardiac arrhythmias (Chapters 51 to 53), and acute respiratory failure (Chapter 90). Management of these complications is largely supportive, with specific therapies as indicated for any critically ill patient. Medications to be avoided include antipyretics and sedatives with hepatic toxicities. Lorazepam (1 to 2 mg administered intravenously during a 2- to 5-minute period, repeated if necessary), which is a safe sedative because of its low hepatotoxicity and rapid metabolism, may be indicated in patients who are combative or exhibit seizure activity.

For exercise-induced and environmental heat illness, no pharmacologic interventions have been proved to augment cooling. For patients with malignant hyperthermia, however, dantrolene should be administered as a loading bolus of 2.5 mg/kg intravenously, with subsequent bolus doses of 1 to 2.5 mg/kg every 5 minutes intravenously as needed (up to a maximum total loading dose of 10 mg/kg) until the signs have abated.

PROGNOSIS

A single episode of heat exhaustion does not imply a predisposition to heat illness, and most patients recover within several hours after cooling and rehydration. For patients who present to a hospital with heatstroke, however, mortality rates can range from 26 to 63%. Mortality in both classic and exertional heatstroke correlates directly with the magnitude and duration of temperature elevation, the delay in time to initiation of cooling, and the number of organ systems affected. The likelihood of survival to discharge can be estimated based on prehospital severity as determined by a respiratory rate 22/minute or higher, a Glasgow coma score (Table 368-1) below 15, a systolic blood pressure below 100 mm Hg, a heart rate above 100/minute, a body temperature of 38° C or higher, and age 65 years or above.[12] Although most patients who survive a heatstroke event will have a full recovery, some can sustain permanent organ damage.[13] Neurologic injury with cerebellar dysfunction is the most common clinical picture. Patients who have recovered from heatstroke with organ damage have a higher long-term mortality from cardiovascular, liver, and digestive diseases.

Patients who have suffered heat injury or heatstroke should not be re-exposed to heat until recovery is complete, which can be many weeks or months, and about 10% of heatstroke patients remain intolerant of heat. Return to physical activity should be a gradual process of increased physical activity without heat exposure and then combined with heat exposure.[14]

COLD INJURY

DEFINITION

Cold injuries are classified as hypothermia and peripheral cold injuries. Hypothermia is whole-body cooling, whereas peripheral cold injuries are localized to the extremities and exposed skin. Hypothermia is further divided into three categories: mild (≈33° C to ≈35° C), moderate (≈27° C to ≈32° C), and profound (<27° C). Peripheral cold injuries can be divided into nonfreezing (chilblain, trench foot) and freezing (frostbite). Both hypothermia and peripheral cold injuries often occur simultaneously, and treatment priority should be given to rewarming in moderate and profound hypothermia.

EPIDEMIOLOGY

Accidental hypothermia can occur in most climates, but exposure to cold, wet conditions pose the greatest risk.[15] A variety of individual factors, health conditions, medications, and environmental factors are associated with a predisposition to cold injury (Table 95-4). Homeless persons are at increased risk owing to climatic exposure, which is often exacerbated by the concomitant use of alcohol and other intoxicating substances. In trauma patients (Chapter 97), hypothermia is associated with increased morbidity and mortality. Unwarmed anesthetized patients (Chapter 400) typically become 1° to 2° C hypothermic because of an internal redistribution of body heat from the core to the periphery, so warming should be considered to maintain normothermia

PATHOBIOLOGY

Cold exposure elicits peripheral vasoconstriction to reduce heat transfer between the body's core and shell (skin, subcutaneous fat). If sufficiently cold, the underlying tissues (e.g., muscle) constrict to thicken the isolative shell while reducing the body's core area. This vasoconstrictor response defends core temperature but at the expense of declining peripheral tissue temperatures, which contribute to peripheral cold injuries. Hypothermia depresses enzymatic activity, interferes with physiologic functions (e.g., clotting, respiration, cardiac conduction and rhythm), impairs the expression of cytokines, and can induce cellular injury and death.

TABLE 95-4 FACTORS PREDISPOSING TO COLD INJURY

INDIVIDUAL FACTORS
Inadequate clothing and shelter
Lean and low body fat
Low physical fitness
Prior exhaustive physical exercise
Advanced age
Young age
Black race (men and women)
HEALTH CONDITIONS
Burns
Diabetes mellitus
Hypoglycemia
Neurologic lesions
Dementia
Hypoadrenalism, hypopituitarism, hypothyroidism
Prior frostbite or trench foot
Raynaud phenomenon
Sickle cell trait
Trauma
Spinal cord injury
DRUGS
Alcohol
Anesthetics
Antidepressants
Antipsychotics
Antithyroid agents
Sedatives and narcotics
ENVIRONMENTAL FACTORS
Cold temperatures
High air motion
Rain and immersion
Skin contact with metal and fuels
Repeated cold exposure
Physical fatigue
Immobility
High-altitude and low-oxygen-tension environments

The pathophysiologic mechanism of frostbite includes four overlapping pathologic phases: prefreeze, freeze-thaw, vascular stasis, and late ischemic. The prefreeze phase consists of tissue cooling with accompanying vasoconstriction and ischemia but does not involve actual ice crystal formation. In the freeze-thaw phase, intracellular ice crystals form, thereby causing protein and lipid derangement, cellular electrolyte shifts, cellular dehydration, cell membrane lysis, and subsequent cell death. In the vascular stasis phase, vessels may fluctuate between constriction and dilation; blood may leak from vessels or coagulate within them. The late ischemic phase results from progressive tissue ischemia and infarction due to a cascade of inflammatory cytokines and prostaglandins, intermittent vasoconstriction with continued thrombus formation, and secondary reperfusion injury.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hypothermia is a core temperature below 35° C (95° F), and clinical manifestations are related to the core temperature achieved (Table 95-5). The classic J wave on the electrocardiogram (Fig. 95-1) appears at a core temperature below about 33.8° C (93° F).

Chilblain (Chapter 66) appears as localized inflammatory lesions of the skin, most often involving the dorsal surface of fingers but also involving the ears, face, and exposed shins. Trench foot is caused by prolonged cold, wet exposure (e.g., wet socks or gloves), which can cause skin breakdown and nerve damage. Trench foot is often accompanied by infection and increased sensitivity to pain.

Frostbite (Chapter 66),[16] which is actual freezing of tissues, has traditionally been categorized as first degree (superficial, "frostnip"), second degree (full skin) with superficial skin vesiculation, third degree (subcutaneous tissue) with hemorrhagic blisters, and fourth degree (extensive tissue and bone). For patients with frostbite, early surgical consultation is advised.

TABLE 95-5 HYPOTHERMIA: STAGES AND ASSOCIATED CLINICAL MANIFESTATIONS

STAGE	CORE TEMPERATURE °F	CORE TEMPERATURE °C	CLINICAL MANIFESTATIONS
Normothermia	98.6	37.0	
Mild hypothermia	95.0	35.0	Cold diuresis, maximal shivering
	93.0	33.8	Ataxia, poor judgment, ECG J wave
	91.0	32.7	Amnesia, blood pressure difficult to measure
Moderate hypothermia	89.0	31.6	Stupor, pupils dilated
	87.0	30.5	Shivering ceases
	85.0	30.0	Cardiac arrhythmias, insulin inactive
	82.0	27.8	Unconsciousness, ventricular fibrillation likely
	80.0	26.6	No muscle reflexes
Profound hypothermia	78.0	25.5	Acid-base disturbances, no response to pain
	75.0	23.8	Pulmonary edema, hypotension
	73.0	22.7	No corneal reflexes
	66.0	18.8	Heart standstill
	62.0	16.6	Isoelectric electrocardiogram
	57.6	14.2	Lowest infant survival from accidental hypothermia
	48.2	9.0	Lowest adult survival from accidental hypothermia

ECG = electrocardiogram.

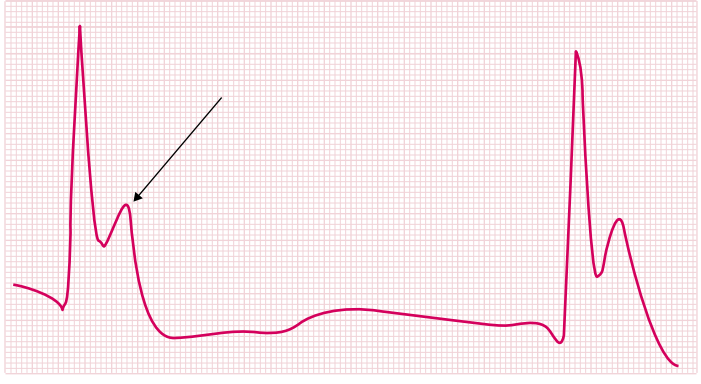

FIGURE 95-1. J (Osborne) wave.

PREVENTION AND TREATMENT

Humans demonstrate minimal cold acclimatization, so prevention depends primarily on avoiding cold exposure and having adequate protection and calorie intake to support metabolism.[17,18] Management of hypothermia depends on the core temperature (Table 95-6). Patients' wet clothing should be removed, and they should be provided with dry insulation. Shivering is an effective physiologic rewarming mechanism and should not be pharmacologically suppressed.

Moderately and profoundly hypothermic patients require active rewarming. Rewarming of the hypothermic patient includes both passive (insulation of the patient to prevent further heat loss) and active core (e.g., warmed saline and warmed humidified oxygen) and external (e.g., warmed water bottles, electric blankets) techniques. Rewarming at a rate of 0.5° to 1.0° C (0.9° to 1.8° F) per hour is acceptable in most cases, except that aggressive rewarming is warranted in patients with significant trauma (because coagulation is hindered by hypothermia) or cardiac arrest.

Complications commonly associated with rewarming of the hypothermic individual include both afterdrop (reduction of core temperature by cold blood returning to the circulation from the periphery) and aftershock (hypotension caused by peripheral vasodilation). Another potential complication of rewarming is ventricular fibrillation, which is more difficult to treat in the presence of moderate or profound hypothermia. If ventricular tachycardia or ventricular fibrillation develops, defibrillation should be attempted (Chapter 50). If ventricular tachycardia or ventricular fibrillation persists after a single shock, additional defibrillation attempts should be made, concurrent with rewarming but without waiting for the patient to warm to a particular target body temperature. Standard resuscitation approaches generally should be followed (Chapter 50). Extracorporeal life support is an option for refractory hypothermia-induced cardiac arrest.[19]

Body cooling induces cold diuresis, so plasma volume must be reestablished to support adequate perfusion. Patients should receive an intravenous infusion of 250 to 1000 mL of heated (40° to 42° C [104° to 108° F]) 5% dextrose in normal saline. Lactated Ringer solution should be avoided because the liver cannot metabolize lactate efficiently during hypothermia. Patients should be monitored for disturbances in potassium and glucose. If hypoglycemia, alcohol, or opiate intoxication is contributing to hypothermia, intravenous glucose (50 to 100 mL of 50% dextrose), thiamine (100 mg), or naloxone (0.4 to 2 mg intramuscularly or intravenously), respectively, may be indicated.

The treatment of frostbite is detailed in Chapter 66.

TABLE 95-6 TREATMENT OF HYPOTHERMIA

STAGE	MANAGEMENT	BODY REWARMING
Mild hypothermia	Monitor vital signs Warm intravenous saline Oxygen Monitor electrocardiogram for arrhythmia	Insulate Shivering Warm bath Active warming blanket
Moderate hypothermia	Diagnostic studies* Intensive care Anticipate infection and multiorgan dysfunction	Prevent extra heat loss by supplementing with airway rewarming Colonic irrigation Peritoneal dialysis
Profound hypothermia	Diagnostic studies*	Central rewarming

*See Table 95-3. Also lactate dehydrogenase, serum lactate, cortisol, thyroid-stimulating hormone, T3, and T4.

PROGNOSIS

Although noninvasive imaging with technetium pyrophosphate or magnetic resonance imaging can often predict the likelihood of tissue viability, it may take weeks to determine the precise demarcation of tissue that will require amputation. As morbidity may result from premature or unnecessary surgical intervention, consultation with a surgeon with experience evaluating and treating frostbite should be obtained to assess the need for and the timing of any amputations.

HYPOTHERMIC SYNDROMES

Exercise-induced bronchospasm (Chapter 75) can be triggered by exercise in cold air, particularly in patients with asthma. Livedo reticularis is patchy mottling of the limbs with cold exposure. Cryoglobulinemia (Chapter 173) occurs when immunoglobulins (IgM, IgG) reversibly precipitate after being cooled and contribute to impaired capillary blood flow in hypothermic tissues. Cold urticaria (Chapters 232 and 407) is the development of localized and general erythema and wheals in skin exposed to cold. Paroxysmal hypothermia is periodic lowering of the thermoregulatory set point and is often associated with hypothalamic abnormalities. Raynaud phenomenon (see Fig. 66-9 in Chapter 66) is intense vasoconstriction with sensitivity to pain in limbs exposed to cold.

TRAUMA HYPOTHERMIA

In trauma patients (Chapter 97), unintended hypothermia (<34° C [93° F]) is associated with increased morbidity and mortality due to impaired coagulation, peripheral vasoconstriction, respiratory depression, and increased risk for cardiac arrhythmias. Shivering aggravates perfusion problems by requiring blood flow to support increased metabolism in contracting muscles. Trauma patients become hypothermic because of heat loss from exposed cavities, environmental exposure, infusion of cool fluids, and ischemia, which depletes cell energy stores. Body temperature should be measured, and appropriate actions, as noted earlier, should be taken to restore normothermia during the early treatment of trauma patients.

THERAPEUTIC HYPOTHERMIA AND HYPERTHERMIA

THERAPEUTIC HYPOTHERMIA

For adults after an out-of-hospital cardiac arrest (Chapter 50), therapeutic cooling (a goal of 36° C for 24 to 48 hours) to prevent the usual hyperthermia

can improve survival and neurologic outcomes[A1,A2] but is no better than therapeutic normothermia (<37.8° C).[A3] However, in-hospital hypothermia does not improve outcomes for patients after brain trauma, patients with intracranial hypertension,[A4] patients after an in-hospital arrest, patients who have undergone decompressive hemicraniectomy for malignant middle cerebral artery stroke,[A5] or patients with convulsive status epilepticus (Chapter 372).[A6]

THERAPEUTIC HYPERTHERMIA

Hyperthermia treatment (whole body or regional) is an experimental technique used as an adjunct to chemotherapy or radiation therapy in patients with advanced cancer. Hyperthermia (40° to 43° C [104° to 109° F]) alone can damage or kill cancer cells but, more important, hyperthermia might potentiate the effectiveness of chemotherapy and radiation by softening the tumor tissue, thus reducing its interstitial pressure.

Externally applied radiant heat, microwaves, or extracorporeal circulation usually induces local, regional, or whole-body hyperthermia. Target tissue temperatures are achieved and maintained based upon the specific cancer protocol, then followed by a passive cooling phase. Patients are usually sedated while core and skin temperatures are monitored. In regional hyperthermia, the part of the body where the tumor is located is heated while being perfused or bathed by a warmed solution containing anticancer drugs. The potential benefit of regional hyperthermia as an adjunct treatment of advanced prostate cancers is currently under investigation.

96 ACUTE POISONING

LEWIS S. NELSON AND DIANE P. CALELLO

EPIDEMIOLOGY

Each year, more than 4 million poisoning cases, suspected or verified, and 300,000 related hospital admissions occur in the United States. Poison centers provide support and collect data on more than 2 million of these exposures annually.[1] Poisoning-related deaths now total about 10,000 annually, and the number of opioid-related deaths has tripled since 2000. Poisonings are the leading cause of injury-related death in the United States, where approximately 90% of these deaths involve drugs, predominantly opioids (75%), such as heroin, fentanyl, and prescription analgesics.[2] Worldwide, however, pesticides, insecticides, caustics, and snakebites (Chapter 98) are also common causes. The incidence of recurrent, purposeful self-poisoning is 12 to 18%, with most events occurring within 3 months of the original attempt. To reduce fatalities and repeated attempts, an emphasis must be placed on measures to improve the safety of prescription drugs, including appropriate prescribing and aggressive treatment of poisoned patients with early psychiatric intervention for suicidal behavior (Chapter 362).

DIAGNOSIS

Despite the vast array of toxins to which a patient may be exposed, the clinical manifestations of poisoning are fairly limited. In most cases, it is less important to predict exactly which toxin is responsible for the acute poisoning than it is to create a differential diagnosis based on a careful history and physical examination as well as basic laboratory assays. The recognition of the specific toxic syndrome, or *toxidrome*, guides the clinician toward the likely diagnosis based on reasonably solid evidence. On this basis, treatment, including initial stabilization, critical care, decontamination, and even the empirical administration of antidotes, can be guided by an understanding of the pharmacology and physiology of the patient's toxidrome. More advanced care, such as methods to enhance the elimination of specific toxicants, commonly requires serial examinations, additional history, and subsequent laboratory testing. Even then, however, the clinical picture is often clouded by exposures to multiple toxicants and an ill-defined time course since the initial exposure.

History

Details elicited about toxic exposures should include the involved drugs and other toxicants, their estimated or known amounts, the time and routes of exposure, the patient's symptoms and signs, and any treatment already administered. Poisoning may result from acute, chronic, or acute-on-chronic exposure. A *toxicant* is defined as a chemical capable of harming a biologic organism; this definition encompasses toxins, which are derived from living organisms (such as plants, bacteria, and venoms), as well as synthetic substances, such as medications, drugs of abuse, and industrial and other chemicals.[3] Determination of chronicity is important because signs and symptoms of chronic exposure (Chapter 20) can differ from those of acute and acute-on-chronic exposure. For example, a history of acute multisystem organ failure narrows the toxicant possibilities to a few gases, chemicals, and drugs. A listing of available medications (e.g., those of the patient, spouse, relatives, or friends), nonprescription medications and herbals, dietary supplements, or ethnic remedies and occupational and avocational activities should be obtained. Occupational and avocational histories should include present and all past jobs and hobbies, with a focus on chemicals, metals, and gases. Known medical conditions may suggest classes of medications available to the patient. The patient's history, which may be incomplete or inaccurate if the patient is confused or suicidal, should be correlated with the clinical manifestations and course. Corroborative history from relatives and friends and findings from the scene as reported by the transporting emergency medical services personnel may be relevant.

Physical Examination

The physical examination should focus on vital signs; the eye, ear, nose, and throat examination; and the neurologic, cardiopulmonary, gastrointestinal, and dermatologic systems. Findings can suggest certain toxidromes, which are clusters of signs and symptoms typical of a specific class of poison. Among the dozens of toxidromes that assist in patient assessment and guide management, those due to adrenergic, anticholinergic, cholinomimetic, opioid, and sedative-hypnotic agents are most relevant to the emergency management of poisoned patients (Table 96-1). Patients may have some or all of these signs and symptoms; an incomplete clinical picture does not exclude a particular toxidrome, and it can still assist the clinician in identifying the correct category of toxicant involved.

Vital Signs

Tachycardia, which can occur with numerous toxicants, is most prominent in patients with anticholinergic and sympathomimetic toxidromes. However, because tachycardia also may occur with anxiety and other nontoxicologic conditions, it is not generally a helpful finding. The differential diagnosis for toxicant-induced *bradycardia* is more limited and includes β-adrenergic receptor antagonists, L-type calcium-channel antagonists (diltiazem or verapamil), cardioactive steroids, peripheral α-adrenergic receptor agonists (e.g., phenylephrine, whose effects are mediated by baroreceptor reflexes), central α_2-agonists such as clonidine, γ-hydroxybutyric acid, opioids, sedative-hypnotics, baclofen, organophosphorus and carbamate pesticides, muscarine-containing mushrooms (*Clitocybe, Inocybe* sp), plant- and animal-derived toxins (e.g., aconitine, andromedotoxin, ciguatoxin, and veratridine, all of which open sodium channels in the myocardium), therapeutic cholinesterase inhibitors (e.g., physostigmine), and some antiarrhythmic drugs (e.g., procainamide, flecainide, and other class IA, IC, and III drugs, such as amiodarone and sotalol). Bradycardia also is a preterminal sign for many highly lethal toxicants, such as cyclic antidepressants and cyanide.

can improve survival and neurologic outcomes[A1,A2] but is no better than therapeutic normothermia (<37.8° C).[A3] However, in-hospital hypothermia does not improve outcomes for patients after brain trauma, patients with intracranial hypertension,[A4] patients after an in-hospital arrest, patients who have undergone decompressive hemicraniectomy for malignant middle cerebral artery stroke,[A5] or patients with convulsive status epilepticus (Chapter 372).[A6]

THERAPEUTIC HYPERTHERMIA

Hyperthermia treatment (whole body or regional) is an experimental technique used as an adjunct to chemotherapy or radiation therapy in patients with advanced cancer. Hyperthermia (40° to 43° C [104° to 109° F]) alone can damage or kill cancer cells but, more important, hyperthermia might potentiate the effectiveness of chemotherapy and radiation by softening the tumor tissue, thus reducing its interstitial pressure.

Externally applied radiant heat, microwaves, or extracorporeal circulation usually induces local, regional, or whole-body hyperthermia. Target tissue temperatures are achieved and maintained based upon the specific cancer protocol, then followed by a passive cooling phase. Patients are usually sedated while core and skin temperatures are monitored. In regional hyperthermia, the part of the body where the tumor is located is heated while being perfused or bathed by a warmed solution containing anticancer drugs. The potential benefit of regional hyperthermia as an adjunct treatment of advanced prostate cancers is currently under investigation.

96 ACUTE POISONING

LEWIS S. NELSON AND DIANE P. CALELLO

EPIDEMIOLOGY

Each year, more than 4 million poisoning cases, suspected or verified, and 300,000 related hospital admissions occur in the United States. Poison centers provide support and collect data on more than 2 million of these exposures annually.[1] Poisoning-related deaths now total about 10,000 annually, and the number of opioid-related deaths has tripled since 2000. Poisonings are the leading cause of injury-related death in the United States, where approximately 90% of these deaths involve drugs, predominantly opioids (75%), such as heroin, fentanyl, and prescription analgesics.[2] Worldwide, however, pesticides, insecticides, caustics, and snakebites (Chapter 98) are also common causes. The incidence of recurrent, purposeful self-poisoning is 12 to 18%, with most events occurring within 3 months of the original attempt. To reduce fatalities and repeated attempts, an emphasis must be placed on measures to improve the safety of prescription drugs, including appropriate prescribing and aggressive treatment of poisoned patients with early psychiatric intervention for suicidal behavior (Chapter 362).

DIAGNOSIS

Despite the vast array of toxins to which a patient may be exposed, the clinical manifestations of poisoning are fairly limited. In most cases, it is less important to predict exactly which toxin is responsible for the acute poisoning than it is to create a differential diagnosis based on a careful history and physical examination as well as basic laboratory assays. The recognition of the specific toxic syndrome, or *toxidrome*, guides the clinician toward the likely diagnosis based on reasonably solid evidence. On this basis, treatment, including initial stabilization, critical care, decontamination, and even the empirical administration of antidotes, can be guided by an understanding of the pharmacology and physiology of the patient's toxidrome. More advanced care, such as methods to enhance the elimination of specific toxicants, commonly requires serial examinations, additional history, and subsequent laboratory testing. Even then, however, the clinical picture is often clouded by exposures to multiple toxicants and an ill-defined time course since the initial exposure.

History

Details elicited about toxic exposures should include the involved drugs and other toxicants, their estimated or known amounts, the time and routes of exposure, the patient's symptoms and signs, and any treatment already administered. Poisoning may result from acute, chronic, or acute-on-chronic exposure. A *toxicant* is defined as a chemical capable of harming a biologic organism; this definition encompasses toxins, which are derived from living organisms (such as plants, bacteria, and venoms), as well as synthetic substances, such as medications, drugs of abuse, and industrial and other chemicals.[3] Determination of chronicity is important because signs and symptoms of chronic exposure (Chapter 20) can differ from those of acute and acute-on-chronic exposure. For example, a history of acute multisystem organ failure narrows the toxicant possibilities to a few gases, chemicals, and drugs. A listing of available medications (e.g., those of the patient, spouse, relatives, or friends), nonprescription medications and herbals, dietary supplements, or ethnic remedies and occupational and avocational activities should be obtained. Occupational and avocational histories should include present and all past jobs and hobbies, with a focus on chemicals, metals, and gases. Known medical conditions may suggest classes of medications available to the patient. The patient's history, which may be incomplete or inaccurate if the patient is confused or suicidal, should be correlated with the clinical manifestations and course. Corroborative history from relatives and friends and findings from the scene as reported by the transporting emergency medical services personnel may be relevant.

Physical Examination

The physical examination should focus on vital signs; the eye, ear, nose, and throat examination; and the neurologic, cardiopulmonary, gastrointestinal, and dermatologic systems. Findings can suggest certain toxidromes, which are clusters of signs and symptoms typical of a specific class of poison. Among the dozens of toxidromes that assist in patient assessment and guide management, those due to adrenergic, anticholinergic, cholinomimetic, opioid, and sedative-hypnotic agents are most relevant to the emergency management of poisoned patients (Table 96-1). Patients may have some or all of these signs and symptoms; an incomplete clinical picture does not exclude a particular toxidrome, and it can still assist the clinician in identifying the correct category of toxicant involved.

Vital Signs

Tachycardia, which can occur with numerous toxicants, is most prominent in patients with anticholinergic and sympathomimetic toxidromes. However, because tachycardia also may occur with anxiety and other nontoxicologic conditions, it is not generally a helpful finding. The differential diagnosis for toxicant-induced *bradycardia* is more limited and includes β-adrenergic receptor antagonists, L-type calcium-channel antagonists (diltiazem or verapamil), cardioactive steroids, peripheral α-adrenergic receptor agonists (e.g., phenylephrine, whose effects are mediated by baroreceptor reflexes), central α_2-agonists such as clonidine, γ-hydroxybutyric acid, opioids, sedative-hypnotics, baclofen, organophosphorus and carbamate pesticides, muscarine-containing mushrooms (*Clitocybe, Inocybe* sp), plant- and animal-derived toxins (e.g., aconitine, andromedotoxin, ciguatoxin, and veratridine, all of which open sodium channels in the myocardium), therapeutic cholinesterase inhibitors (e.g., physostigmine), and some antiarrhythmic drugs (e.g., procainamide, flecainide, and other class IA, IC, and III drugs, such as amiodarone and sotalol). Bradycardia also is a preterminal sign for many highly lethal toxicants, such as cyclic antidepressants and cyanide.

ABSTRACT

Although there are thousands of potentially toxic substances to which humans can be exposed, the majority of patients who are clinically evaluated can be managed with readily available clinical information. Historical information, including potential home and workplace toxins, plus a brief physical examination generally allow identification of one of the various toxicologic syndromes that expedites the decision making regarding treatment. For some patients, the use of routine or specialized clinical laboratory testing or imaging may be needed to confirm a diagnostic suspicion. More advanced testing is occasionally required for certain patients but is generally not available in a clinically relevant time frame, highlighting the need for empiric therapy in these cases. Some patients with toxic exposures may benefit from specific antidotal therapy or elimination techniques, but many require little more supportive and symptomatic care.

TABLE 96-1 TOXIDROMES AND ASSOCIATED DRUGS AND TOXICANTS

	SYNDROME FEATURES		
TOXIDROME	**VITAL SIGNS**	**END ORGAN**	**REPRESENTATIVE DRUGS AND TOXICANTS**
Adrenergic	Hypertension, hyperthermia, tachycardia, tachypnea	Agitation, dysrhythmias, diaphoresis, mydriasis, seizures	Amphetamines, caffeine, cathinone derivatives, cocaine, ephedrine, pseudoephedrine, *Ephedra* sp, phenylephrine,* synthetic cannabinoids, theophylline
Anticholinergic	Hyperthermia, tachycardia, blood pressure generally normal	Agitation, delirium, decreased or absent bowel sounds, dry flushed skin and mucous membranes, mydriasis or blurred vision, seizures, urinary retention	First-generation H_1-receptor antagonists (e.g., diphenhydramine), belladonna alkaloids (e.g., scopolamine, atropine) from plants (e.g., *Datura* sp—deadly nightshade, henbane), benztropine, cyclic antidepressants, dicyclomine, muscle relaxants (e.g., orphenadrine, cyclobenzaprine), trihexyphenidyl
Cholinomimetic	Tachycardia or bradycardia†	Agitation, delirium, coma; bronchorrhea, bronchospasm; diaphoresis; fasciculations; lacrimation; miosis; urination; diarrhea, vomiting; seizures	Carbamate cholinesterase inhibitors (e.g., physostigmine, neostigmine), organophosphorus compounds including pesticides (e.g., diazinon, malathion) and nerve agents (e.g., soman, sarin, VX, novichok), *Inocybe* or *Clitocybe* mushroom spp
Opioid	Bradypnea or apnea, bradycardia, hypotension (late), hypothermia	CNS depression; hypotonia; miosis	Fentanyl, fentanyl analogs, heroin, hydrocodone, oxycodone, morphine, buprenorphine, central α_2-agonists (e.g., clonidine, guanfacine)
Sedative-hypnotic	Generally near normal with benzodiazepines, but bradypnea or apnea, mild hypotension, and mild hypothermia can occur	Ataxia, CNS depression, hyporeflexia, slurred speech, stupor, or coma	Barbiturates, benzodiazepines, bromides, ethanol, gamma-hydroxybutyrate and its precursors, meprobamate, propofol, zolpidem

*Reflex bradycardia can occur as a result of a pure α-adrenergic agonist effect.
†Depending on the specific toxicant, tachycardia can occur early as a result of a preganglionic nicotinic effect; as toxicity progresses, postganglionic muscarinic effects may predominate, and bradycardia develops.
CNS = central nervous system.

Many toxicants cause *hypotension* (Chapter 7). The primary mechanisms are decreased peripheral vascular resistance, decreased myocardial contractility, hypovolemia secondary to gastrointestinal or dermal loss of intravascular volume, and, occasionally, dysrhythmias. Common causes of *hypertension* (Chapter 64), which is generally due to vasoconstriction with or without enhanced inotropy, include amphetamines, cocaine, ephedrine and similar agents, ergots, phencyclidine, nicotine, phenylephrine, thyroid hormones, yohimbine, and chronic lead toxicity. Blood pressure can rise early in poisoning with central α_2-adrenergic agonists and monoamine oxidase inhibitors, but subsequent hypotension should be expected and is more concerning.

Hyperthermia (Chapter 95) occurs with toxicants that cause agitation or excessive psychomotor activity (e.g., cocaine, phencyclidine, monoamine oxidase inhibitors, strychnine), uncouple oxidative phosphorylation (e.g., salicylates, 2,4-dinitrophenol), increase the metabolic rate (e.g., thyroid hormones), impair sweating (e.g., first-generation antihistamines, anticholinergics, phenothiazines), cause vasoconstriction (e.g., amphetamines, cocaine, ephedrine), or alter perception of heat (e.g., cocaine). Other toxicant-induced states associated with hyperthermia include malignant hyperthermia, neuroleptic malignant syndrome, serotonin syndrome, metal fume fever, and aspiration pneumonitis. Toxicant-induced *hypothermia* is typically due to sedative-hypnotics, opioids, barbiturates, ethanol, phenothiazines, or hypoglycemic agents (such as insulin, sulfonylureas, and meglitinides) or rarely to unripe ackee fruit. Oxygen saturation (see Fig. 90-1 in Chapter 90), as measured by *pulse oximetry,* decreases with true hypoxemia (see Table 90-3 in Chapter 90) or methemoglobinemia (not proportionally to concentration) (Chapter 144) but remains normal or may be increased in patients with carbon monoxide or cyanide poisoning (Chapter 82).

Eyes, Ears, Nose, and Throat

Toxicant-induced bilateral miosis (Fig. 96-1) has a limited differential diagnosis that includes central α_2-agonists such as clonidine, guanfacine, and the imidazolines; olanzapine; opioids; organophosphorus compounds or carbamates; therapeutic cholinesterase inhibitors (e.g., pyridostigmine); topical miotic ophthalmic drugs (e.g., pilocarpine, carbachol); and, variably, phencyclidine, phenothiazines, ethanol, and some sedative-hypnotics (Chapter 392). Pontine hemorrhage is a major nontoxicologic diagnosis to consider in a comatose patient with miotic pupils (Chapter 377). Mydriasis is a nonspecific finding. A unilateral dilated pupil may be due to topical ocular application of sympathomimetics (e.g., phenylephrine), antihistamines, or anticholinergic agents (e.g., inhaled anticholinergics such as ipratropium or tiotropium, dust or sap from *Datura* sp) and can be caused by a postauricular scopolamine patch. Failure of topical 4% pilocarpine ophthalmic drops to constrict the pupil supports the diagnosis of pupillary dilation from a topical mydriatic agent. Visual disturbances, including partial or total blindness as a result of systemic toxicity, have been reported with anticholinergic agents, carbon monoxide, digitalis, ethambutol, methanol, methyl bromide, quinine, and agents that are associated with pseudotumor cerebri, including antimicrobials (e.g., ampicillin, metronidazole, nalidixic acid, nitrofurantoin, sulfa drugs, tetracycline), glucocorticosteroids, lead, lithium, oral contraceptives, phenothiazines, phenytoin, and vitamin A. Nonarteritic anterior ischemic optic neuropathy has developed after the use of sildenafil and other related drugs (Chapter 216); the causal relationship is unknown.

Neurologic Signs

Many toxicants affect the central nervous system (CNS) and can produce agitated delirium,[4] decreased level of consciousness,[5] or seizures (Table 96-2). Distinguishing features of various toxicants may assist in making the correct diagnosis. Patients who are withdrawing from opioids because of abstinence (as opposed to after being administered naloxone) are alert and oriented, whereas patients withdrawing from alcohol, barbiturates, benzodiazepines, and other sedative-hypnotics are often disoriented. Initial CNS depression can also develop with large ingestions of acetaminophen or ibuprofen. Isoniazid and theophylline are noted for producing seizures refractory to the usual doses of benzodiazepines and barbiturates. Pyridoxine treats isoniazid-induced seizures by increasing CNS γ-aminobutyric acid, synthesis of which is inhibited by isoniazid. Bupropion can cause seizures at both therapeutic doses and overdoses. Phenytoin is relatively ineffective for the majority of toxicant-induced seizures, perhaps because of the absence of a discrete seizure focus in most poisoned patients. Plant or mushroom ingestion can also produce CNS depression (e.g., *Rhododendron* sp, *Solanum* [bittersweet], *Taxus* [yew], *Sophora* [mescal bean]), CNS stimulation (e.g., *Catha edulis* [khat], *Strychnos nux-vomica* [contains strychnine], *Cicuta* sp [water hemlock], *Ephedra* [Mormon tea]), atropine-like effects (e.g., *Atropa belladonna* [deadly nightshade], *Datura* sp [jimsonweed]), and cholinomimetic effects (e.g., *Nicotiana* genus [tobacco], *Conium maculatum* [poison hemlock], *Inocybe* and *Clitocybe* mushrooms). Seizures can also occur with many of these plants and with mushrooms that contain gyromitrins (e.g., false morel, *Gyromitra* sp) and muscimol (e.g., *Amanita muscaria, Amanita pantherina*).

Distal axonopathy, a primary degeneration of peripheral nervous system axons with secondary degeneration of the myelin sheath, is the predominant type of toxicant-induced peripheral neuropathy. It usually is insidious in onset

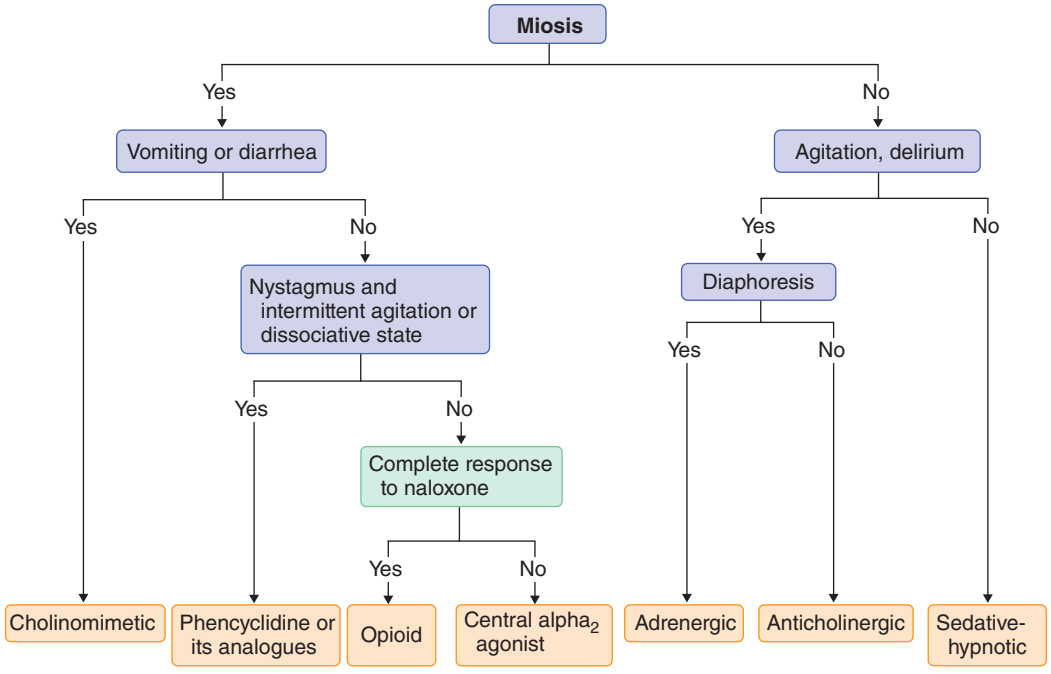

FIGURE 96-1. Diagnostic algorithm for assessing toxicant-induced bilateral miosis. Note that atypical toxidromes are common because of mixed toxicant exposures, so the examiner can be misled if relying only on this sign.

and follows chronic exposure; there is often slow recovery following termination of exposure, but, depending on the exposure and extent of neuronal damage, the clinical effects may be permanent. Neuropathy may be sensory, motor, or mixed. Common causative agents include acrylamide monomer, allyl chloride, arsenic (inorganic), capsaicin, carbon disulfide, chloramphenicol, cisplatin, colchicine, cyanate, dapsone, dideoxycytidine, dideoxyinosine, disulfiram, ethambutol, ethanol, ethylene oxide, gold salts, hexachlorophene, *n*-hexane, hydralazine, interferon, isoniazid, lead, linezolid, mercury, methyl bromide, methyl *n*-butyl ketone, metronidazole, nitrofurantoin, nitrous oxide, some organophosphorus compounds, phenol, platinum, podophyllotoxin, polychlorinated biphenyls, pyridoxine, tacrolimus, taxoids, thalidomide, thallium, vidarabine, vinca alkaloids, and vinyl chloride. Amiodarone, arsenic, and trichloroethylene can produce a demyelinating neuropathy, whereas pyridoxine can produce a sensory, sometimes painful, neuropathy. In addition, the neuropathy may be multifactorial in nature, such as vitamin deficiency associated with chronic ethanol consumption (Chapter 384). Neuronal transmission can be altered by aminoglycosides; the venom of *Latrodectus* species (widow spiders; see also Chapter 98 on envenomation and related injuries), scorpions (only the bark scorpion, *Centruroides sculpturatus*, in the United States), and crotaline (e.g., rattlesnakes) and elapid snakes; brevetoxin (shellfish) and ciguatoxin (various fish); neuromuscular blocking drugs; nicotine and related alkaloids; paralytic shellfish toxins; saxitoxin (shellfish); organophosphorus compounds and carbamates; tetrodotoxin (puffer fish [fugu], blue-ringed octopus, salamanders, newts, and others); and veratridine (e.g., false hellebore). Cranial nerves can be affected by carbon disulfide, ciguatoxin, domoic acid (shellfish), elapid venom, ethylene glycol metabolites, paralytic shellfish toxins, bark scorpion, saxitoxin, tetrodotoxin, thallium, and trichloroethylene. Mononeuropathies and vasculitic neuropathies are unlikely to be induced by toxicants (Chapter 98).

Cardiopulmonary Effects

The examination should focus on blood pressure, heart rate, electrocardiographic abnormalities (e.g., rhythm, conduction, depolarization, repolarization), and pulmonary findings, including pulse oximetry. Drugs and other toxicants that can cause dysrhythmias or conduction abnormalities include β-adrenergic receptor antagonists, butyrophenones (e.g., haloperidol), L-type calcium-channel antagonists, cardioactive steroids (e.g., bufadienolides, found in toxic toad venom and incorporated into some illicit aphrodisiacs; cardenolides, such as digoxin,[6] found in plants such as foxglove, oleander, and lily of the valley), halogenated hydrocarbons, chloroquine, cocaine, cyclic antidepressants, ethanol, halogenated hydrocarbons (e.g., halothane, trichloroethylene), magnesium salts, potassium salts, propoxyphene, thioridazine or mesoridazine, bupropion, and antiarrhythmics and other agents that affect the myocardial voltage-gated sodium channels (e.g., bupivacaine, chloroquine, cocaine, cyclic antidepressants, flecainide, mexiletine, quinidine, procainamide, propafenone) and potassium channels (e.g., typical and atypical antipsychotics, citalopram/escitalopram, erythromycin [especially when taken concomitantly with cytochrome P-450 A inhibitors; Chapter 25], quinidine, sotalol, terfenadine). Bedside echocardiography may reveal depressed myocardial contractility as a result of agents that block the myocardial voltage-gated sodium channel, β-adrenergic receptor antagonists, calcium-channel antagonists, cyclic antidepressants, magnesium salts, arsenic salts, ciguatoxin, cyanide, ethanol, iron salts, and scorpion venom.

Toxicants can produce myriad pulmonary effects, including airway irritation, parenchymal and pleural diseases, vascular diseases, and barotrauma. Typical syndromes and etiologic agents include pulmonary edema (β-adrenergic receptor antagonists, calcium-channel antagonists, antiarrhythmics, daunorubicin, doxorubicin), acute respiratory distress syndrome (Chapter 90) (amphetamines, cadmium, chlorine, cocaine, ethchlorvynol, methotrexate, opioids, heroin, paraquat, salicylates; inhalation of smoke, zinc chloride, methyl bromide, methyl chloride, and hydrocarbons), and rapidly developing pulmonary fibrosis or bronchiolitis obliterans (oxides of nitrogen, paraquat). For organophosphorous nerve agent and insecticide poisoning, acute respiratory failure is the most common primary cause of death, but some patients develop delayed neuromuscular junction dysfunction (i.e., intermediate syndrome), aspiration pneumonia, and acute respiratory distress syndrome.[7]

Gastrointestinal Effects

Symptoms of nausea, vomiting, diarrhea, and abdominal pain are nonspecific and must be interpreted in the context of other findings. Agents that produce severe or life-threatening toxicity with early gastrointestinal findings include acid or large alkali ingestions; cardioactive steroids; colchicine and other microtubular toxicants (e.g., podophyllin, vincristine); metal salts such as arsenic, iron, mercury salts, and thallium; mushrooms containing amanitin (*Amanita phalloides, Amanita virosa, Amanita verna, Lepiota chlorophyllum*), gyromitrins (*Gyromitra esculenta*), orellanines (*Cortinarius orellanus*), or allenic norleucine (*Amanita smithiana*); nicotine; organophosphorus compounds; and theophylline. Caustic damage is found with ingestion of alkalis (e.g., ammonium hydroxide, sodium hydroxide, potassium hydroxide, or sodium hypochlorite), acids (e.g., acetic acid, hydrochloric acid, oxalic acid, phosphoric acid, selenous acid, sulfuric acid, or hydrofluoric acid), and other agents (e.g., benzalkonium chloride, hydrogen peroxide, phenol, and zinc chloride).[8] Severe abdominal pain and rigidity can occur with lower extremity envenomation by *Latrodectus* species (widow spiders), unrelated to any direct organ injury. Hepatotoxicity can occur as an adverse effect of the therapeutic use of many drugs; in the United States, acetaminophen and ethanol are the most common causes of toxicant-induced hepatotoxicity (Chapter 136). For acetaminophen overdose,

TABLE 96-2 CENTRAL NERVOUS SYSTEM EFFECTS OF TOXICANTS

	CNS EFFECTS		
TOXICANT CATEGORIES AND AGENTS	**AGITATED DELIRIUM**	**DECREASED LEVEL OF CONSCIOUSNESS**	**SEIZURES**
CLASSES			
Anticholinergic agents	+	+	+
Anticonvulsants	+	+	+ (paradoxical with some agents)
Antipsychotic drugs		+	+
β-Adrenergic receptor antagonists	+	+	+ (theophylline/caffeine)
Hallucinogenic agents	+	+	+ (MDMA, substituted amphetamines)
Monoamine oxidase inhibitors	+	+	+
Opioids	+ (withdrawal, tramadol)	+	+ (meperidine, tramadol, dextromethorphan)
Sedative-hypnotics	+ (rare, paradoxical)	+	
Antidepressants	+ (serotonin syndrome)	+	+ (bupropion, venlafaxine)
AGENTS			
Amphetamines, cocaine	+	+ (following binge use)	+
Antidepressants (non SSRI)	+ (MAOI)	+	+
Antihistamines (first generation, e.g., diphenhydramine)	+	+	+
Barbiturates		+	
Benzodiazepines	+ (rare, paradoxical)	+	
Cytochrome oxidase inhibitors (e.g., carbon monoxide, cyanide, hydrogen sulfide, azides)		+	+
Ephedra alkaloids and similar agents	+	+	+
Ethylene glycol, methanol		+	+
γ-Hydroxybutyrate and precursors	+ (paradoxical, withdrawal)	+	+ (vs. myoclonus, withdrawal)
Lithium	+	+	+ (rare)
Organophosphorus compounds (e.g., diazinon, malathion, nerve agents) and carbamates (e.g., carbaryl, physostigmine)	+	+	+
Salicylates	+ (delirium)	+	+ (often pre-terminal)
SSRIs/SRIs/SNRI antidepressants	+ (serotonin syndrome)	+	+
Withdrawal from alcohol, barbiturates, benzodiazepines, other sedative-hypnotics	+		+
Withdrawal from opioids	+		+ (only in neonates)

CNS = central nervous system; MAOI = monamine oxidase inhibitor; MDMA = 3,4,-Methylenedioxymethamphetamine, also known as ecstasy or Molly; SNRIs = serotonin and norepinephrine re-uptake inhibitors; SRIs = serotonin re-uptake inhibitors; SSRIs = selective serotonin re-uptake inhibitors.

early measurement of the concentration of acetaminophen-protein adducts can predict the likelihood of hepatotoxicity.[9] Other notable hepatotoxicants include aflatoxins (in food contaminated with *Aspergillus flavus*), anabolic steroids, arsenicals, carbon tetrachloride, copper sulfate, cyclopeptide mushrooms (e.g., *Amanita phalloides*),[10] *Ephedra* species (e.g., ma huang), iron salts, methamphetamine, pennyroyal oil, pyrrolizidine alkaloids (various plant species used in herbal teas), and vitamin A in chronic excessive doses.

Dermatologic Signs

The skin, hair, nails, and mucous membranes should be examined for evidence of intravenous drug use; the presence or absence of skin and mucous membrane moisture; abnormal skin coloration, including erythema and cyanosis; alopecia; and nail abnormalities. Bullous skin lesions have been reported with chronic barbiturate use, glutethimide, carbon monoxide, meprobamate, methadone, and valproic acid. Sulfur mustard gas produces large yellow bullae on affected skin. Bluish discoloration may be dermal in origin (as with argyria from excessive exposure to colloidal silver) or due to cyanosis. Cyanosis may reflect hypoxemia or methemoglobinemia. Commonly used agents that can cause methemoglobinemia include aniline dyes, benzocaine and other amide anesthetics, dapsone, naphthalene, nitrates, nitrites, phenazopyridine, rifampin, and sulfonamides. Skin erythema or flushing occurs with anticholinergic agents, boric acid ingestion, monosodium glutamate, niacin, scombroid toxicity as a result of the ingestion of inadequately refrigerated fish with a high histidine content (e.g., tuna, mahi-mahi, amberjack), vancomycin, and interactions between ethanol and numerous agents that produce disulfiram or disulfiram-like reactions (e.g., carbon disulfide, some cephalosporins, *Coprinus atramentarius* mushroom, disulfiram, griseofulvin, metronidazole, thiuram herbicides, trichloroethylene).

Specific Toxicants

Some common toxicants can be suspected from their characteristic manifestations (Table 96-3). These suspicions should guide specific diagnostic and therapeutic strategies that complement general decontamination and supportive treatments.

Diagnostic Tests

Drug testing should be guided by the history and physical examination, with emphasis on tests that can influence management. Rapid qualitative urine drug screening tests are readily available in most hospitals, but their clinical value is limited by the number of drugs that can be tested and the reliability of the tests themselves. Although such testing may be valuable for subsequent psychiatric evaluation, it is less reliable for urgent diagnosis and therapy. For example, a positive test result may be unrelated to the patient's condition because drug analytes may be detectable for days after drug use, depending on the drug, dose, and frequency of use. In addition, both false-positive and false-negative results occur (Table 96-4), so the screening result must be verified with a

TABLE 96-3 PATHOPHYSIOLOGY, CLINICAL EFFECTS, AND MANAGEMENT OF SPECIFIC DRUGS AND TOXICANTS

DRUG OR TOXICANT	PATHOPHYSIOLOGY	TOXIC EFFECTS	LABORATORY	SPECIFIC THERAPY
Acetaminophen	NAPQI (toxic metabolite) binds hepatic and renal tubular cells, where it causes oxidant tissue damage; acetaminophen itself induces transient decrease in functional coagulation factor VII and can increase INR	Initial: nausea, vomiting, coma, lactic acidosis in severe cases Days 1-3: elevated INR, aminotransferase levels; RUQ tenderness; increased creatinine level in severe cases Days 4-14: gradual recovery or continued increase in INR and creatinine, lactic acidosis, coma, cerebral edema, death	Potentially toxic level ≥150 μg/mL 4 hours after single acute ingestion* INR may be transiently elevated in first 24 hours because of decrease in functional factor VII, and further increases indicate hepatic necrosis; elevated serum lactate levels and acidosis correlate with severity, but elevated aminotransferase and bilirubin levels are not predictive of hepatic failure Creatinine elevated in severe cases	N-acetylcysteine (see dosing guidelines in Table 96-6); NAC can increase INR but not aPTT†
Amphetamines (also cathinones, which are a class of keto substituted amphetamines)	Increased release of presynaptic norepinephrine and dopamine Increased serotonin release (especially MDMA, cathinones, other novel psychoactive drugs)	Mild: euphoria, decreased appetite, repetitive behavior, hallucinations Moderate: vomiting, agitation, hypertension, tachycardia, mydriasis, bruxism, diaphoresis Severe: hypertension or hypotension, dysrhythmias, hyperthermia, seizures, coma, multisystem organ failure, hyponatremia (SIADH), cerebral infarction or hemorrhage	Not helpful; many false-positives and false-negatives on screening tests (see Table 96-4)	IV crystalloids External cooling Benzodiazepines to control agitation or seizures Benzodiazepines for hypertension See SSRIs/SRIs for features and treatment of serotonin syndrome
β-Adrenergic receptor antagonists[11]	Blocks catecholamines from β-adrenergic receptors Additional actions: • α- and β-adrenergic receptor antagonism: carvedilol, labetalol • Delayed rectifier potassium-channel blockade: sotalol	Bradydysrhythmias (with high doses), decreased myocardial contractility, hypotension, respiratory depression, decreased consciousness with seizures or coma (lipophilic agents, e.g., propranolol), prolonged QT interval (sotalol)	ECG No specific tests	Regular insulin, 1 U/kg by IV bolus followed by 1 U/kg/hr (plus dextrose, usually needed within 20-30 min to maintain euglycemia), with upward titration every 10 min to max of 10 U/kg/hr. Other options include (1) IV glucagon (3-5 mg over 2-minute period; if no increase in BP or HR, can repeat up to 10 mg); if effective, immediately start continuous infusion at 2-10 mg/hr; or (2) norepinephrine infusion titrated to desirable BP and HR (less predictable) Electrical pacing, IABP, or intravenous lipid emulsion therapy in refractory cases
Calcium-channel antagonists	Blocks L-type voltage-sensitive calcium channels, thereby decreasing calcium entry into myocardial (verapamil, diltiazem) and vascular smooth muscle cells (all, but predominant effect of dihydropyridines) Decreases pancreatic insulin release and increases insulin resistance	Bradydysrhythmias (verapamil, diltiazem), hypotension, hyperglycemia Tachycardia and hypotension (dihydropyridines such as amlodipine, nifedipine)	ECG No specific tests	3 g (30 mL of 10% calcium gluconate solution) over 10 minutes (60 seconds if in extremis). Repeat in 10-20 minutes up to three times as needed. Alternative preferably via a central line: calcium chloride 10%, 10 mL (1 g) over 10 minutes (60 seconds if in extremis). Ionized Ca^{2+} levels should not exceed 2× normal (severe cases will be refractory to calcium therapy). Glucagon, high-dose insulin and dextrose, catecholamines, and milrinone (as for β-adrenergic antagonists). Intravenous lipid emulsion therapy for verapamil and diltiazem, unclear for dihydropyridines; indicated only for moribund patients.

TABLE 96-3 PATHOPHYSIOLOGY, CLINICAL EFFECTS, AND MANAGEMENT OF SPECIFIC DRUGS AND TOXICANTS—cont'd

DRUG OR TOXICANT	PATHOPHYSIOLOGY	TOXIC EFFECTS	LABORATORY	SPECIFIC THERAPY
Cardioactive steroids, including digoxin, bufadienolides (toxic toad venom), and cardenolides (e.g., oleander, lily of the valley, dogbane)	Inhibits Na^+,K^+-ATPase Decreased CNS sympathetic output Decreased baroreceptor sensitivity Increased vagal acetylcholine discharge	Bradydysrhythmias, including second- and third-degree AV block and asystole Ventricular ectopy, tachycardia, fibrillation Junctional tachycardia, paroxysmal atrial tachycardia with block Weakness, visual disturbances, nausea, vomiting	ECG Serum digoxin level Serum potassium (hyperkalemia occurs in acute poisoning and is prognostic for poor outcome without Fab; hypokalemia may be present in chronic poisoning due to concomitant medications such as furosemide), magnesium, and creatinine levels	Digoxin-specific antibody fragments (Fab) indicated if patient has rhythm disturbances such as sinus bradycardia, Mobitz II, or third-degree AV block, ventricular ectopy, serum potassium ≥5 mEq/L if acute overdose, ingestion of bufadienolide- or cardenolide-containing agents, or renal insufficiency Empiric dose: Acute: 10-20 vials Chronic: 3-6 vials Calculated dose: Acute: number of vials = 2 × oral digoxin dose (mg) × 0.8. Correcting the hyperkalemia with standard interventions is not helpful. Do not give calcium salts. If hypokalemic (generally chronic overdose), replete serum potassium. Chronic: number of vials = serum digoxin level (ng/mL) × wt (kg)/100
Cyclic antidepressants	Myocardial sodium- and potassium-channel blockade Blockade of α-adrenergic and cholinergic muscarinic receptors Inhibition of norepinephrine re-uptake	Decreased level of consciousness (can develop rapidly), myoclonus, seizures, coma Anticholinergic toxidrome (see Table 96-1) Sinus tachycardia, ventricular conduction delays, ventricular dysrhythmias, asystole Hypotension	Serum levels not helpful in management	Intermittent IV boluses of $NaHCO_3$ (1 mEq/kg) to narrow QRS to <100 msec; infusion of $NaHCO_3$ is less effective; maintain arterial pH at 7.5 because alkalemia and sodium ions can improve cardiovascular performance Contraindicated drugs: types IA and IC antiarrhythmic agents, physostigmine, flumazenil
Ethylene glycol, methanol (e.g., antifreeze, window cleaners, camping stove fuels)[12]	Ethylene glycol: toxic metabolites (glycolate and oxalate) produce cytotoxicity in CNS, kidneys, lungs, heart, liver, muscles; metabolic acidosis is due to glycolate accumulation; oxalate complexes with calcium, so hypocalcemia can develop Methanol: metabolized to formic acid, which is responsible for metabolic acidosis and inhibition of cytochrome aa_3; target organs include retina, optic nerve, CNS	Ethylene glycol: CNS depression, cerebral edema, seizures, anion gap metabolic acidosis, renal failure with acute tubular necrosis, pulmonary edema, myositis Methanol: nausea, vomiting; cerebral edema, hemorrhage, infarcts; necrosis of thalamus and putamen; anion gap metabolic acidosis; visual disturbances, papilledema, hyperemic optic disc, nonreactive pupils	Serum ethylene glycol and methanol levels; levels may be low or undetectable if significant metabolism has occurred Osmolar gap must be interpreted with caution, but a very high value (>50) more likely indicates the presence of a toxic alcohol Ethylene glycol: serum calcium, creatinine, BUN levels; examine urine for calcium oxalate crystals; false hyperlactatemia occurs with certain analyzers using L-lactate oxidase, which cross-reacts with glycolic and glyoxylic acid metabolites	For both: fomepizole[13] (inhibits alcohol dehydrogenase and blocks formation of toxic metabolites), 15 mg/kg IV loading dose, then 10 mg/kg IV every 12 hours for four doses during the next 48 hours, then 15 mg/kg for subsequent doses; interval dosing is q12h (q4h during hemodialysis, with dosing interval adjustments at start and finish); continue until ethylene glycol or methanol is no longer detectable Treatment with ethanol is no longer recommended Hemodialysis: initiate if level is ≥25 mg/dL or metabolic acidosis with end-organ toxicity; continue until acidosis resolves and serum level of ethylene glycol or methanol is undetectable (if available) Monitor for cerebral edema with possible herniation Ethylene glycol: IV calcium for symptomatic hypocalcemia Methanol: folic acid 1-2 mg/kg (50-75 mg) IV q4h × 24 h; extra dose at completion of hemodialysis; continue until methanol not detectable and acidosis cleared
γ-Hydroxybutyrate (GHB) and its precursors (γ-butyrolactone and 1,4-butanediol)	Agonist effect on CNS GHB receptors; indirect action with opioid receptors (may increase proenkephalins); metabolized to GABA, interacts with $GABA_B$ receptors; decreases dopamine release	CNS: rapid loss of consciousness, myoclonus/seizure, with recovery typical within 2-4 hours Respiratory depression; bradycardia; nausea, vomiting	No specific tests for acute management. Forensic testing available	Supportive care, including respiratory support as needed Withdrawal resembles sedative-hypnotic withdrawal and can be treated with benzodiazepines or phenobarbital

TABLE 96-3 PATHOPHYSIOLOGY, CLINICAL EFFECTS, AND MANAGEMENT OF SPECIFIC DRUGS AND TOXICANTS—cont'd

DRUG OR TOXICANT	PATHOPHYSIOLOGY	TOXIC EFFECTS	LABORATORY	SPECIFIC THERAPY
Lithium	Decreases brain inositol; alters CNS serotonin, dopamine, and norepinephrine; inhibits adenylate cyclases, including those that mediate vasopressin-induced renal concentration and thyroid function	Chronic toxicity usually more severe than acute toxicity: tremor, hyperreflexia, drowsiness, incoordination, clonus, confusion, ataxia; in severe cases, seizures (rare), coma, death (very rare); recovery may take weeks, and CNS deficits may persist (common) Sinus node dysfunction, QT prolongation, T wave abnormalities, U waves Nephrogenic diabetes insipidus, hypothyroidism, hyperthyroidism, hypercalcemia, pseudotumor cerebri Acute toxicity: nausea, vomiting, diarrhea, and milder neurologic findings	Peak serum levels: Normal dose, 2-3 hours; up to 5 hours for sustained-release lithium Acute overdose: peak may be delayed ≥4-12 hours	Replenish intravascular volume, maintain urinary output at 1-2 mL/kg/hr Consider gastrointestinal decontamination with oral or NG polyethylene glycol electrolyte solution within 1-2 hours after acute overdose of sustained-release drug Hemodialysis[‡] in patients with altered mental status, ataxia, seizures, or coma or in patients with mild symptoms in the setting of acute overdose or renal insufficiency Ineffective or contraindicated therapies include oral activated charcoal, diuretics
Opioids (e.g., opiate [natural]: morphine, codeine; semisynthetic: heroin, oxycodone, hydrocodone; synthetic: methadone, fentanyl and fentanyl analogs such as carfentanil and acetylfentanyl)	Agonist effect at CNS μ, κ, and δ opioid receptors; result is cell hyperpolarization and decreased neurotransmitter release	CNS depression, respiratory depression, miosis (see Table 96-1) Nearly all fatalities due to respiratory depression, highlighting the importance of assessing and managing based on oxygenation and ventilation Seizure risk with tramadol, meperidine QTc prolongation and torsades de pointes with methadone	Rapid urine drug screens detect morphine, poorly detect semisynthetic opioids, and do not detect synthetic opioids at all; some interferents/irrelevants (see Table 96-4)	Ventilate and oxygenate IV naloxone, 0.04 mg initial dose and titrate every 2-3 minutes in patients with likely opioid dependence; in patients known to be naïve, start 0.4 mg; repeat in frequent, escalating doses up to 10 mg if no response Continuous infusion for recurrent symptoms or sustained-release opioid ingestion; give 50% of dose that produces desired effect 15 minutes after initial effect is obtained, then infuse two thirds of this dose every hour; infusion rate can be increased or decreased to maintain normal ventilation and to avoid withdrawal symptoms Contraindicated therapies: naltrexone should not be used for acute opioid reversal Intranasal naloxone (2-4 mg) can be given if IM/IV not possible
Organophosphorus compounds and carbamates (e.g., diazinon, mevinphos, fenthion, aldicarb); nerve agents (e.g., sarin); medicinals (pyridostigmine for myasthenia gravis and donepezil for Alzheimer disease)	Inhibits acetylcholinesterase, resulting in excessive acetylcholine stimulation of nicotinic and muscarinic receptors in autonomic and somatic motor nervous systems and CNS	Nicotinic-mediated effects: tachycardia, mydriasis, hypertension, delirium, coma, seizures, muscle weakness, fasciculations Muscarinic-mediated effects: salivation, lacrimation, urination, vomiting, defecation, miosis, bronchorrhea, bronchospasm, bradycardia Muscarinic or nicotinic effects may be mixed and unpredictable in an individual patient	Plasma (butyrylcholinesterase) or RBC (acetylcholinesterase) activity <50% of normal (see Table 96-6) Clinical recovery occurs before plasma cholinesterase levels normalize	Atropine, 1-2 mg by initial IV bolus; double the dose every 5 minutes (2 mg, 4 mg, 8 mg, 16 mg, and so on) until drying of bronchial secretions and adequate oxygenation is achieved or progress ceases; continuous infusion at 10-20% of total stabilizing dose per hour; stop infusion when patient develops concerning signs or symptoms of anticholinergic toxidrome (see Table 96-1); restart infusion at lower rate when signs or symptoms abate Pralidoxime chloride 30 mg/kg (maximum 2 g) IV over 30 minutes, then 8-10 mg/kg/hr (maximum 650 mg/hr) continuous infusion; administer as soon as possible after poisoning; continue 12-24 hours after atropine no longer required and symptoms resolve[§] Benzodiazepines for agitation or seizures Magnesium sulfate (4 g IV over 30minutes upon ICU admission) can decrease the need for atropine, the need for intubation, and the length of ICU stay[A1] Treatment not generally needed for overdose of Alzheimer medications

TABLE 96-3 PATHOPHYSIOLOGY, CLINICAL EFFECTS, AND MANAGEMENT OF SPECIFIC DRUGS AND TOXICANTS—cont'd

DRUG OR TOXICANT	PATHOPHYSIOLOGY	TOXIC EFFECTS	LABORATORY	SPECIFIC THERAPY
Salicylates[14]	Inhibit cyclooxygenase; decrease formation of prostaglandins and thromboxane A_2; stimulate CNS medullary respiratory center and chemoreceptor trigger zone; impair platelet function; disrupt carbohydrate metabolism; uncouple oxidative phosphorylation; increase vascular permeability	Acute toxicity Mild: nausea, vomiting, diaphoresis, tinnitus, decreased hearing, hyperpnea, tachypnea Moderate-severe: confusion, delirium, coma, seizures, hyperthermia, ARDS; death can occur within hours of overdose Chronic toxicity: same as acute, but may not have diaphoresis or vomiting Consider diagnosis in patients with new-onset confusion, anion gap metabolic acidosis, or acute lung injury	Serum salicylate level: acute: toxic ≥30 mg/dL; level ≥100 mg/dL indicates life-threatening toxicity with possible sudden, rapid clinical deterioration; in chronic toxicity, levels may be minimally elevated (>30 mg/dL), and clinical evaluation is more reliable for gauging degree of toxicity Arterial blood gases: respiratory alkalosis with metabolic acidosis Anion gap metabolic acidosis Prolonged PT and PTT, ketonuria, ketonemia	Multidose activated charcoal q2-3h in acute overdose Frequent monitoring of salicylate level and acid-base status Alkalinization of serum and urine with IV $NaHCO_3$ Hemodialysis with progressive clinical findings, particularly neurologic, hyperthermia, renal failure, ARDS, with any moderately elevated salicylate level or salicylate level >100 even with minor clinical findings
SSRIs/SRIs	Inhibit re-uptake of serotonin SRIs have additional effects (e.g., duloxetine inhibits norepinephrine re-uptake, nefazodone inhibits serotonergic 5-HT_2 receptors, trazodone inhibits peripheral α-adrenergic receptors, venlafaxine inhibits norepinephrine and dopamine re-uptake)	Vomiting, blurred vision, CNS depression, tachycardia Seizures and coma rare except with bupropion Torsades de pointes reported with citalopram Serotonin syndrome: clonus, agitation, tremor, diaphoresis, hyperreflexia; hyperthermia and hypertonicity in severe cases	No specific tests If serotonin syndrome suspected: electrolytes, BUN, glucose, liver enzymes, coagulation panel, blood gases, chest radiograph	Respiratory support as needed Benzodiazepines for agitation or seizures Serotonin syndrome: consider cyproheptadine, 4-12 mg PO initial dose, then 2 mg PO q2h (to a maximum of 32 mg/day) until symptoms resolve Critical therapies for hyperthermia, rhabdomyolysis, DIC, ARDS, renal and hepatic dysfunction, torsades de pointes; dantrolene not indicated

*A nomogram to evaluate the potential toxicity of levels drawn more than 4 hours after ingestion is available at: https://en.wikipedia.org/wiki/Rumack–Matthew_nomogram.

†Intravenous *N*-acetylcysteine (NAC) has generally replaced oral NAC for the majority of cases, largely because of convenience, not efficacy. The full 21-hour course of intravenous NAC should be administered in most situations in which it is used. Oral NAC, which remains an acceptable alternative, can be discontinued in patients with uncomplicated disease after a loading dose plus six maintenance doses if hepatic aminotransferase levels are normal and acetaminophen is not detected; otherwise, the full regimen should be administered.

‡Continue hemodialysis until the serum lithium level is less than 1 mEq/L. Recheck the level 4 to 8 hours after dialysis, and restart hemodialysis if the level rebounds significantly or if clinical findings of lithium toxicity are present. Repeat this cycle until the serum lithium level remains low or the patient remains clinically well.

§Randomized, placebo-controlled trials of pralidoxime in acute organophosphorus poisoning have not found a significant difference in mortality rates or need for intubation.

aPTT = activated partial thromboplastin time; ARDS = acute respiratory distress syndrome; AV = atrioventricular; BP = blood pressure; BUN = blood urea nitrogen; CNS = central nervous system; DIC = disseminated intravascular coagulation; DOB = 4-bromo-2,5-dimethoxyamphetamine; ECG = electrocardiogram; GABA = γ-aminobutyric acid; HR = heart rate; IABP = intra-aortic balloon counterpulsation; ICU = intensive care unit; INR = international normalized ratio; IV = intravenous, MDMA = 3,4-methylenedioxymethamphetamine, also known as ecstasy or Molly; Na^+,K^+-ATPase = sodium, potassium adenosine triphosphatase; NAC = *N*-acetylcysteine; NAPQI = *N*-acetyl-*p*-benzoquinone imine; NG = nasogastric; NMDA = *N*-methyl-D-aspartate; PMA = paramethoxyamphetamine; PO = orally; PT = prothrombin time; PTT = partial thromboplastin time; QT = QT interval from an electrocardiogram, QTc = rate-corrected QT interval from an electrocardiogram; RBC = red blood cell; RUQ = right upper quadrant (abdomen); SIADH = syndrome of inappropriate antidiuretic secretion; SRIs = serotonin re-uptake inhibitors; SSRIs = selective serotonin re-uptake inhibitors.

TABLE 96-4 QUALITATIVE URINE DRUG SCREENS: CAUSES OF ERRONEOUS RESULTS*

DRUG/TOXICANT	INTERFERENTS/CROSS-REACTIONS†	COMMENTS
Amphetamines	Amantadine, bupropion, chlorpromazine, ephedrine, pseudoephedrine, desoxyephedrine, ephedra alkaloids (from *Ephedra* sp), mexiletine, phenylephrine, phenylpropanolamine, selegiline, trazodone	Many false-positives from medicinal sympathomimetics or true positives from prescribed stimulants; nasal inhaler (desoxyephedrine) and selegiline cause positive GC-MS findings; chiral confirmation is required; newer immunoassays have reduced false rates but also lower sensitivity for the class of amphetamines
Benzodiazepines	Oxaprozin, sertraline	Most assays directed against oxazepam; poor detection of benzodiazepines without the oxazepam metabolite (e.g., alprazolam, lorazepam, triazolam)
Cocaine	Coca leaf teas (clinical false-positive; still considered illicit use)	Few analytical false-positives; urine is reliable for detecting true positives
Opioids	Poppy seeds (contain morphine)	Assay directed against morphine; poorly detects semisynthetic opioids and does not detect synthetic opioids (e.g., fentanyl, meperidine, methadone, propoxyphene, oxycodone, buprenorphine)
Phencyclidine	Dextromethorphan, diphenhydramine, doxylamine, ibuprofen, ketamine, tramadol, venlafaxine	Can be used, although not reliably, to identify dextromethorphan or ketamine
Tetrahydrocannabinol	Dronabinol, efavirenz, proton pump inhibitors	Positive result is seldom clinically relevant and does not indicate recent use; synthetic cannabinomimetics (e.g., spice, K2) are not reliably detected
Tricyclic antidepressants	Carbamazepine, cyclobenzaprine, cyproheptadine, diphenhydramine, phenothiazines, quetiapine	

*Advances in drug screening and variability in immunoassay results should be considered by the clinician when interpreting qualitative drug screening results. There are many marketed assays, so consultation with the testing laboratory is advised. Positive screening results are considered presumptive and should be verified by GC-MS or another advanced analytical methodology.

†Cross-reactants are agents causing true-positive but clinically irrelevant results on laboratory screening tests; they vary, depending on the screening method.

GC-MS = gas chromatography–mass spectrometry.

TABLE 96-5 CLINICALLY IMPORTANT QUANTITATIVE DRUG LEVELS

DRUG OR TOXICANT	LEVELS: THERAPEUTIC	LEVELS: TOXIC*
SOURCE: BLOOD OR SERUM		
Acetaminophen†	10-30 µg/mL	≥150 µg/mL 4 hours after ingestion‡
Carbamazepine	4-12 µg/mL	>15 µg/mL
Carboxyhemoglobin	Nonsmoker: 0.5-1.5% Smoker: 4-9%	>20%§
Cholinesterase|		
Serum (butyrylcholinesterase)	3100-6500 U/L	<50% of normal value
Red blood cell (acetylcholinesterase)	26.7-49.2 U/g of hemoglobin	<50% of normal value
Digoxin (≥6 hours after oral dose for long-term therapy)	0.8-2.0 ng/mL¶	>2.0 ng/mL
Ethanol	None measured	>80 mg/dL**
Ethylene glycol	None measured	>25 mg/dL
Iron	50-175 µg/dL	>350 g/dL
Lead	<5 µg/dL	>25 µg /dL
Lithium	0.6-1.2 mEq/L	>1.2 mEq/L††
Methanol	None measured	>25 mg/dL
Methemoglobin	1-2%	>15%
Phenobarbital	15-40 µg/mL	>40 g/mL
Phenytoin	10-20 µg/mL	>20 g/mL
Salicylate	≤30 mg/dL	>30 mg/dL
Theophylline	8-20 µg/mL	>20 g/mL
Valproic acid	50-100 µg/mL	>100 g/mL
	NORMAL	**TOXIC***
SOURCE: URINE		
Arsenic	<50 µg/day	>100 g/24-hr urine††
Mercury	<20 µg/L	>20 g/L††
Thallium	<5.0 µg/L	>200 g/L††

*The "toxic" level is provided for perspective. For many toxicants, simply being above this value does not imply a specific need for therapy or a necessarily poor prognosis. It does, however, generally suggest a need for additional evaluation, observation, or monitoring. Similarly, depending on the clinical context, levels below the "toxic" range may still be consequential.

†False-positive levels of 16 to 28 µg/mL have been reported in patients with bilirubin levels greater than 17 mg/dL.

‡Levels drawn more than 4 hours after ingestion should be plotted on the nomogram provided by Rumack and Matthew (Rumack BH, Matthew H. Acetaminophen poisoning and toxicity. *Pediatrics*. 1975;55:871-876) to assess the potential for toxicity.

§Lower levels may be toxic in pregnant patients and in those with prolonged exposure to carbon monoxide.

|Consult a reference laboratory for normal values; results are assay dependent.

¶Some patients may require levels above the therapeutic range to control symptoms.

**The value of 80 mg/dL (0.08 g/dL) for ethanol is the statutory limit for operating a motor vehicle, but not for other activities. Consequential clinical effects other than inebriation are uncommon with concentrations below 200 mg/dL, even in ethanol-naïve patients.

††Lower values may indicate toxicity if appropriate clinical findings are present. For mercury and arsenic, both inorganic and organic levels should be measured when total levels are elevated.

second method, such as gas chromatography–mass spectrometry. The type of drug use in a population should be considered in determining the drugs to be screened to decrease the incidence of false-positive results. A test with 99% specificity for a drug with a prevalence of 0.1% in a population would produce 10 false-positive results for every true-positive result. Clinically irrelevant true-positive findings also occur, such as when poppy seeds produce a positive opiate assay result. Failure to consider these limitations of drug screens can result in misdiagnosis.

For a limited number of drugs and toxicants, levels in blood or urine are useful for diagnosis, therapy, or monitoring (Table 96-5). Threshold levels of certain toxicants indicate the need for specific therapies: acetaminophen (*N*-acetylcysteine), ethylene glycol (fomepizole and hemodialysis), iron (deferoxamine), methanol (fomepizole and hemodialysis), methemoglobin (methylene blue), and salicylates (urine alkalinization and hemodialysis). In chronic poisoning with some drugs, such as salicylates or theophylline, these therapies may be indicated at lower drug levels. In general, any end-organ toxicity that is evident or anticipated (on the basis of the toxicant, amount ingested, and time required to produce toxic effects) is more important than a specific level in determining the need for treatment.

Occult acetaminophen ingestion with toxic serum levels occurs in 0.3 to 1.9% of intentional ingestions. Given that these patients may be asymptomatic until hepatotoxicity develops and that administration of an antidote can prevent this hepatotoxicity, the current recommendation is to test the serum for acetaminophen in all patients with intentional self-harm ingestions.

Other Blood Tests

Anion gap metabolic acidosis resulting from primary lactic acidosis can be caused by cyanide, hydrogen sulfide, iron, isoniazid, metformin, nucleoside reverse transcriptase inhibitors, phenformin, sodium azide, and, rarely, acetaminophen with high serum levels. Anion gap metabolic acidosis not related to lactic acidosis occurs with diethylene glycol, ethylene glycol, nonsteroidal anti-inflammatory drugs, methanol, salicylates, and toluene. In poisonings resulting from ibuprofen, methanol, propylene glycol, and salicylates, lactic acid can also be produced, but the level is insufficient to account for the anion gap. Anion gap metabolic acidosis can also develop in patients with ongoing agitation, hyperthermia, and muscle rigidity, such as in neuroleptic malignant syndrome (Chapter 402), or in some cases of rhabdomyolysis (Chapter 99) secondary to toxicants such as doxylamine, phencyclidine, strychnine, cocaine, and amphetamines. Elevated serum creatinine and blood urea nitrogen levels indicative of declining renal function may be seen with numerous toxicants. Direct renal toxicity occurs with acetaminophen, aminoglycosides, cadmium, Chinese weight-loss botanicals containing *Stephania tetrandra* or *Magnolia officinalis*, chromium, *Crotalus durissus* venom, diethylene glycol, diquat, ethylene glycol, fluorinated anesthetics, gold, heroin, lithium (diabetes insipidus), mercury salts, mushrooms (*Amanita smithiana* and *Cortinarius* sp), paraquat, radiocontrast agents, solvents (e.g., carbon tetrachloride, trichloroethylene, tetrachloroethylene, toluene), and sulfonamides. Agents that decrease glomerular perfusion by reducing renal blood flow include amphotericin, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, cocaine,

cyclosporine, mannitol (excessive chronic doses), methotrexate, and nonsteroidal anti-inflammatory drugs.

Imaging

A computed tomographic scan of the head can detect life-threatening cerebral edema secondary to toxicant-induced hepatic failure, ethylene glycol, and methanol. It also detects intracranial bleeding caused by anticoagulants, scorpion venom, and sympathomimetics (e.g., amphetamines, cocaine, phenylpropanolamine). An abdominal radiograph can reveal radiopaque ferrous sulfate tablets, drug-filled packets in illicit drug smugglers (body packers), or metals such as arsenic, lead, mercury, and thallium.

Diagnostic Syndromes

Given the myriad combinations of signs, symptoms, and laboratory findings, making the correct diagnosis in a noncommunicative patient can be daunting. A thorough history from bystanders, friends, and prehospital medical personnel may yield crucial information. In addition, the diagnostic possibilities can be narrowed by findings that can narrow the differential diagnosis with modest certainty. For example, consider a patient with sudden loss of consciousness, anion gap metabolic acidosis, and bradycardia without hypoxemia. Among the relevant possible causes from the list of toxicants that cause an anion gap metabolic acidosis (see earlier) along with sudden loss of consciousness are hydrogen sulfide, cyanide, and sodium azide.

TREATMENT

Initial Stabilization

Intubation and Respiratory Support

Appropriate airway management should be instituted to correct hypoxemia and respiratory acidosis and to protect against pulmonary aspiration (Fig. 96-2); intubation should be considered if the patient has depressed consciousness and a decreased gag reflex.[15] Rapid-sequence intubation facilitates airway management. Anatomic difficulties should be anticipated in patients with caustic ingestions (e.g., hypopharyngeal burns that may perforate); angioedema caused by angiotensin-converting enzyme inhibitor therapy or envenomation by some rattlesnakes, such as the canebrake (*Crotalus horridus atricaudatus*) and eastern diamondback (*Crotalus adamanteus;* Chapter 98); and swelling secondary to direct tissue injury (e.g., huffing compressed hydrocarbons, smoking crack) or secondary to anaphylactoid and anaphylactic reactions. Endotracheal intubation by flexible fiberoptic nasopharyngoscopy may be indicated in these cases. Hypoxemia can occur with toxicants that produce CNS depression, such as opioids, antidepressants, barbiturates, sedative-hypnotics, and central α_2-adrenergic receptor agonists (clonidine), or agents causing peripheral neuromuscular impairment, such as nicotine, organophosphorus compounds, tetrodotoxin (puffer fish, blue-ringed octopus), botulinum, or envenomation from elapids (coral snake), Mojave rattlesnakes, or certain coelenterates (box jellyfish; Chapter 98).

Respiratory acidosis can rapidly worsen the toxicities of cyclic antidepressants and salicylates; sedation of these patients should be accompanied by immediate airway placement and ventilatory support to match the patient's intrinsic minute ventilation. Intoxicated patients may have an increased risk for pulmonary aspiration because of concomitant CNS depression, attenuated airway reflexes, full stomachs, and delayed gastric emptying.

Succinylcholine can cause prolonged paralysis in patients with organophosphorus poisoning and can exacerbate hyperkalemia from cardioactive steroids (e.g., digoxin), hydrofluoric acid, or rhabdomyolysis (Chapter 99). Rhabdomyolysis has been reported with adrenergic agents, doxylamine, phencyclidine, heroin, carbon monoxide, *Tricholoma equestre* mushrooms, and envenomation by crotaline snakes, scorpions, or widow spiders (*Latrodectus* sp); short-acting nondepolarizing agents, such as vecuronium and rocuronium, are preferable in these cases.

Advanced Life Support

Standard emergency cardiovascular care algorithms (Chapter 50) must be modified for effects caused by specific poisons. Atropine often does not reverse bradycardia secondary to β-adrenergic receptor antagonists, L-type calcium-channel antagonists, or cardioactive steroids, and it may actually impair the ability to perform adequate gastrointestinal decontamination. In these cases, more specific therapy with intravenous calcium (calcium-channel antagonists), high doses of glucagon (β-adrenergic receptor antagonists, calcium-channel antagonists), or digoxin-specific Fab antibody (cardiac glycosides) is indicated. High-dose insulin-glucose therapy can successfully reverse myocardial depression and conduction abnormalities in humans poisoned with β-adrenergic receptor antagonists and calcium-channel antagonists (Table 96-6). Intravenous sodium bicarbonate may reverse cardiac conduction delays caused by antiarrhythmic drugs with sodium-channel blockade recovery rates of greater than 1 second (Vaughn-Williams classification IA and IC), cocaine, cyclic antidepressants, diphenhydramine, and quinine. β-Adrenergic receptor antagonists are relatively contraindicated in patients with acute cocaine-induced myocardial ischemia because they can result in unopposed α-adrenergic–mediated vasoconstriction, but phentolamine can reverse the agonistic effects of cocaine on α-adrenergic receptors (see Table 96-6). Benzodiazepines can reverse the significant sinus tachycardia seen with sympathomimetic agents by reducing autonomic outflow from the CNS. Calcium may also be life-saving in systemic hydrofluoric acid poisoning and severe hypermagnesemia, and it is indicated for symptomatic hypocalcemia caused by ethylene glycol toxicity (see Table 96-6). Drug-induced hypertension may be transitory; nitroprusside, phentolamine, or labetalol should be used if treatment is clinically indicated. (See Table 96-6.) Conversely, vasopressor infusions may be indicated in drug-induced hypotension (Chapter 92). In patients with toxicant-induced circulatory collapse refractory to maximal therapy, intravenous lipid emulsion therapy should be administered to those poisoned by lipophilic toxicants (e.g., calcium-channel blockers), and circulatory assist devices may support the patient until sufficient toxicant is eliminated (see Table 96-6 for dosing details) (Chapter 93).

Decontamination

Activated Charcoal

Activated charcoal consists of pyrolysis products that have been specially cleaned to produce an internal pore structure to which substances can adsorb, thereby limiting their systemic absorption. Single-dose activated charcoal without prior gastric emptying has been the preferred method of treatment for the ingestion of substances that have the potential to cause moderate to life-threatening toxicity and are known to adsorb to activated charcoal. The decision to administer activated charcoal should be based on a risk/benefit assessment that includes nature of the exposure, clinical effects displayed during evaluation, and abilities of the medical facility and staff. For patients likely to have a good outcome without decontamination, charcoal administration introduces unnecessary inconvenience and risk. Its use is justified in patients who present early (1 to 2 hours) after exposures to a large amount of a concerning toxin that is likely to be adsorbed to charcoal or to an unknown toxin that has presented with a concerning clinical picture. However, the documented efficacy of activated charcoal for reducing toxicant blood levels has not translated into a reduction in mortality.[A2]

The oral dose is approximately 1 g/kg body weight, with a maximum single dose of 100 g. Activated charcoal can be administered with antiemetic drugs or given through a nasogastric tube, when necessary. Efficacy in preventing toxicant absorption declines with time, so activated charcoal should be given as soon as possible after ingestion.

Activated charcoal should not be used in patients at risk for aspiration until the airway is secure to minimize aspiration; the patient's head should also be elevated unless it is contraindicated. Activated charcoal is contraindicated in patients with a perforated bowel, functional or mechanical bowel obstruction, ingestion of a pure aliphatic hydrocarbon such as gasoline or kerosene (no benefit and increased risk for aspiration), and ingestion of caustic acid and alkali (no benefit and obscures endoscopy). Certain agents, such as lithium, iron, and metal salts and ethanol, do not adsorb significantly to activated charcoal, but its use is not precluded if the patient has ingested other toxicants that do adsorb to activated charcoal. Pulmonary aspiration and bowel obstruction from inspissated activated charcoal are the most common complications; both occur more frequently when multidose activated charcoal is administered, but they can be avoided by withholding treatment in patients who have suboptimal bowel function or decreased fecal elimination.

Gastric Emptying

Two methods of gastric emptying, syrup of ipecac and orogastric lavage through a large-bore tube, are no longer routinely used; both are relatively ineffective therapies that potentially increase the risk for aspiration. Syrup of ipecac is no longer recommended, and no well-designed study has documented any benefit of gastric lavage compared with the use of activated charcoal alone. Nevertheless, gastric emptying may be of benefit in patients who have ingested toxicants that do not adsorb to activated charcoal and are known to produce significant morbidity or for which aggressive decontamination may offer the best chance for survival (e.g., colchicine, sodium azide, sodium fluoroacetate). Removal of a liquid toxicant, such as ethylene glycol, may be accomplished by simple aspiration of gastric contents (without lavage) through a nasogastric tube. Contraindications to gastric emptying include those for activated charcoal, a bleeding diathesis, and the ingestion of sharp objects. Placement of a cuffed endotracheal tube before gastric lavage may be necessary to protect the airway in patients who have a decreased level of consciousness and impaired gag reflex, but it is not required in all cases. Major complications of gastric emptying include pulmonary aspiration, esophageal tears and perforations, and laryngospasm (with lavage).

Whole Bowel Irrigation

Whole bowel irrigation with a nonabsorbable polyethylene glycol solution has been recommended for iron and sustained-release medications, for agents not

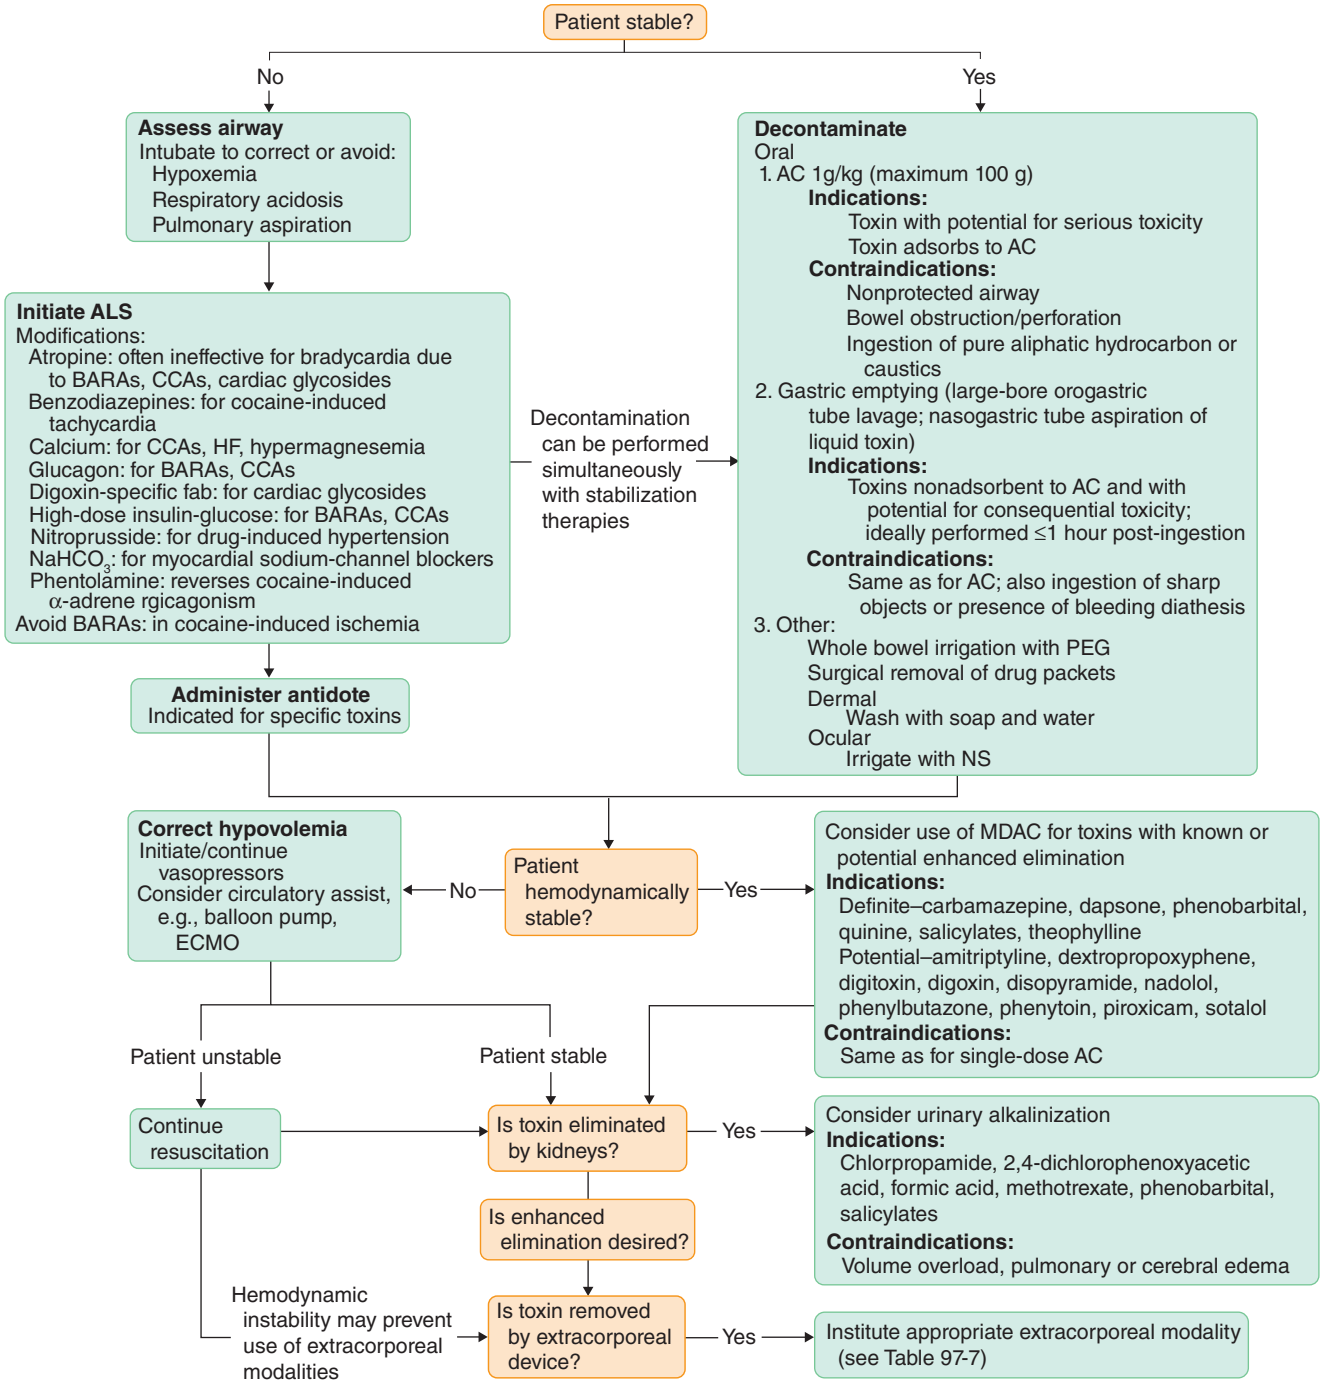

FIGURE 96-2. Algorithm for the management of acute poisoning. AC = activated charcoal; ALS = advanced life support; BARAs = β-adrenergic receptor antagonists; CCAs = L-type calcium-channel antagonists; ECMO = extracorporeal membrane oxygenation; HF = hydrofluoric acid; MDAC = multidose activated charcoal; NS = 0.9% saline solution; PEG = nonabsorbable polyethylene glycol solution.

adsorbed to activated charcoal, and for body packers (smugglers who swallow packets of illicit drugs, usually heroin or cocaine). The most common complication is vomiting, and whole bowel irrigation is contraindicated in patients with bowel perforation, obstruction, hemorrhage, or hemodynamic or respiratory instability. The initial recommended dose is 500 mL/hour given orally or by nasogastric tube, with titration to 2000 mL/hour as tolerated; treatment continues until the rectal effluent clears. Rarely, surgery may be necessary to remove packets in smugglers who have symptoms of cocaine toxicity or are obstructed; heroin toxicity is usually adequately managed with naloxone. Endoscopic removal of cocaine packets should never be attempted because of the risk of packet rupture.

Antidotes

Few toxicants have specific therapies (see Table 96-6). Although antidotes may be essential in treating patients exposed to certain toxicants, their use does not preclude the need for ongoing supportive care and, in some cases, extracorporeal elimination.

Enhanced Elimination

Methods to accelerate the elimination of toxicants or drugs from the body include multiple doses of activated charcoal, urinary alkalinization, and extracorporeal removal. Another method, using the oral ion exchange resins sodium polystyrene sulfonate and cholestyramine, has experimentally enhanced the elimination of lithium, digoxin, digitoxin, and organochlorines but has limited clinical usefulness.

Multiple Doses of Oral Activated Charcoal

The rationale for administering multiple doses of oral activated charcoal includes the adsorption of any toxic agent remaining in the gastrointestinal tract (e.g., sustained-release drugs or drugs that retard their absorption, such as anticholinergics), interference with the enterohepatic and enteroenteric recirculation of toxicants, and enhancement of the elimination of drugs with a long half-life, a volume of distribution less than 1 L/kg body weight, and low protein binding (termed gastrointestinal dialysis). The existing evidence shows enhanced elimination of carbamazepine, dapsone, phenobarbital, quinine, salicylates, and

theophylline, but multiple doses of activated charcoal may also be effective for amitriptyline, dextropropoxyphene, digitoxin, digoxin, disopyramide, nadolol, phenytoin, piroxicam, and sotalol. Whether enhanced elimination provided by repeated doses of activated charcoal translates into decreased morbidity and mortality has not been adequately examined in large controlled clinical trials, except for yellow oleander and organophosphate ingestion, for which it has shown no benefit. The usual recommendations are an average dose of 12.5 g of activated charcoal (after the initial dose of 1 g/kg body weight, with a maximum single dose of 100 g) administered every 4 to 6 hours after the previous dose. The contraindications to single-dose activated charcoal also apply to multidose activated charcoal. Reported complications include pulmonary aspiration, bowel obstruction from inspissated charcoal, and fluid and electrolyte imbalance from multiple doses of a simultaneously administered cathartic.

Urinary Alkalinization

Alkalinization of the urine, which increases the renal elimination of weak acids, is used primarily to enhance the elimination of salicylates, but the elimination of chlorpropamide, 2,4-dichlorophenoxyacetic acid, formic acid, methotrexate, and phenobarbital may be increased with this method. Urinary alkalinization is accomplished by an intravenous bolus of 1 to 2 mEq of sodium bicarbonate per kilogram body weight, followed by three ampules (150 mL) of sodium bicarbonate (44 mEq/50 mL) in 850 mL of 5% dextrose in water infused at two to three times the normal maintenance fluid rate. Urinary pH should be checked hourly, and the infusion should be adjusted to maintain a urine pH of 7.5 to 8.0. Potassium should be administered simultaneously to avoid hypokalemia, which prevents urinary alkalinization because the distal tubule excretes hydrogen ion in exchange for potassium (Chapters 103 and 104). Serum pH should be monitored and kept below 7.55 to avoid excessive alkalemia. Contraindications to this therapy include volume overload and cerebral or pulmonary edema. Urinary acidification is not recommended to enhance the elimination of weak bases, such as amphetamines, because of the danger of precipitating tubular myoglobin in patients with rhabdomyolysis.

Extracorporeal Removal

Extracorporeal techniques enhance the elimination of a few drugs and toxicants, especially those that exist in the blood and are otherwise poorly eliminated.[17,18] Such drugs generally have single-compartment kinetics, a volume of distribution less than 1 L/kg, and endogenous clearance of less than 4 mL/minute/kg (Table 96-7). For hemodialysis, the toxicant must be water soluble, have a small molecular weight, and exhibit low protein binding. For continuous renal replacement therapy, the toxicant must have a molecular weight less than the permeability limit of the filter membrane. As a group, these latter forms of elimination are slow and likely to be of limited benefit to most patients with acute poisoning. Rarely, extracorporeal removal has been used for aminoglycosides, atenolol, bromide, carbamazepine, diethylene glycol, isopropanol, magnesium, metformin, methotrexate, *N*-acetylprocainamide, phenobarbital, procainamide, sotalol, and trichloroethanol (chloral hydrate).

TABLE 96-6 ANTIDOTES AND INDICATIONS FOR USE[§]

ANTIDOTE	INDICATION FOR USE	DOSE*	TREATMENT END POINT	COMMENTS
Antivenom, *Crotalidae* (Fab)[†¶A3]	Crotaline snake (e.g., rattlesnakes, copperhead; see Chapter 98)	Variable (several products available); initial dose followed by repeated doses as needed	Halt in progression of circumferential and proximal swelling Resolving systemic effects	Better safety profile than historical equine-derived antivenom Repetitive dosing indicated for recurrent soft tissue swelling Less effective at correcting hematologic (i.e., coagulation and platelet) disorders
Antivenom, *Latrodectus* (equine)[†,¶]	Black widow spider (*Latrodectus* sp)	1 vial diluted in 50-100 mL NS, infused over 1 hour; can repeat	Resolution of symptoms, vital signs normal	Dilution and slow infusion rate are **critical** to avoid anaphylactoid reaction Indications include severe pain unresponsive to opioids and severe hypertension Serum sickness can occur IV calcium is ineffective
Atropine	Carbamates Nerve agents Organophosphorus compounds	2 mg IV; double the dose every 5 minutes to achieve atropinization and hemodynamic stability; then start continuous infusion of 10-20% of total stabilizing dose per hour	Cessation of excessive oral and pulmonary secretions, >80 beats/min, systolic blood pressure >80 mm Hg	Doubling of the dose every 5 minutes (e.g., 2 mg, 4 mg, 8 mg, 16 mg) estimated to achieve atropinization within 30 minutes Stop infusion when patient develops concerning signs or symptoms of anticholinergic toxidrome (see Table 96-1); restart infusion at lower rate when signs or symptoms abate
Calcium salt[‡]	Calcium-channel antagonists	Calcium gluconate 10%, 30 mL (3 g) over 10 minutes; can be given in 1 minute if critically ill Calcium chloride 10%, 10 mL (1 g) over 10 minutes; can be given in 1 minute if critically ill	Reversal of hypotension; may not reverse bradycardia	*All indications:* Monitor ionized calcium levels IV extravasation causes tissue necrosis, especially with calcium chloride Can administer at faster than stated rates for immediate life-threatening conditions (i.e., in 1 minute) Calcium chloride contains three times more elemental calcium than calcium gluconate does
	Hydrofluoric acid	Systemic toxicity: calcium gluconate 10%, 1-3 g (10-30 mL) per dose IV over 10-minute period; repeat as needed every 5-10 minutes Topical toxicity: calcium chloride 10%, 1 g (10 mL) mixed into water-soluble lubricant	Reversal of life-threatening manifestations of hypocalcemia and hyperkalemia Topical: reversal of severe neuropathic pain from dermal exposure	Can dilute and give intra-arterially or IV with a Bier block for extremity exposures and burns Topical: apply to skin under occlusive dressing
	Hyperkalemia (except due to cardiac glycosides)	Calcium gluconate 10%, 1 g (10 mL) per dose IV over 10-minute period; repeat as needed every 5-10 minutes	Reversal of myocardial depression and conduction delays	May precipitate ventricular dysrhythmias
	Hypermagnesemia	Calcium gluconate 10%, 1-2 g (10-20 mL) per dose IV over 10-minute period; repeat as needed every 5-10 minutes	Reversal of respiratory depression, hypotension, and cardiac conduction blocks	Simultaneous therapies to increase magnesium elimination should be instituted
	Hypocalcemia (e.g., ethylene glycol)	Calcium gluconate 10%, 0.5-1.0 g (5-10 mL) per dose over 10-minute period; repeat as needed every 10 minutes	Reversal of tetany	Correct symptomatic hypocalcemia; avoid excessive administration that may increase production of calcium oxalate crystals in ethylene glycol poisoning

TABLE 96-6 ANTIDOTES AND INDICATIONS FOR USE[§]—cont'd

ANTIDOTE	INDICATION FOR USE	DOSE*	TREATMENT END POINT	COMMENTS
L-Carnitine	Valproate-induced hyperammonemia or hepatotoxicity	100 mg/kg (maximum 6 g) IV over 30 minutes, then 15 mg/kg IV over 30-minute period q4h (maximum 6 g/day)	Treat until clinical improvement occurs	Levocarnitine is active form Adjust dose for end-stage renal disease
Cyanide antidote kit Hydroxocobalamin (preferred) Sodium thiosulfate	Cyanide	Hydroxocobalamin 5 g IV over 5 minutes (15 mL/min); second dose of 5 g if needed; the entire cyanide antidote kit is rarely indicated if hydroxocobalamin is available. Sodium thiosulfate 25%: 50 mL (12.5 g) IV over 10-minute period	Resolution of lactic acidosis and moderate to severe clinical signs and symptoms: seizures, coma, dyspnea, apnea, hypotension, bradycardia	Hydroxocobalamin causes red discoloration of urine and blood, may interfere with laboratory testing for carbon monoxide and lactate Sodium thiosulfate dosing can be repeated (the other components of the "cyanide antidote kit" cause methemoglobinemia and should not be administered to patients with possible carbon monoxide poisoning; e.g., fire exposure)
Deferoxamine	Iron salts	Initiate at 5 mg/kg/hr, titrate to 15 mg/kg/hr IV (maximum 8 g/day) Mild to moderate: administer for 6-12 hours Severe toxicity: administer for 24 hours	Resolution of clinical signs and symptoms Urine may appear rose-colored but is not a reliable marker for iron clearance Laboratory testing is unreliable while antidote is being received	Indications: symptomatic patients with lethargy, severe abdominal pain, hypovolemia, acidosis, shock; any symptomatic patient with peak serum iron level >350 g/dL Rate-related hypotension may occur Prolonged therapy can cause pulmonary toxicity
Digoxin-specific antibody fragments (Fab)	Digoxin Digitalis and related plants (e.g., oleander, lily of the valley) Other cardiac glycosides (e.g., bufadienolides [Bufo toads])	Unknown digoxin dose or serum level acute toxicity—10 vials; chronic toxicity—3-6 vials Digoxin dose known: number of vials = 2 × oral digoxin dose (mg) × 0.8 Digoxin serum level known: number of vials = [serum level (ng/mL) × weight (kg)] ÷ 100 Infuse dose over 30 minutes Plant or toad source of cardioactive steroid; 10-20 vials	Resolution of hyperkalemia, symptomatic bradydysrhythmias, ventricular dysrhythmias, Mobitz II or third-degree heart block	Each vial binds 0.5 mg of digoxin or digitoxin Monitor ECG and potassium levels Digoxin serum levels unreliable after antidote administered unless test is specific for free serum digoxin
Dimercaprol (BAL)	Arsenic salts Lead salts Mercury, elemental and inorganic salts	Inorganic arsenic: 3-5 mg/kg IM q4h for 48 hours and then q12h for 7 to 10 days Lead: 75 mg/m^2 (4 mg/kg) IM q4h for 5 days Inorganic mercury: 5 mg/kg IM, then 2.5 mg/kg IM q12h for 10 days or until patient is clinically improved	Arsenic: 24-hour urinary arsenic <50 µg/L Lead: encephalopathy resolved, blood lead level <100 µg/dL, and succimer therapy can be started Mercury, elemental and inorganic: 24-hour urinary mercury <20 µg/L	Formulated in peanut oil; painful IM injection is painful and is contraindicated in patients with peanut allergy Maximum adult dose is 3 g/day BAL started 4 hours before initiation of concomitant $CaNa_2EDTA$ for lead encephalopathy Dosing not well established for arsenic and elemental or inorganic mercury toxicity; not used for organic mercury poisoning Adverse effects: painful injections, fever, diaphoresis, agitation, headache, salivation, nausea and vomiting, hemolysis in G6PD-deficient patients, chelation of essential metals Check essential metal levels if chelation is prolonged Succimer is replacing BAL for many indications except lead encephalopathy Treatment end points for arsenic and mercury include improving clinical condition
Edetate calcium disodium ($CaNa_2EDTA$)	Lead	1500 mg/m^2/24 hr (maximum 3 g) by continuous infusion	Treat for 5 days, followed by 2-day hiatus; repeat until encephalopathy resolved, lead level <100 µg/dL, and succimer therapy can be started	Use in patients with lead encephalopathy or lead level >100 g/dL Administer BAL 4 hours before initiating $CaNa_2EDTA$ Hydrate patient and establish good urinary output before starting therapy Avoid thrombophlebitis by diluting in NS or D_5W to a concentration ≤0.5% Substitution of Na_2EDTA can cause fatal hypocalcemia

TABLE 96-6 ANTIDOTES AND INDICATIONS FOR USE[§]—cont'd

ANTIDOTE	INDICATION FOR USE	DOSE*	TREATMENT END POINT	COMMENTS
Flumazenil[A4]	Benzodiazepines	0.1 mg/min IV to a total dose of 1 mg Alternative: 0.2 mg IV over 2 min; repeat with 0.3 mg, then 0.5 mg. Total dose remains at 1.0 mg	Reversal of coma	Limit use to reversal of inadequate ventilation in benzodiazepine-toxic patients Acute benzodiazepine withdrawal may occur in patients dependent on benzodiazepines Increases intracranial pressure and risk for seizures in presence of underlying seizure disorder or ingestion of seizure-producing toxicants Monitor for resedation up to 2 hours after last dose
Folinic acid (tetrahydrofolic acid [leucovorin])	Methanol Methotrexate	Methanol intoxication: 50 mg IV q4h Methotrexate overdose: 100 mg/m^2 IV over 15-30 minutes q3-6h; dosing lower when used as "rescue" in chemotherapy	Methanol: methanol undetectable, metabolic acidosis cleared Methotrexate: serum level $<1 \times 10^{-8}$ mol/L	Essential therapy for both toxicants Little concern with excessive dosing when used for methotrexate overdose Methotrexate: large overdoses may require increased dose If indicated, glucarpidase administered 2-4 hours before or after folinic acid
Fomepizole	Ethylene glycol Methanol	Initial dose: 15 mg/kg IV bolus 10 mg/kg IV q12h for four doses (48 hr) All subsequent doses: 15 mg/kg IV q12h When hemodialysis (HD) performed: HD initiation: additional dose if >6 hours since last dose HD ongoing: q4h End of HD (based on time of last dose): <1 hour, no dose until next scheduled dose immediately after HD completion; 1-3 hours, 50% dose; >3 hours, 100% dose	For both: serum level <25 mg/dL and metabolic acidosis resolved	Start immediately if toxic alcohol suspected, without waiting for confirmatory levels Dose amount is not affected by interval timing of doses
Glucagon	β-Adrenergic receptor antagonists Calcium-channel antagonists	Bolus of 3-5 mg IV; can repeat to achieve clinical effect, then infusion of 2-10 mg/hr	Reversal of hypotension and bradycardia; taper infusion	Can precipitate vomiting; be prepared to protect airway Mild hyperglycemia occurs Maximum dosing amounts unknown; bolus doses up to 30 mg reported Duration of effect is 15 minutes; thus, infusion must be started immediately
Hydroxocobalamin	Cyanide	Initial: 5 g IV over 15-minute period Second dose: 5 g IV over 15 minutes to 2 hours; maximum total dose is 10 g Follow each hydroxocobalamin dose with sodium thiosulfate 25%: 50 mL (12.5 g) IV over 10-minute period	Resolution of lactic acidosis and moderate to severe clinical signs and symptoms: seizures, coma, dyspnea, apnea, hypotension, bradycardia	Can be administered IV push if patient is in cardiac arrest Do not give hydroxocobalamin and sodium thiosulfate through the same IV line Adverse effects: red discoloration of plasma, urine, mucous membranes, skin; transient hypertension Interference with laboratory colorimetric assays: Levels increased: bilirubin; creatinine; glucose; hemoglobin; magnesium; co-oximetry total Hb, COHb%, MetHb% Levels decreased: AST, ALT, creatinine, co-oximetry O_2Hb%
Hyperbaric oxygen (HBO)	Carbon monoxide COHb >25% independent of symptoms, 15% if pregnant Serious symptoms or findings with any elevated COHb concentration	3.0 atm pressure for 60 minutes (25 minutes O_2, 5 minutes air, 25 minutes O_2, 5 minutes air), then 2.0 atm for 65 minutes (30 minutes O_2, 5 minutes air, 30 minutes O_2), then "surface" to 1.0 atm	One treatment Repeated treatment controversial	Carbon monoxide: treatment protocols may vary HBO indicated for loss of consciousness; seizures; cerebellar dysfunction; impaired cognition; headache, nausea/vomiting persisting after 4 hours of O_2 therapy regardless of repeat carboxyhemoglobin level
Insulin-glucose (hyperinsulinemic euglycemic therapy)	Calcium-channel antagonists β-Adrenergic receptor antagonists	Regular insulin, 1 U/kg IV bolus, followed by 0.5-1 U/kg/hr; titrate up to 10 U/kg/hr as needed Titrate 50% dextrose IV to avoid hypoglycemia and replete serum potassium as needed	Reversal of myocardial depression	Initiate early to reverse myocardial depression Monitor glucose and potassium; hypoglycemia can occur during and after therapy Hyperglycemia results from calcium-channel antagonist–induced insulin resistance, and initial dextrose requirements may be less than anticipated Recovery may be heralded by normalization of glucose levels, with increased dextrose required to avoid hypoglycemia

TABLE 96-6 ANTIDOTES AND INDICATIONS FOR USE[§]—cont'd

ANTIDOTE	INDICATION FOR USE	DOSE*	TREATMENT END POINT	COMMENTS
Lipid emulsion	Cardiac toxicity from local anesthetics (e.g., bupivacaine, ropivacaine) and other lipophilic toxicants Provisional: verapamil, diltiazem, tricyclic antidepressants, bupropion, propranolol and other lipophilic toxicants	Use 20% formulation Initial bolus: 1.5 mL/kg IV during 1 minute, followed immediately by infusion of 0.25 mL/kg/min for 30-60 minutes Can repeat bolus for asystole	Return of hemodynamic stability	Use for other than bupivacaine based on animal experiments and human case reports Use if advanced life support measures fail and generally only if the patient is moribund; continue CPR as needed during drug administration
Methylene blue	Methemoglobin-producing agents	1-2 mg/kg body weight (0.1-0.2 mL/kg of 1%) methylene blue IV over 5-minute period; repeat dose for persistent or recurrent symptoms or signs	Resolution of dyspnea and altered mental status	Use if patient is symptomatic (i.e., dyspneic, altered mental status) Maximum dose should not exceed 7 mg/kg (0.7 mL/kg) Contraindicated in G6PD-deficient patients; may cause hemolysis Some toxicants (e.g., dapsone) may require prolonged therapy
N-Acetylcysteine (NAC)	Acetaminophen[A5] Other hepatotoxins: carbon tetrachloride, chloroform, pennyroyal oil, amatoxin[16]	Intravenous (preferred) Load: 150 mg/kg over 1-hour period Maintenance infusion: 12.5 mg/kg/hr over 4-hour period, then 6.25 mg/kg/hr over 16 hours as continuous infusion Oral (total 72 hours) Load: 140 mg/kg Maintenance (starting 4 hours after load): 70 mg/kg q4h × 17 doses IV (total 21 hours)	At the end of therapy, repeat AST and APAP levels: if AST normal and APAP not detected, treatment complete; if AST normal and APAP detected, continue NAC; if AST elevated, continue NAC After patient has received full course of NAC therapy, if INR ≥2.0 or severe hepatotoxicity present (AST > 1000 U/L), continue NAC until INR <2.0 and aminotransferases normalize	Most effective if initiated within 8 hours after acetaminophen ingestion; may be started any time after ingestion and is beneficial in patients with severe hepatotoxicity Longer duration of treatment may be required in patients with persistently elevated acetaminophen levels or ongoing hepatotoxicity Treatment end points simplified for ease of use INR result not valid indicator if fresh frozen plasma recently administered
Naloxone	Opioids	Possible opioid dependence: 40-50 µg (0.04-0.05 mg) IV titrated upward to reverse symptoms while providing respiratory support if needed and cautiously avoiding withdrawal Opioid dependence not likely: 0.4 mg by any route and titrate up to 10 mg Intranasal naloxone (2-4 mg) may be given if IM/IV not possible Continuous infusion: establish bolus dose required to reverse respiratory depression; begin infusing two thirds of reversal dose every hour and titrate to maintain adequate respirations; repeated bolus with half of reversal dose 15 minutes after reversal of respiratory depression	Initial: reversal of respiratory depression with resolution of hypoxemia and hypercapnia Final: resolution of CNS and respiratory depression Avoid rapid and full awakening in opioid-dependent patients to avoid precipitating opioid withdrawal Since the duration of naloxone is shorter than most opioids, re-sedation may occur—so several hours of observation is optimal	Pre-ventilate patients with respiratory depression by bag-valve-mask or intubation before administration Use smaller doses in opioid-dependent patients Some opioids (e.g., buprenorphine) may require larger doses of naloxone (fentanyl does not) Use continuous infusion for recurrent symptoms and prolonged action of some formulations (e.g., sustained-release morphine, methadone) Re-sedation can occur Do not use naltrexone to reverse acute toxicity
Octreotide	Sulfonylurea-induced hypoglycemia	50 µg SQ q6h	Resolution of hypoglycemia and dextrose no longer required to maintain euglycemia	Maintain dextrose infusion as needed Not for insulin-induced hypoglycemia
Physostigmine	Anticholinergic agents (e.g., diphenhydramine, jimsonweed [*Datura* sp], scopolamine)	1-2 mg IV during 5-minute period; can repeat in 5 minutes if no effect and cholinergic effects do not occur	Reversal of anticholinergic effects	Duration of effect is 60-90 minutes Benzodiazepine used for subsequent treatment of agitation and seizures; additional physostigmine used rarely (e.g., refractory seizures or agitation) Adverse effects include seizures, excessive oral secretions, bradydysrhythmias; contraindicated in cyclic antidepressant toxicity

TABLE 96-6 ANTIDOTES AND INDICATIONS FOR USE[§]—cont'd

ANTIDOTE	INDICATION FOR USE	DOSE*	TREATMENT END POINT	COMMENTS
Pralidoxime chloride	Organophosphorus compounds Nerve agents: sarin, VX	30 mg/kg IV bolus (maximum 2 g) over 30 minutes, followed by continuous infusion of 8-10 mg/kg/hr (maximum 650 mg/hr)	Resolution of signs and symptoms, atropine no longer required	Can give initial dose over 2-minute period for life-threatening clinical events Administer early when diagnosis known or strongly suspected Efficacy variable, depending on the organophosphate Fat-soluble organophosphates may require prolonged treatment
Pyridoxine	Ethylene glycol Isoniazid Monomethylhydrazine (*Gyromitra esculenta* mushrooms)	100 mg IV (ethylene glycol) 5 g IV, repeat for refractory seizures	One dose Resolution of seizures	Efficacy theoretical for ethylene glycol to enhance elimination of toxic metabolites Pyridoxine may be required even with benzodiazepines to stop seizures, but patient can remain comatose (isoniazid, *Gyromitra* mushrooms) Excessive dosing can cause neuropathy
Sodium bicarbonate ($NaHCO_3$)	Reversal of myocardial sodium-channel blockers (e.g., cyclic antidepressants, cocaine, sodium-channel–blocking antiarrhythmics with $\tau_{recovery}$ >1 second, piperidine phenothiazines (thioridazine, mesoridazine)	1-2 mEq $NaHCO_3$/kg by intermittent IV bolus; repeat as needed	Narrowing of prolonged QRS, resolution of ventricular dysrhythmias, reversal of hypotension	Monitor blood pH (optimal pH approximately 7.50); avoid pH > 7.55
	Altered tissue distribution or enhanced elimination of salicylates; may be used for chlorophenoxy herbicides, formic acid, methotrexate, phenobarbital	1-2 mEq $NaHCO_3$/kg, followed by 3 ampules (150 mL) $NaHCO_3$ (44 mEq per 50 mL) in 850 mL of D_5W, infused at two to three times normal maintenance fluid rate	Serum salicylate <30 mg/dL and patient clinically stable	Target blood pH: 7.50-7.55 Monitor urinary pH hourly; adjust infusion to maintain urine pH of 7.5-8.0 (avoid blood pH >7.55) Monitor ABGs Maintain normokalemia to allow urinary alkalinization
Succimer (DMSA)	Arsenic Lead Mercury, all forms	10 mg/kg/dose q8h for 5 days, followed by q12h for 14 days Drug holiday for 2 weeks; repeat if treatment end point not reached	Arsenic: 24-hour urinary arsenic <50 µg/L Lead: resolution of encephalopathy, gastrointestinal symptoms, neuropathy, nephropathy, arthralgias, myalgias, and blood lead level <70 µg/dL Mercury, elemental and inorganic: 24-hour urinary mercury <20 µg/L Mercury, organic: end point not well established	Oral chelator; adverse effects include rash, transient AST and alkaline phosphatase elevations, and gastrointestinal distress; minimal chelation of essential metals occurs Dosing for arsenic and mercury not well established Therapeutic end point for organic mercury not established; neurotoxicity not responsive to chelation therapy; suggest chelation until blood mercury level within normal value range for reference laboratory
Vitamin K	Vitamin K antagonist anticoagulants (e.g., warfarin, long-acting anticoagulant rodenticides [LAARs]) (note this is not for normalizing a supratherapeutic INR in patients prescribed warfarin)	Subcutaneous: phytonadione (K_1), 10-25 mg, repeat every 6-12 hours until oral vitamin K_1 started Oral: 25-50 mg q6h; larger doses may be required	INR is normal 48-72 hours after stopping vitamin K_1 therapy Can also monitor factor VII activity	Anaphylactoid reaction can occur with rapid IV administration Severe bleeding may also require FFP, prothrombin protein concentrate (off-label), or factor concentrates Base decision to treat on finding of elevated INR; do not administer prophylactic vitamin K_1 Oral therapy may be required for months with LAAR poisoning because of lipophilicity of toxicant, with slow body clearance

*Dose concentrations and infusion times are not given. Drug dosages may require adjustment in patients with renal or hepatic failure.

†Administer antivenom in a monitored setting; antivenom must be reconstituted and then diluted; initially infuse at a rate of 2 to 5 mL/hr, and double the infusion rate every 5 minutes as tolerated to administer antivenom during a 1-hour period.

‡Ten percent calcium chloride solution = 100 mg/mL (27.2 mg/mL elemental calcium); 10% calcium gluconate solution = 100 mg/mL (9 mg/mL elemental calcium).

§See also Chapter 98.

¶Given the relative infrequency of use of these antidotes, it is prudent that, when possible, the indications, alternatives, and doses for these antidotes should be confirmed if possible with a poison control center or medical toxicologist.

ABGs = arterial blood gases; ALT = alanine aminotransferase; APAP = acetyl-*p*-aminophenol (acetaminophen); AST = aspartate aminotransferase; BAL = British antilewisite; CNS = central nervous system; COHb% = percentage carboxyhemoglobin; CPR, cardiopulmonary resuscitation; D_5W = 5% dextrose in water; DMSA = 2,3-dimercaptosuccinic acid; ECG = electrocardiogram; FFP = fresh-frozen plasma; G6PD = glucose-6-phosphate dehydrogenase; Hb = hemoglobin; HD = hemodialysis; INR = international normalized ratio; IV = intravenous; MetHb% = percentage methemoglobinemia; NS = normal saline; O_2Hb% = percentage oxyhemoglobin; SQ = subcutaneous; $\tau_{recovery}$ = drug blockade recovery rate.

TABLE 96-7 COMMON TOXICANTS REMOVED BY HEMODIALYSIS

TOXICANT	INDICATIONS	COMMENTS
Ethylene glycol	Serum level ≥50 mg/dL, or lower levels with concomitant metabolic acidosis and evidence of end-organ toxicity, or if fomepizole not available	Not routinely required in a patient with normal creatinine clearance and acid-base status who is receiving fomepizole
Lithium*	Clinical indications, primarily CNS toxicity (e.g., decreased level of consciousness, ataxia, coma, seizures) in patients with an elevated blood lithium concentration	Use dialysate containing bicarbonate to decrease Na^+/K^+ antiporter intracellular sequestration of lithium
Methanol	Serum level ≥50 mg/dL, or lower levels with concomitant metabolic acidosis and evidence of end-organ toxicity, or if fomepizole not available	Usually required because of slow elimination half-life in presence of fomepizole (mean, 52 hours; range, 22-87 hours), even in patients with no metabolic acidosis or evidence of end-organ toxicity
Phenobarbital	Clinical indications (e.g., deep coma)	Rarely necessary except when a patient is hemodynamically unstable despite aggressive support
Salicylates	Acute toxicity: serum level ≥100 mg/dL without clinical abnormality or <100 mg/dL in the presence of a clinical indication. Chronic toxicity: any clinical indication, typically altered mental status	Serum protein binding decreases with increasing toxic levels, increasing the amount of free salicylate available for HD removal; clinical indications are one or more of the following: impaired kidney function, altered mental status, seizures, pulmonary edema, intractable acidosis
Valproic acid	Severe intoxication with serum concentration >900 mg/L	Clinical indications include hepatic dysfunction; coma, especially with hyperammonemia; deteriorating clinical status despite aggressive support

*Hemodiafiltration removes lithium; the clinical benefit of this technique is unknown.
CNS = central nervous system; HD = hemodialysis.

PROGNOSIS

Almost all patients who reach the hospital alive survive with appropriate care. Inpatient mortality rates are 0.2 to 0.5%.

97 MEDICAL ASPECTS OF TRAUMA AND BURNS

ROBERT L. SHERIDAN

Injured or burned patients are complex to manage not only because of the vast number of potential anatomic derangements but also because of the complex physiologic cascades triggered by injury. Although most intense after extensive burns, stereotypical physiologic derangements are a characteristic of all injuries. As a result, needed interventions are often predictable regardless of the mechanism of injury.

EPIDEMIOLOGY

In the United States alone each year, about 2.5 million people are injured and about 35,000 to 40,000 are killed in automobile crashes, whereas about 120,000 are injured and about 40,000 are killed by gunshots. Burns and falls follow in frequency. Worldwide, injury by trauma and burns is the leading cause of death in children and young adults.[1] In the United States, injury follows only cancer and heart disease as a cause of death. Many long-term survivors of trauma and burns have high degrees of disability, which creates a particularly difficult and expensive problem given the young age of many victims.

The time of death after injury has a trimodal distribution. At least 50% of fatalities occur within minutes of the injury as a result of massive hemorrhage or nonsurvivable brain injury. Approximately one third of deaths occur within a few hours of injury, usually by hemorrhage, anoxia, or progressive brain trauma. This interval provides an opportunity for emergent intervention. Later fatalities are usually the result of multisystem organ dysfunction or overwhelming infection in the days and weeks after the injury. The likelihood of surviving a severe injury is better in communities that are closer to major trauma centers.[2]

PATHOBIOLOGY

Early Local Response to Injury

The local response to blunt, penetrating, electrical, crush, thermal, blast, or other injury varies with the energy transferred. All are associated with some degree of secondary injury by progressive microvascular thrombosis, progressive edema, and secondary compromise of perfusion. The most common preventable mechanisms are related to progressive edema beneath an inelastic eschar or fascial compartments or direct injury to vascular inflow or outflow.

Early Systemic Response to Injury

The early systemic response to burns and local trauma is driven by fluid loss and release of vasoactive mediators from injured tissue. In more severe injuries, including surface burns greater than about 20% of the body surface, interstitial edema develops in unburned skin as well as in distant organs and soft tissues. These distant microvascular effects, which can compromise the function of organs that were not directly injured, explain the frequent occurrence of pulmonary and other organ dysfunctions in patients with large burns.

The capillary leak syndrome, in which the leak is typically proportional to the scope of the injury, is caused by the release of vasoactive substances from the injured and reperfused tissue. As a result, during the first 18 to 24 hours after a serious burn, both electrolytes and large colloid molecules freely diffuse into the interstitial space.

Late Local Response to Injury

At about 72 hours after the initial trauma, local wound issues are particularly important in patients who have extensive soft tissue damage, especially after burns or crush injury with extensive volumes of devitalized tissue. Tissue that has been crushed or suffered reduced blood flow is subject to progressive necrosis. As bacteria multiply in the avascular tissue during the succeeding days, proteases liquefy the eschar and necrotic tissue, which then separates and leaves a bed of granulation tissue. In healthy patients with

ABSTRACT

Injured or burned patients are complex to manage not only because of the vast number of potential anatomic derangements but also because of the complex physiologic changes triggered by injury. Proper support and management of these derangements is an essential component of successful care, regardless of the mechanism of injury. Practical care and long-term outcomes can be further complicated by the emotional impact of the injuries.

TABLE 97-1 INJURY CLASSES

INJURY CLASS	CLINICAL IMPLICATIONS	COMMON ERRORS
Blunt	Graded soft tissue and bone injury, edema Occult vascular or visceral injury	Delayed consequences of edema Missed visceral injury and secondary consequences
Penetrating	Soft tissue and bone injuries vary with energy of injuring object (e.g., knife vs. fragment vs. bullet) Occult vascular or visceral injury	Missed vascular or visceral injury Secondary consequences of missed vascular injury
Thermal	Graded soft tissue injury (first- to fourth-degree burns) Capillary leak phenomenon	Inadequate appreciation of capillary leak phenomenon and consequent under-resuscitation Inaccurate wound evaluation and over-resuscitation Unanticipated local injury progression
Electrical	Range of soft tissue injury with increasing voltage and contact duration and quality	Occult cardiac and muscle injury Secondary compartment syndrome complications
Crush	Graded soft tissue, bone, and visceral injury with secondary consequences of edema and of reperfusion	Underappreciation of injury severity Missed muscle ischemia due to primary ischemia and to reperfusion edema
Blast	Graded injury severity (primary to quaternary injury patterns) Occult visceral injury	Underappreciation of secondary, tertiary, and quaternary components of injury Missed associated visceral injury
Fragmentation injury	Multiple unpredictable penetrations with associated visceral and vascular injury	Missed visceral and vascular injury Associated blast trauma

smaller wounds and burns (<20% of the body surface), this septic process is usually tolerated. When injuries are larger, however, systemic infection results and explains the rare survival of patients who have burns in excess of 40% of body surface area or who have massive soft tissue injuries with incomplete early wound excision.

Late Hypermetabolic Systemic Response to Injury

Successfully resuscitated patients with large burns or major non-burn trauma demonstrate an initial decrease in cardiac output and metabolic rate. After successful resuscitation, a hypermetabolic response occurs, with a near doubling of cardiac output and resting energy expenditure during the next 24 to 72 hours. The magnitude of the response, which becomes greater with larger burns and more severe injuries, peaks at up to twice the normal metabolic rate in otherwise healthy patients with burn involving 60% or more of the body surface area. This hypermetabolic response is characterized by enhanced gluconeogenesis, insulin resistance, and increased protein catabolism. Although the causes of these physiologic changes are not well understood, they seem to involve the systemic release of bacterial products, the breakdown of gastrointestinal barrier dysfunction with translocation of bacteria and their byproducts into the circulation, and increases in the secretion of glucagon, cortisol, and catecholamines.

CLINICAL MANIFESTATIONS

Common mechanisms of injury include blunt, penetrating, electrical, thermal, blast, and crush (Table 97-1), often in combination. For example, patients crushed in building collapses frequently suffer a concomitant penetrating component, and patients who suffer high-voltage injury frequently fall from a height, such as a utility pole. In all mechanisms, edema or vascular injury can compromise perfusion and lead to secondary injury.

Blunt injury is commonly seen in motor vehicle accidents and falls. Injuries are often multisystem. Penetrating soft tissue injuries vary widely (Fig. 97-1), but the overarching concern is the possibility of occult injury to vascular, bone, or visceral structures. The degree of trauma is directly related to the energy of the injury. For example, high-velocity gunshots cause greater injury than lower velocity rounds because they create a local blast effect, called cavitation, along their trajectory.

Thermal injury (Fig. 97-2) by whatever mechanism (flame, scald, contact) is associated with a graded soft tissue injury described in degrees. As thermal injuries increase beyond about 15% of the body surface, a diffuse capillary leak phenomenon occurs that continues for 18 to 24 hours after injury and involves both burned and unburned tissue. This phenomenon can result in cardiovascular collapse and is the key physiologic derangement underlying the shock state accompanying burns.[3]

The severity of electrical injuries (Fig. 97-3) varies with voltage, current flow, and contact quality. Low-voltage injuries are rarely associated with distant sequelae, whereas high-voltage injuries are commonly associated with compartment syndromes, cardiac complications, pigmenturia, and other trauma.

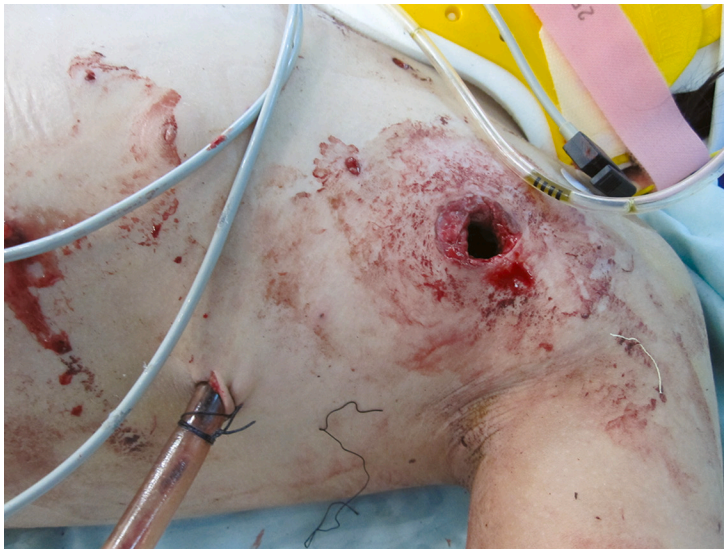

FIGURE 97-1. Penetrating injury often is associated with visceral and bone trauma.

FIGURE 97-2. Thermal injury is of variable depth. Initial evaluation usually underestimates this depth.

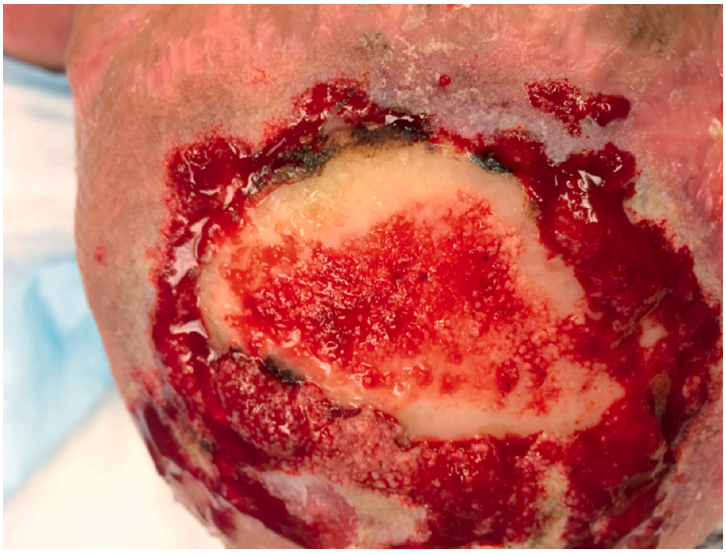

FIGURE 97-3. Electrical injury can be associated with a number of systemic sequelae, depending on current strength and pattern of flow.

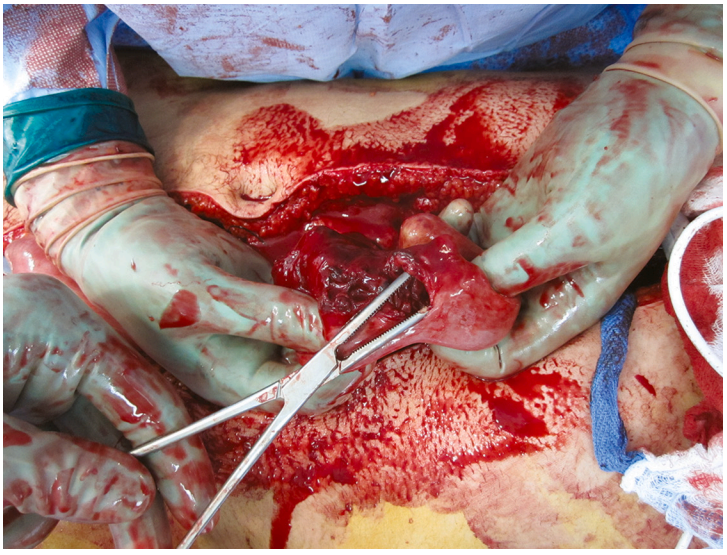

FIGURE 97-5. Blast injury is a complex of four injury subtypes. Missed injuries are common.

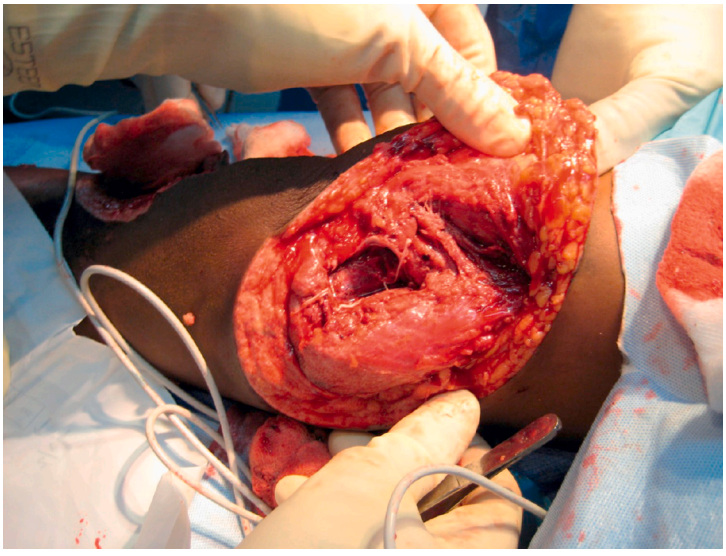

FIGURE 97-4. Crush injury is often associated with underappreciated deep muscle injury.

FIGURE 97-6. Fragmentation injury is a particular form of penetrating injury frequently associated with missed injuries.

Crush injuries (Fig. 97-4) include direct soft tissue injuries as well as secondary ischemic damage due to a compartment syndrome or ischemia-reperfusion. Associated bone, visceral, and vascular injuries are common. Major septic complications are common when necrotic soft tissues are left unexcised.

Blast injuries (Fig. 97-5) are graded complex injuries with four characteristics: primary injury to air-filled structures and the central nervous system, secondary injury from flying debris, tertiary injury from collisions with stationary objects, and quaternary injury from associated crush or other trauma. Blast injuries of all types can be subtle or have a delayed clinical presentation, and visceral injuries often are not diagnosed promptly.

Fragmentation injuries (Fig. 97-6) are penetrating injuries characterized by multiple foreign bodies of variable size and energy as well as unpredictable trajectories. As with blast injuries, the full extent of injury is often underestimated initially.

DIAGNOSIS AND TREATMENT

Complex burns and trauma are most successfully and cost-effectively managed in high-volume programs.[4] Trauma and burn center programs emphasize the comprehensive nature of injury care, including community involvement with injury prevention programs, thorough prehospital care, early resuscitation and surgery, and long-term rehabilitation and reconstruction. Most programs include embedded specialty intensive care units and operating rooms. Multidisciplinary staff include physicians, physician assistants, nurse practitioners, nurses, physical and occupational therapists, respiratory therapists, psychiatrists, social workers, and nurse administrators. Coordination and scheduled communication are essential.

Care of individual patients with serious multisystem injury is complex and requires a longitudinal four-phase approach.[5] Phase One, which describes the initial evaluation and resuscitation, generally is completed in the first 24 hours. Phase Two includes initial wound excision for burn patients and initial resuscitative surgery and fracture stabilization for non-burn trauma patients. This phase frequently overlaps with Phase One but is usually completed within 72 hours. Phase Three involves definitive wound closure for burns and the completion of surgery for trauma patients. The duration of this phase varies greatly with injury but is usually complete at the time of discharge. Phase Four describes the sometimes long process of reconstruction, rehabilitation, and reintegration. This phase of care commonly spans the later part of the acute hospitalization, inpatient rehabilitation, and variable amounts of time in the home-based setting.

Prehospital Care and Interhospital Transport

When prehospital and interhospital transfers are being arranged, key issues include control of the airway, secure venous access, placement of bladder and nasogastric catheters, maintenance of body temperature, fluid administration if transport time will be more than 1 hour, documentation of the events of the injury from personnel who will not be available to the receiving facility, efforts to notify family members, and clear documentation of all interventions.

Hypothermia (Chapter 95) is a particular problem in burn patients because of their evaporative heat losses. Transporting vehicles and emergency department receiving areas should be heated before the patient's arrival. Initial burn dressings should be dry, clean sheets rather than wetted dressings. Cooling of a wound involving less than 15% of the body surface within minutes of injury may help limit burn depth without causing systemic hypothermia, whereas cooling after a few minutes is generally unhelpful.

Phase One: Initial Evaluation and Resuscitation

Primary Survey

The organized approach to the initial evaluation of injured patients requires primary and subsequent patient surveys. The primary survey is an initial look for major aberrations in airway, circulatory, or neurologic status that justify emergent intervention. The airway is controlled with intubation if needed. Clinically obvious pneumothoraces (Chapter 86) should be decompressed, and hemothoraces must be diagnosed and drained. In suspicious cases, pericardial tamponade (Chapter 62) can usually be documented or excluded by handheld bedside ultrasonography. Vascular access is obtained and fluid resuscitation started. A very brief neurologic assessment (Chapter 366), including use of the Glasgow Coma Scale, is critical.

Secondary Survey

The secondary survey includes a much more detailed head-to-toe physical examination after the patient has a reliable airway and has been hemodynamically stabilized. The physical examination should assess for evidence of closed head injury, skull and facial fractures, and eye and ear injuries, with a low threshold for a head computed tomography (CT) scan. The neck must be stabilized and assessed for possible injury. Burns should be categorized as first-degree burns, involving only the epidermis; second-degree burns, involving variable amounts of dermis; third-degree burns, involving the entire dermis; and fourth-degree burns, involving fat, muscle, and bone.

A constant concern is the potentially missed injury. In the chaos of initial care, major issues can be missed if they do not have a dramatic initial presentation. Unfortunately, many injuries, such as epidural hematoma and small bowel perforations, are initially subtle and become catastrophic hours or days later. The best way to deal with this difficult reality is to have a highly organized approach that includes both a detailed initial evaluation and subsequent reevaluation so that all potential injuries are considered and reasonably excluded.

Projectiles often follow an unpredictable course through tissue and bone, thereby increasing the likelihood of missed injury. Missed visceral injury is also common with fragmentation injuries, especially because surgical exploration of all potential sites of injury is often impractical. Selected exploration is guided by initial and serial examination and by imaging when available.

Appropriate laboratory and imaging studies should be obtained. The fundamental goal is to consider carefully the injury mechanism and to exclude all potential occult injuries to a reasonable level of confidence. High-energy injuries, such as electrical burns, motor vehicle crashes, and blasts, are notorious for generating significant injuries that are missed during the initial evaluation. Bedside ultrasonography has emerged as a routine, rapid, and repeatable method to assess for abdominal fluid, usually blood. CT scanning of the head, chest, abdomen, and pelvis is justified if the mechanism of injury is consistent with head or abdominal trauma, and conventional imaging with selective CT scanning is as good as immediate total-body CT scanning.[A1] Rapid imaging has largely supplanted operative exploration for diagnostic purposes, except in unstable patients, in whom immediate operative exploration is performed for ongoing hemorrhage.

Chest Injuries

Tension pneumothorax (Chapter 86), hemothorax, cardiac tamponade (Chapter 62), flail chest, open pneumothorax, and disruption of the thoracic aorta (Chapter 63) are among the life-threatening injuries that should be considered during the primary and secondary surveys. All trauma patients should have a supine chest radiograph to examine the lung fields, mediastinal contour, and chest wall. Thoracic aortic injury is usually an immediately fatal complication of severe acceleration-deceleration injury, but some patients may have a contained mediastinal hematoma that requires urgent diagnosis and medical or surgical management.

Myocardial contusion should be suspected in patients with blunt trauma, especially if they have a sternal fracture or anterior rib fractures. Such blunt cardiac injuries can result in electrocardiographic abnormalities, ventricular arrhythmias, and cardiogenic shock. Coronary artery injuries are uncommon, although lacerations and dissections can occur and require emergent percutaneous coronary intervention similar to a typical ST elevation myocardial infarction (Chapter 58).

Commotio cordis is sudden cardiac arrest (Chapter 50) after acute blunt chest trauma from softballs, baseballs, hockey pucks, or collisions. The trauma presumably occurs during an electrically vulnerable period between 30 and 15 msec before the T-wave peak and produces ventricular fibrillation. Death is essentially universal unless the victim receives immediate cardiopulmonary resuscitation.

Abdominal Injuries

The liver and spleen are the most frequently injured intra-abdominal organs. Suggested findings on physical examination include lower rib fractures, upper quadrant pain or tenderness, and pain referred to the shoulder secondary to diaphragmatic irritation. CT scanning is the test of choice. High-grade injuries require surgery, but most lesser injuries can be managed nonoperatively. Focused abdominal sonography has a sensitivity of 95% for detection of free blood in the abdomen (Fig. 97-7) but is not usually able to identify the source. An alternative in unstable patients or in austere environments is diagnostic peritoneal aspiration or lavage. Abdominal CT is a reliable determinant of both intraperitoneal and retroperitoneal injury (Fig. 97-8) and is preferable to diagnostic aspiration or lavage in stable patients. For selected stable patients whose blunt liver or spleen injury is originally treated nonoperatively, discharge on day 3 may be as safe as discharge on day 5, provided that the patient is stable and does not have other indications for continued hospitalization.[A2]

Head and Spine Injuries

Neurologic issues often dominate the quality of long-term outcome. The initial evaluation of the neurotrauma patient focuses on detection of reversible causes of elevated intracranial pressure or reduced perfusion (Chapter 368), but routine

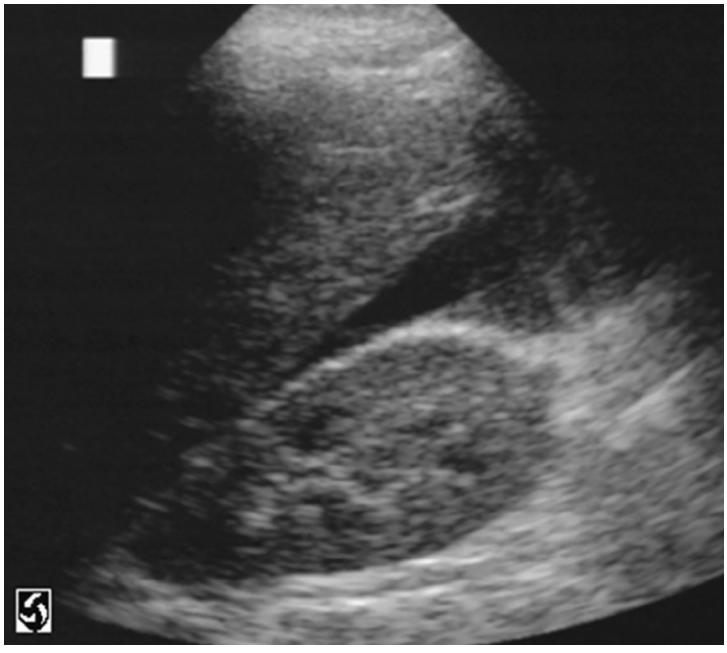

FIGURE 97-7. Positive focal abdominal sonography in trauma (FAST) study. There is a collection of fluid that shows up as a black strip between the liver and kidney. The white appearance is fat around the kidney. These findings are consistent with a fluid collection in the Morison pouch. (Courtesy Robert H. Demling, MD.)

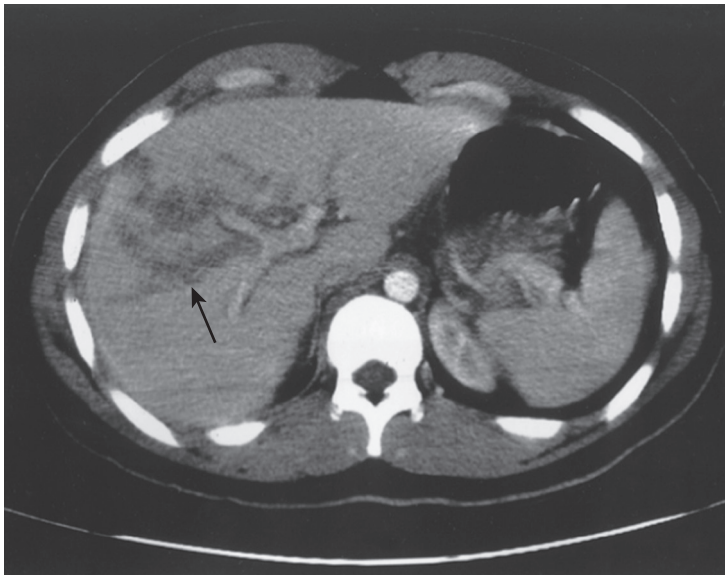

FIGURE 97-8. Abdominal injury. An abdominal computed tomography scan shows an injury to the right lobe of the liver (*arrow*). (Courtesy Robert H. Demling, MD.)

measurement of intracranial pressures does not improve outcome.[6] Although many outcomes are fixed from the time of injury, opportunities for early intervention should not be missed. It is particularly important to avoid secondary neurologic injury, most commonly due to reduced perfusion from hypotension and cerebral edema.

Prevention of spinal cord injury (Chapter 368) and evaluation of the spine for bone and ligamentous disruption are also important components of the early evaluation. Multidetector CT images can be obtained quickly to detect occult spinal injuries, and routine magnetic resonance imaging is rarely clinically indicated.[7]

A multidisciplinary approach to the evaluation and management of pain and anxiety in injured patients has important short- and long-term benefits. An organized approach facilitates dealing with the inevitable pain and anxiety in an organized and consistent manner and allows the unit to determine the effectiveness of new interventions.

Tertiary Survey

The tertiary survey is a planned repeat physical examination, usually 1 or 2 days after admission, often accompanied by focused imaging tests.[8] The goal is to exclude missed subtle injuries that might otherwise cause significant long-term morbidity. Examples include minor fractures of the wrist or foot, small deep lacerations of the scalp, subtle eye injuries, and some abdominal injuries, particularly retroperitoneal duodenal or colonic perforations. Such injuries can become the patient's dominant source of long-term morbidity if they are missed during initial evaluation and treatment.

Key Management Issues

Fluid Resuscitation and Transfusion

The clinical goal is to administer adequate, but not excessive, fluid[9] while ensuring that soft tissues are not rendered ischemic by increasing pressure beneath inelastic eschar or tense muscle compartments. The severity of hemorrhagic shock should be assessed and treated appropriately (Table 97-2).

For burn patients, several formulas based on weight, surface area, and burn size have been developed over the years. These are general guides, and physiologic monitoring is needed with individual titration of infusions to meet set resuscitation end points, such as urine output, base deficit, and vital signs (E-Table 97-1).[10]

In well-resuscitated trauma and burn patients, capillary integrity generally returns at 18 to 24 hours, and fluid requirements decrease to approximately 1.5-fold maintenance in most patients. With the reduction in the infusion rate of isotonic crystalloid, topical care of large wounds will have a major impact on serum electrolytes. Wounds treated with nonaqueous topical antimicrobials, such as silver sulfadiazine cream or mafenide acetate cream, promote transeschar water loss and generate a free water requirement. By comparison, wounds treated with aqueous topical agents are associated with electrolyte leaching and secondary hyponatremia (Chapter 102). Serum levels of potassium, calcium, and magnesium (Chapters 103-105 and 227) should be monitored frequently and replaced as needed. In most patients, enteral feedings (Chapter 198) can be started.

Current fluid resuscitation practices in trauma patients emphasize initial "permissive hypotension" to reduce early bleeding (Chapters 90 and 92). Patients with mean systemic arterial pressures in the range of 60 to 80 mm Hg are resuscitated initially to modest hypotension (i.e., the range of 80 to 90 mm Hg) if they are otherwise alert and well perfused. They are then taken expeditiously to the operating room for surgical control before targeting a normotensive state. Early use of blood products such as fresh-frozen plasma and red cells rather than crystalloid can minimize the coagulopathy and improve outcomes in rapidly hemorrhaging patients. Among patients with severe trauma and major bleeding, early administration of plasma, platelets, and red blood cells in a 1 : 1:1 ratio of infusion units is better than a 1 : 1:2 ratio for achieving hemostasis and reduces early death due to exsanguination.[A3] Liberal use of tourniquets and compressive dressings before surgery further improves outcome by reducing blood loss. Among the various crystalloids, none seem to have any obvious advantages or disadvantages for treatment of hemorrhage. Tranexamic acid (e.g., loading dose of 1g during 10 minutes, then infusion of 1 g during 8 hours), which inhibits thrombolysis, beginning within 8 hours of injury may reduce bleeding and improve survival in selected patients who require massive transfusion.[A4]

Pigmented urine is commonly seen in the setting of high-voltage, crush, blast, or very deep thermal injury. Myoglobin and hemoglobin that are liberated from lysed muscle (Chapter 99) and red cells cause the pigmentation. To avoid renal tubular injury (Chapter 106), crystalloids should be administered to achieve a urine output of 2 mL/kg/hour (Chapter 99).

Decompression Procedures

An important component of the initial evaluation of the trauma and burn patient is to find and to rectify compartment syndromes before irreversible tissue ischemia occurs.[11] Perfusion of the extremities can be compromised by inelastic near-circumferential burns, and the normal fascial envelopes of major muscle groups can cause high soft tissue pressure if muscles are injured by crush, thermal, or electrical injury or in association with major fractures. Extremities at risk should be dressed simply to facilitate frequent assessment for temperature, pliability, voluntary motion, pain with passive motion, detectable pulsations, and low-pressure flow by capillary refill and Doppler signals in the digital vessels and digital pulp. In assessing capillary refill, it is important to elevate the extremity, as even a mottled nonperfused extremity will demonstrate venous refill when it is dependent. Measurement of compartment pressures may be valuable in selected patients, with decompression recommended when measured pressures are above 30 cm H_2O. In most situations, serial clinical examination is sufficient to determine the need for escharotomy or fasciotomy, thereby avoiding the risk of bacterial seeding posed by passing pressure-monitoring catheters through contaminated wounds. Compromised extremities should be promptly decompressed by escharotomy or fasciotomy before the development of irreversible tissue necrosis (E-Fig. 97-1).

Abdominal Compartment Syndrome

If abdominal viscera become extremely edematous, abdominal compartment syndrome may result.[12] This syndrome, which is usually caused by edema of the bowel wall, occurs after abdominal trauma or after the gut is reperfused by resuscitative therapies. When intra-abdominal pressures exceed 25 mm Hg (34 cm H_2O), renal blood flow, inferior vena cava blood return, and diaphragmatic excursion are impaired. This syndrome typically is manifested with oliguria, hypotension, and difficult ventilation. Diagnosis is by physical examination and measurement of bladder pressure. Treatment is by laparotomy with temporary abdominal closure.

Phase Two: Initial Surgical Care

Phase Two includes initial wound excision for burn patients and initial resuscitative surgery and fracture stabilization for non-burn trauma patients. This phase frequently overlaps with Phase One but is usually completed within 72 hours. Multiple subspecialty surgical teams may need to be coordinated by a trauma surgeon who directs overall care and reconciles conflicting priorities.

Early Wound Excision

Excisional débridement of nonviable soft tissues or deep burns during the first days following injury, before heavy microbial colonization occurs, will reduce the incidence and severity of sepsis from burns, crush, or other soft tissue trauma.

TABLE 97-2 CATEGORIZATION AND INITIAL TREATMENT OF HEMORRHAGIC SHOCK*

	CLASS I	CLASS II	CLASS III	CLASS IV
Blood loss (mL)	≤750	750-1500	1500-2000	≥2000
Blood loss (% of blood volume)	≤15	15-30	30-40	≥40
Pulse rate	<100	>100	>120	≥140
Blood pressure	Normal	Normal	Decreased	Decreased
Capillary refill test	Normal	Positive	Positive	Positive
Respiratory rate	14-20	20-30	30-40	>35
Urine output (mL/hr)	≥30	20-30	5-15	Negligible
Mental status	Slightly anxious	Mildly anxious	Anxious and confused	Confused and lethargic
IV fluid replacement (3 : 1 rule)	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

*Based on a 70-kg adult.
IV = intravenous.

E-TABLE 97-1 BURN INTRAVENOUS RESUSCITATION FORMULA

FIRST 24 HOURS

Adults and Children >20 kg

- Lactated Ringer solution: 2-4 mL/kg per percentage of total body surface area (TBSA) burned per 24 hours (first half in first 8 hours)
- Colloid: in many patients, particularly those with small injuries, no colloid is advised in the first 24 hours. However, colloid, generally as 5% albumin solution, is increasingly used early in resuscitation of patients with large burn injuries. This is program specific and should ideally be discussed with the unit to which the child with a large injury will be referred.

SECOND 24 HOURS—ALL PATIENTS

- Crystalloid: to maintain urine output. If silver nitrate is used, sodium leaching will mandate continued isotonic crystalloid. If other topical agents are used, then free water requirement is significant. Serum sodium should be monitored closely.
- Nutritional support should begin, ideally by the enteral route.
- Colloid (5% albumin):
  - 0-30% burn: none
  - 30-50% burn: 0.3 mL/kg per percentage of TBSA burned per 24 hours
  - 50-70% burn: 0.4 mL/kg per percentage of TBSA burned per 24 hours
  - 70-100% burn: 0.5 mL/kg per percentage of TBSA burned per 24 hours

E-FIGURE 97-1. **Tight extremities should be promptly decompressed by escharotomy or fasciotomy before the development of irreversible tissue necrosis.**

Damage Control Surgery

Damage control surgery identifies the most important surgical tasks that must be done to save the patient's life, and only these tasks are performed initially, thereby allowing a more stable patient to return to the operating room later for a subsequent definitive and often time-consuming operation. The prototypical example is for abdominal trauma, when bleeding and gastrointestinal contamination are addressed initially but the abdomen is left open so a warmed and more stable patient can return to the operating room in 12 to 36 hours for a definitive bowel anastomosis and abdominal closure. This concept can also be applied to the trauma care system. If multiple patients need to share limited operating room resources, truncating individual operations allows more patients to be treated urgently.

Early Fracture Fixation

Early surgical fixation of long bone fractures benefits injured patients by reducing the complications of immobilization, enhancing rehabilitation, and likely reducing the systemic inflammatory state and proclivity to thromboembolic complications.

Prophylaxis for Thromboembolic Complications, Gastrointestinal Hemorrhage, and Infection

Trauma incites a hypercoagulable state, and seriously injured patients are prone to deep venous thrombosis and pulmonary embolism. Prophylaxis using low-molecular-weight heparin and/or automatic compression stockings has become routine in most trauma programs.

During the early hypodynamic phase with reduced splanchnic blood flow, gastrointestinal hemorrhage may occur in the seriously injured or burned patient. This complication can be sharply reduced with routine pharmacologic prophylaxis, including proton pump inhibitors or histamine-2 receptor blockers.

Prophylactic antibiotics are not recommended[A5] except perhaps in patients who have severe burns and require mechanical ventilation or who have undergone split-thickness skin grafting, because they can promote the growth of resistant organisms.[13] However, careful observation and prompt cultures in febrile patients are critical for optimal management.

Critical Care of the Injured or Burned

Many injured patients require transient intubation and mechanical ventilation (Chapter 91) to facilitate resuscitation, evaluation, and initial care. Some will go on to develop respiratory failure (Chapter 90) requiring protracted ventilator support.

Multiple mechanical and injury factors contribute to respiratory insufficiency in trauma patients, including chest wall trauma and pulmonary contusion. In patients with more severe injuries, including flail chest, rib fixation is a useful intervention.

In burn patients, inhalation injury (Chapter 82) is an important cause of respiratory failure. The diagnosis of inhalation injury is best made by history and clinical examination revealing singed nasal vibrissae and carbonaceous debris in the mouth and pharynx (E-Fig. 97-2). Chest radiographs are usually normal initially. Airway management is challenging but generally is similar to non-burn patients.[14] Carbon monoxide poisoning (Chapter 82) can be seen in conjunction with inhalation injury; the standard of care is 100% oxygen at the prevailing atmospheric pressure for 6 hours, with hyperbaric oxygen reserved for patients with a carboxyhemoglobin level above 30% or neurologic changes.

Pneumonia (Chapter 85) or tracheobronchitis (Chapter 84) occurs in about 30% of burn patients with inhalation injury. Acute respiratory distress syndrome (Chapter 90) also is common in burn and trauma patients, particularly those who go on to develop sepsis, pneumonia, and multiple organ failure. Antibiotic therapy is directed by sputum Gram stain and cultures and should not be prolonged beyond a 7- to 10-day therapeutic course. Vigorous pulmonary toilet, with directed bronchoscopy to clear secretions in selected patients, is an important component of therapy.

Post-Resuscitation Metabolic Issues

In the days that follow successful resuscitation, a hyperdynamic state predictably occurs, characterized by a high cardiac output and low peripheral resistance. Excision of necrotic tissue, prevention of tissue ischemia by repair of vascular injuries, and prompt management of compartment syndromes will minimize the burden of necrotic tissue and reduce post-injury infection and hypermetabolism (E-Fig. 97-3).

Several formulas have been devised to predict non-protein calorie needs (E-Table 97-2). A very rough estimate of calorie needs is a range of 25 to 35 kcal/kg/day, with the lower number applying to more stable and older patients and the upper number applying to more seriously injured and younger patients. Protein administration of 2 to 3 g per kilogram per day will adequately support the needs of most injured patients.

The route of nutritional support is ideally enteral (Chapter 198), with tube feeding beginning during resuscitation. However, some patients, particularly those with very severe and abdominal injuries or those with intervening sepsis, will not tolerate enteral feedings at goal rates and will require supplemental parenteral nutrition to ensure delivery of all needed nutrients (Chapter 198).

Safe and reliable modification of adverse components of the hypermetabolic response, particularly protein catabolism, has proved an elusive goal. Anabolic agents such as recombinant human growth hormone and anabolic steroids may help restore positive nitrogen balance but are not universally used because of their complications, expense, and conflicting data regarding the efficacy. Other attempted interventions, such as enteral glutamine,[A6] antipyretics, β-adrenergic blockade, β-adrenergic supplementation, nonsteroidal anti-inflammatory agents, recombinant growth hormone, insulin-like growth factor-I, and anabolic steroids, have been tried, but available data are inadequate to support any of these therapies as standard care.

Septic Complications and Multiple Organ Failure

Injured patients are at elevated risk for a multitude of infectious complications (Chapter 261). Multiple organ dysfunction and septic shock (Chapter 94) are manifestations of uncontrolled systemic inflammation for severe infection.

Phase Three: Definitive Surgical Care

Phase Three involves definitive wound closure for burns and completion surgery for trauma patients. In non-burn trauma patients, this phase may involve removal of vacuum wound dressings and definitive closure, closure of fasciotomy sites, and fixation of facial fractures. The duration of this phase varies greatly with injury, but it is usually complete at the time of acute hospital discharge. For example, in burn patients, this phase of care is defined by replacement of temporary membranes with permanent grafts and the important but time-consuming grafting of hands and face.

Phase Four: Rehabilitation and Reintegration

Phase Four describes the sometimes long process of reconstruction, rehabilitation, and reintegration.[15] This phase of care may begin in an inpatient rehabilitation setting and progress into the home environment. Depending on the specifics of the injury, the process may be a few weeks to months or years. Daily passive range-of-motion movements, splinting, anti-deformity positioning, and strengthening can reduce the frequency of these complications.

The environment of recovery is an important therapeutic consideration. Data suggest that specific qualities of the family have a major impact on multiple aspects of recovery, some that can potentially be modified. Community resources can be used to enhance recovery and are an important part of discharge planning. Attempts to reduce opiod use during the acute phase may reduce overall opiod use during the hospital course and afterwards.[A7]

REHABILITATION OF THE INJURED PATIENT

REHABILITATION IN THE CRITICALLY ILL PATIENT

Passive range-of-motion movement, splinting, and anti-deformity positioning will minimize the capsular contraction and shortening of tendon and muscle groups that otherwise occur with protracted immobilization.

Emotional recovery after severe trauma can be limited by neurologic injury and post-traumatic stress. These issues can be anticipated and their adverse effects blunted by early and continuous involvement of emotional supports for the family and patient. Ideally, psychiatric, social service, and psychological resources are available.

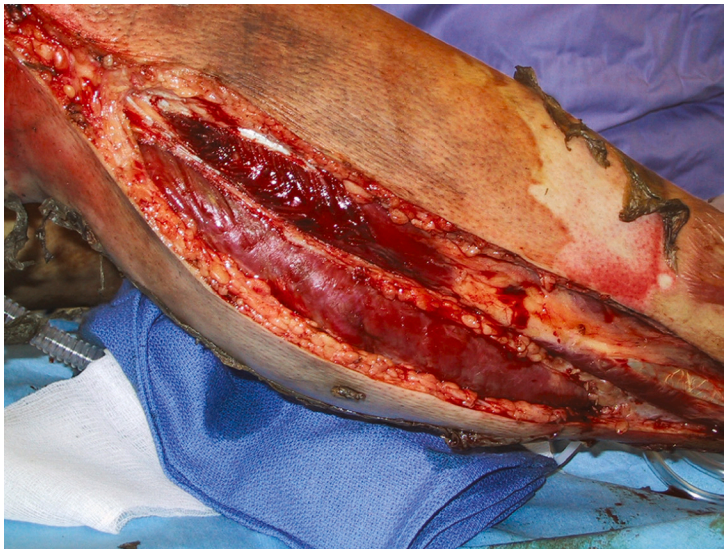
SPECIAL CONSIDERATIONS

Electrical Injury

Cardiopulmonary arrest can be caused by low-voltage electrical injury but is more common with high-voltage electrical injury. Extensive tissue necrosis may also liberate enough potassium to cause cardiac dysfunction. Because cardiac arrhythmias may recur after resuscitation or develop 24 to 48 hours after injury, all patients who have sustained high-voltage electrical injury should undergo continuous electrocardiographic monitoring for at least 24 to 48 hours after the last documented arrhythmia.

Deep muscle necrosis can be initially inapparent, so many patients benefit from serial operative evaluation and débridement. Recovery of function after direct electrical nerve damage is rare. Conversely, the nerves that are not injured directly commonly recover. Rarely, a polyneuritic syndrome of relatively late onset can cause deficits in the function of peripheral nerves far removed from the points of contact. Among patients hospitalized with serious high-voltage electrical injuries, about 8% die and another 22% have permanent neurologic deficits despite optimal care. Most patients with low-voltage injuries, such as can be caused by electrical flash burns, also develop long-term sequelae, including neurologic (memory loss, numbness, headache, chronic pain, weakness) and musculoskeletal (pain, reduced range of motion, contracture) symptoms.

E-FIGURE 97-2. Inhalation injury is predicted by history and physical findings, including soot in the mouth and teeth as shown here.



E-FIGURE 97-3. Prevention of tissue ischemia of edematous limbs by escharotomy or fasciotomy will minimize the burden of necrotic tissue.

E-TABLE 97-2 MODIFIED HARRIS-BENEDICT EQUATION

MALE PATIENTS
BMR = 88.362 + (13.397 × weight in kg) + (4.799 × height in cm) − (5.677 × age in years)
FEMALE PATIENTS
BMR = 447.593 + (9.247 × weight in kg) + (3.098 × height in cm) − (4.330 × age in years)

BMR = basal metabolic rate.

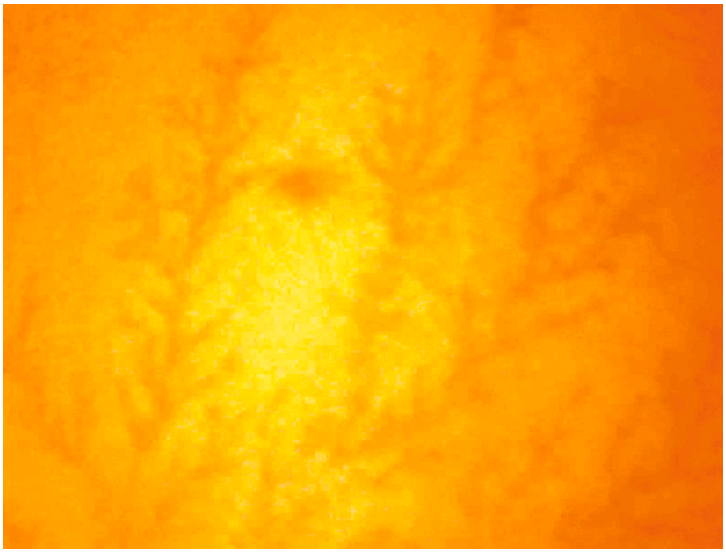

FIGURE 97-9. The "flowers of Lichtenberg" is an evanescent cutaneous phenomenon commonly seen in lightning-struck patients.

Lightning Injury

Cardiopulmonary arrest is common in patients struck by lightning.[16] The "flowers of Lichtenberg" is an evanescent cutaneous phenomenon commonly seen in lightning-struck patients (Fig. 97-9). Coma is also common acutely but typically resolves in a few hours. Keraunoparalysis, which is lightning-induced paralysis, is characterized by usually transient paresthesias and paralysis that develop during several days and typically involve the lower limbs. Ruptured tympanic membranes and hearing loss may also occur. With immediate cardiopulmonary resuscitation, about two thirds of lightning victims survive, and persistent neurologic deficits are relatively uncommon.

Considerations at the Extremes of Age

Injured patients at the extremes of age bring with them a number of important physiologic and psychosocial issues that directly affect their care (E-Table 97-3). Older adults do not have the depth of physiologic reserve of the young (Chapter 24). Cardiopulmonary function may be compromised, and peripheral vascular disease is common. Muscle mass and respiratory muscle strength are often reduced. Reduced renal reserve increases sensitivity to nephrotoxic drugs. The skin is relatively atrophic and consequently tolerates burning and donor harvest poorly. Nutritional needs are not well predicted by standard equations.

As a result, a major injury is often the event that changes the subsequent living condition of an elderly person. Injuries are often the result of cognitive or functional changes (Chapter 361) and may be associated with syncopal episodes (Chapter 49) that need to be concurrently evaluated. Resuscitation should be carefully considered if burns are very large or trauma is severe. Data suggest that mortality is nearly 90% in patients who are older than 60 years, have burns of more than 40% of their body surface, and have concomitant inhalation injury. Patients may have advanced directives, interested families, or health care proxies who should be consulted as early as possible in the care of such patients (Chapter 3).

Older adults bring unique psychosocial issues to the trauma and burn center. They may live alone or have a spouse who cannot meet their discharge care needs for wound care, transportation, or general support. Children may live far away and be unable to support them. Discharge planning can be very involved, requiring orchestration of many community resources, and must be started early.

Emotional Consequences of Injury

Most patients who suffer significant injury will develop some degree of acute stress disorder characterized by anxiety, hypervigilance, fear, and re-experiencing the event.[17] This normal reaction can become pathologic and debilitating as post-traumatic stress disorder (Chapter 362). Early recognition and emotional support can blunt this progression and enhance both short-term rehabilitation and long-term recovery.

98 ENVENOMATION, BITES, AND STINGS

STEVEN A. SEIFERT†, RICHARD C. DART, AND JULIAN WHITE

EPIDEMIOLOGY

Envenomation (e.g., snakebite, spider bite, scorpion stings, jellyfish stings) may seem to be a rare medical problem, but envenomation affects millions of humans annually and results in hundreds of thousands of deaths (Table 98-1). For example, the annual number of venomous snakebites is estimated to be in excess of 2.5 million per year, with more than 100,000 fatalities and hence a case fatality rate of about 1 : 25. Another common envenomation, jellyfish stings, affects more than 1 million people per year, with a case fatality rate of about 1 : 10,000. The epidemiology of envenomations will differ by region. In Australia, for example, spider bites cause nearly twice as many hospital visits as compared with snakebites. In the United States, spider bites reported to poison centers are roughly equal to the number of venomous snakebites (about 5000 to 10,000 per year),[1] whereas reports of scorpion envenomations are nearly double that number.

PATHOBIOLOGY

Envenomation occurs when a venomous animal, usually via a bite or sting, injects a physiologically impactful quantity of venom into a target animal. A venomous animal may bite or sting without injecting enough venom to cause effects (a "dry bite"),[2] so signs of envenomation will not always develop. The rate of dry bites will vary by species and other circumstances. In the United States, for example, viperid bites have about a 20% dry bite rate, whereas elapid bites have about a 50% rate. Some snake species lack the capacity to envenomate because they have no venom apparatus.

Venom is an often complex mixture of a number of substances, including toxins. Venoms can be produced in specialized glands (e.g., venomous snakes, scorpions, spiders, cone snails, venomous stinging fish, stingrays) or cell structures (e.g., jellyfish nematocysts), or they can be acquired from the environment and concentrated in specific glands/organs (e.g., venomous octopuses). The function of venom is to assist the animal as a predator and/or in defense against predation.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most envenomations are accompanied by dermatologic findings, commonly at the site of the bite or sting (Fig. 98-1), starting with the puncture mark(s) of

†Deceased.

E-TABLE 97-3 PSYCHOSOCIAL AND PHYSIOLOGIC CONSIDERATIONS IN GERIATRICS

- Injury mechanisms more often involve compromised mobility or dexterity.
- Injuries may reflect an inability to safely live alone.
- Injuries occur during syncopal episodes.
- Resuscitation should be carefully considered if burns are very large, particularly in the presence of inhalation injury.
- Patients may have advanced directives, interested families, or health care proxies who should be consulted as early as possible in their care.
- Older adults often do not have the physiologic reserve of the young.
- Pulmonary function may be compromised by years of smoking.
- Occult or overt coronary artery or peripheral vascular disease may exist.
- Muscle strength, including respiratory muscles, may be reduced.
- Renal function may be reduced with resulting greater sensitivity to nephrotoxic drugs or hypotensive insults.
- Nutritional needs of the elderly are poorly predicted by standard predictive equations.
- The skin of the elderly person is thin and therefore sustains full-thickness injury more readily and tolerates repeated donor harvest less well.
- Older adults may live alone or have a spouse who cannot reasonably meet post-discharge needs.
- Discharge planning may be very involved and must be started early.

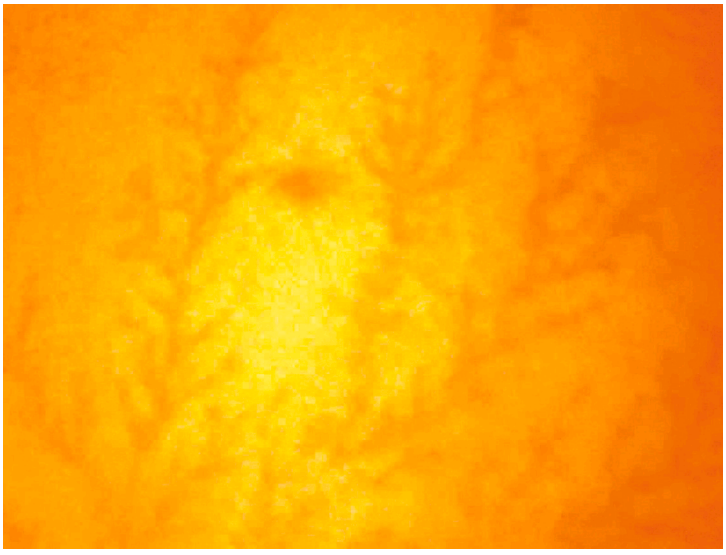

FIGURE 97-9. The "flowers of Lichtenberg" is an evanescent cutaneous phenomenon commonly seen in lightning-struck patients.

Lightning Injury

Cardiopulmonary arrest is common in patients struck by lightning.[16] The "flowers of Lichtenberg" is an evanescent cutaneous phenomenon commonly seen in lightning-struck patients (Fig. 97-9). Coma is also common acutely but typically resolves in a few hours. Keraunoparalysis, which is lightning-induced paralysis, is characterized by usually transient paresthesias and paralysis that develop during several days and typically involve the lower limbs. Ruptured tympanic membranes and hearing loss may also occur. With immediate cardiopulmonary resuscitation, about two thirds of lightning victims survive, and persistent neurologic deficits are relatively uncommon.

Considerations at the Extremes of Age

Injured patients at the extremes of age bring with them a number of important physiologic and psychosocial issues that directly affect their care (E-Table 97-3). Older adults do not have the depth of physiologic reserve of the young (Chapter 24). Cardiopulmonary function may be compromised, and peripheral vascular disease is common. Muscle mass and respiratory muscle strength are often reduced. Reduced renal reserve increases sensitivity to nephrotoxic drugs. The skin is relatively atrophic and consequently tolerates burning and donor harvest poorly. Nutritional needs are not well predicted by standard equations.

As a result, a major injury is often the event that changes the subsequent living condition of an elderly person. Injuries are often the result of cognitive or functional changes (Chapter 361) and may be associated with syncopal episodes (Chapter 49) that need to be concurrently evaluated. Resuscitation should be carefully considered if burns are very large or trauma is severe. Data suggest that mortality is nearly 90% in patients who are older than 60 years, have burns of more than 40% of their body surface, and have concomitant inhalation injury. Patients may have advanced directives, interested families, or health care proxies who should be consulted as early as possible in the care of such patients (Chapter 3).

Older adults bring unique psychosocial issues to the trauma and burn center. They may live alone or have a spouse who cannot meet their discharge care needs for wound care, transportation, or general support. Children may live far away and be unable to support them. Discharge planning can be very involved, requiring orchestration of many community resources, and must be started early.

Emotional Consequences of Injury

Most patients who suffer significant injury will develop some degree of acute stress disorder characterized by anxiety, hypervigilance, fear, and re-experiencing the event.[17] This normal reaction can become pathologic and debilitating as post-traumatic stress disorder (Chapter 362). Early recognition and emotional support can blunt this progression and enhance both short-term rehabilitation and long-term recovery.

98 ENVENOMATION, BITES, AND STINGS

STEVEN A. SEIFERT†, RICHARD C. DART, AND JULIAN WHITE

EPIDEMIOLOGY

Envenomation (e.g., snakebite, spider bite, scorpion stings, jellyfish stings) may seem to be a rare medical problem, but envenomation affects millions of humans annually and results in hundreds of thousands of deaths (Table 98-1). For example, the annual number of venomous snakebites is estimated to be in excess of 2.5 million per year, with more than 100,000 fatalities and hence a case fatality rate of about 1 : 25. Another common envenomation, jellyfish stings, affects more than 1 million people per year, with a case fatality rate of about 1 : 10,000. The epidemiology of envenomations will differ by region. In Australia, for example, spider bites cause nearly twice as many hospital visits as compared with snakebites. In the United States, spider bites reported to poison centers are roughly equal to the number of venomous snakebites (about 5000 to 10,000 per year),[1] whereas reports of scorpion envenomations are nearly double that number.

PATHOBIOLOGY

Envenomation occurs when a venomous animal, usually via a bite or sting, injects a physiologically impactful quantity of venom into a target animal. A venomous animal may bite or sting without injecting enough venom to cause effects (a "dry bite"),[2] so signs of envenomation will not always develop. The rate of dry bites will vary by species and other circumstances. In the United States, for example, viperid bites have about a 20% dry bite rate, whereas elapid bites have about a 50% rate. Some snake species lack the capacity to envenomate because they have no venom apparatus.

Venom is an often complex mixture of a number of substances, including toxins. Venoms can be produced in specialized glands (e.g., venomous snakes, scorpions, spiders, cone snails, venomous stinging fish, stingrays) or cell structures (e.g., jellyfish nematocysts), or they can be acquired from the environment and concentrated in specific glands/organs (e.g., venomous octopuses). The function of venom is to assist the animal as a predator and/or in defense against predation.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most envenomations are accompanied by dermatologic findings, commonly at the site of the bite or sting (Fig. 98-1), starting with the puncture mark(s) of

†Deceased.

ABSTRACT

Envenomation (e.g., snakebite, spider bite, scorpion stings, jellyfish stings) may seem to be a rare medical problem, but envenomation affects millions of humans annually and results in hundreds of thousands of deaths. For example, the annual number of venomous snakebites is estimated to be in excess of 2.5 million per year, with more than 100,000 fatalities (and hence a case fatality rate of about 1 : 25). Another common envenomation, jellyfish stings, affects more than 1 million people per year, with a case fatality rate of about 1 : 10,000. Envenomation by arthropods is also a substantial worldwide problem. Dangerous scorpions, limited to mainly the Buthidae family, are distributed worldwide. Ticks, mites, hymenoptera, and various other insects also produce a wide array of envenomation syndromes. Finally, marine animals not only produce envenomations but also are a major source of foodborne illness.

TABLE 98-1 ESTIMATED ANNUAL GLOBAL IMPACT OF SOME SELECTED MAJOR GROUPS OF VENOMOUS ANIMALS AFFECTING HUMANS

VENOMOUS ANIMAL GROUP	ESTIMATED NUMBER OF NEW CASES PER YEAR	ESTIMATED NUMBER OF FATAL CASES PER YEAR
Venomous snakes	>2.5 million	>100,000
Scorpions	>1 million	<5000
Stinging insects	>1 million	>1000 (mostly due to anaphylactic reaction to venom in sting)
Jellyfish	>1 million	<100
Spiders	>100,000	<100
Venomous spiny fish and stingrays	>100,000	<10
Paralysis ticks	>1000	<10
Venomous mollusks (blue-ringed octopus, cone snails)	<1000	<10

the biting or stinging apparatus. Local tissue injury might result from mechanical effects and/or cytotoxic venom components that produce tissue edema, which may remain local, spread, or progress to necrosis. Snakes, scorpions, spiders, and jellyfish commonly have venoms that can injure tissue.

Systemic effects may include nausea and vomiting, bleeding, thrombosis, renal impairment, neurotoxicity, and even pituitary abnormalities or more specific end-organ effects, such as hematologic derangements, vascular toxicity, nephrotoxicity,[3] or neurotoxicity. For example, some snake, scorpion, and caterpillar venoms can produce thrombosis or uncontrolled bleeding. Snake, tick, blue-ringed octopus, and cone snail venoms are all capable of impairing transmission at the neuromuscular junction and causing paralysis (Table 98-2). Some scorpions, spiders, and jellyfish have venoms that can cause excitatory neurotoxicity, with pain, sweating, autonomic effects, cardiotoxicity, and pulmonary edema.

Key points of the history include time, place, and circumstances of the bite or sting; whether the patient was bitten/stung once or multiple times; a description of the offending animal if witnessed; the type and timing of first aid application; the type and time of onset of any symptoms; relevant past medical history; and any medications used. Some envenomation scenarios (e.g., attempting to capture or kill an offending animal, collections of venomous animals, multiple stings by a colony of marine animals) may include multiple bites or stings and may include multiple envenomating animals. Any symptoms of specific toxic effects (e.g., symptoms of progressive paralysis, neuroexcitation, myolysis, coagulopathy, cardiotoxicity, acute kidney injury, allergy) and systemic effects (e.g., headache, nausea/vomiting, abdominal pain, collapse, convulsions) should be sought. Examination should similarly target specific venom effects, including careful examination of the bite or sting site and a careful neurologic examination (Chapter 366).

Laboratory tests will vary depending on the likely animal and the consequent likely risks (e.g., a coagulation profile for venomous snakes). Clinical venom identity testing is available only for Australian snakebites. Hematologic tests typically should include a complete blood and platelet count, a fibrinogen level, and an international normalized ratio (INR). In some locations, the 20-minute whole-blood clotting test may be useful.

TREATMENT

Envenomation may be an obvious diagnosis or a cryptic presentation in which a bite/sting may not be suspected. Many cases of venomous bites/stings result in only mild effects, but clinical events can progress rapidly and require similarly time-sensitive treatment. The best approach is to assume every case may develop into severe envenomation and to ensure urgent and context-sensitive initial assessment, followed by ongoing reassessment over the major at-risk period. It is often very important to reassess all patients at 10- to 15-minute intervals for 8 to 12 hours to detect any developing symptoms, signs, and laboratory abnormalities.

The first aid provided to an envenomated patient before reaching definitive medical care may significantly impact final outcome. Bites and stings are traumatic wounds and should undergo thorough cleansing, evaluation for retained foreign bodies (e.g., teeth, fangs), and tetanus prophylaxis as for any contaminated wound (Chapter 15). In general, prophylactic antibiotics are not effective at preventing infection, and there is no role for glucocorticoids, antihistamines, or other allergy treatments unless the patient is having an acute allergic reaction. In addition, many commonly used first-aid methods, such as tourniquets, incisions, suction devices, electric shock, and snake stones, are ineffective or dangerous and should not be used. Key worthwhile first aid includes immobilizing the bitten limb and the patient if possible; anticipation of swelling with removal of jewelry and loosening or removal of tight-fitting clothing; support of airway, breathing, and circulation (Chapters 7, 50, 90, 92) as needed; and rapid transport to medical care. Local cryotherapy reduces the local inflammatory response and may reduce the needed dose of antivenom therapy and length of hospitalization.[A1] For snakebites by species that do not cause significant local tissue damage (e.g., Australian snakes, sea snakes, coral snakes, kraits, non-necrotic cobras, and South American rattlesnakes) and for Australian funnel web spider bites, the Australian pressure bandage and immobilization technique (E-Fig. 98-1)—which involves wrapping the entire extremity with a bandage, achieving lymphatic obstructive pressures of 40 to 70 mm Hg in the upper extremity and 55 to 70 mm Hg in the lower extremity, followed by immobilization to retard venom absorption—obstructs lymphatic flow but requires substantial training to apply effectively. Box jellyfish stings should be copiously irrigated with distilled ("white") vinegar (5 to 8% acetic acid), whereas all other jellyfish stings and fish/stingray stings respond to immersion in hot water (up to 45° C).

Some types of envenomation are associated with acute coagulopathy, so potentially problematic cannulations and injections should be avoided until any coagulopathy has been corrected. Hemolysis may result in insufficient oxygen-carrying capacity. The risk of spontaneous hemorrhage increases with platelet counts below 50,000/μL, and uncontrolled hemorrhage or thrombosis may occur with complete or near-complete consumption of fibrinogen. Consumption of clotting factors in the coagulation cascade may also increase the risk of spontaneous hemorrhage with an INR greater than 3.

In many cases of suspected envenomation, an intravenous fluid bolus (e.g., normal saline or a balanced salt solution, 10 to 20 mL/kg in the first hour of treatment) may be helpful, particularly in patients with fluid losses from subcutaneous edema, diarrhea, or decreased intake.

A swollen limb should be elevated with frequent monitoring to exclude severe rhabdomyolysis or an acute compartment syndrome (Chapter 97). Other than for bites by snakes with particularly long fangs, such as Gaboon vipers, tissue compartments bounded by rigid fascia are generally deeper than most venomous animals' fangs can reach. An exception is the anterior tibial compartment, which is relatively close to the surface. Nevertheless, elevated tissue pressures may result from subcutaneous deposition of venom and local fluid accumulation that extends to the elastic limits of the skin. Surgical intervention may be considered for patients with directly measured increases in tissue pressures despite adequate antivenom, elevation, and 20% mannitol (1 to 2 g/kg, IV over 1 to 2 hours), but animal studies have shown superior outcomes with antivenom alone. Similarly, dèbridement of necrotic tissue should generally be delayed until after acute envenomation problems have resolved, and it should be delayed for weeks for recluse spider bites.

In patients with evidence for neurotoxic paralysis, intubation and mechanical ventilation may be required (Chapter 91). Antivenom may reverse postsynaptic paralytic neurotoxicity, but an anticholinesterase (neostigmine, 35 μg/kg IV) may also be useful as adjunctive treatment. Patients who respond convincingly to the initial dose of neostigmine may receive repeated doses (up to 35 μg/kg every 1 to 3 hours, and up to 140 μg/kg per 24 hours), together with atropine as needed to block its muscarinic side effects. However, antivenom may not reverse established respiratory paralysis caused by presynaptic neurotoxins. Acute kidney injury may require dialysis (Chapter 117) for days to weeks, but renal function usually recovers. For important venomous animals without a corresponding effective antivenom, non-antivenom treatments must be used.

Antivenom

Antivenom is made by hyperimmunizing an animal (most commonly a horse, but also sheep, goats, dogs, and rabbits) against the venom, harvesting the antibody, and refining it into the final product.[4] The product may be whole IgG, or its $F(ab')_2$ or Fab fractions, and these products may further undergo purification by various methods to reduce adverse effects.

If the identity of the venomous animal is known, a monovalent genus- and/or species-specific antivenom should be administered. If the identity of the animal is uncertain, a polyvalent antivenom or mixture of antivenoms is preferred. Geographically appropriate, species-specific antivenom should be sought, but a paraspecific antivenom, which was produced for a different genus or species, occasionally may be effective. Antivenoms are typically dosed by the vial, as specified in the products' package inserts, because their neutralizing power varies from product to product. Since the amount of venom to be neutralized is not based on the victim's size, children may require the same or even higher doses of antivenom and may also require that the antivenom be reconstituted in a smaller volume to help manage the fluid load.

Adverse effects of antivenom include type 1 hypersensitivity reactions, with immediate or early onset of pruritus, urticarial rash, wheezing, laryngeal edema, hypotension, and other signs of an anaphylactoid reaction

E-FIGURE 98-1. Pressure bandage with immobilization. (This technique is to delay central progression of venom via lymphatics until definitive therapy (antivenom) can be administered. It was developed for Australian Elapid snakes and other snakes that do not routinely produce significant local tissue injury, including sea snakes, coral snakes, kraits, mambas, and some nonspitting cobras. This technique is considered inappropriate for most viperid envenomations (e.g., U.S. rattlesnakes, copperheads, cottonmouths) in which local tissue injury is a major effect. **Upper image:** A clean broad bandage (crepe or elastic) is bound over the bite site at about the same pressure as for a sprain. For bites to digits, the bandage should be applied proximally to the hand or foot, then over all digits together, rather than binding up the bitten digit alone, because this may potentially cause significant vascular impairment if local swelling develops, thereby increasing the likelihood of tissue injury to the affected digit. **Central image:** An elastic bandage is wrapped from the toes to the groin at about the same pressure as for a sprain. Ideally, obtain a constant under-bandage pressure of 50 to 70 mm Hg, ensuring there is no vascular compromise of the limb. **Bottom image:** The extremity is loosely splinted to ensure immobility. It also is important to keep the patient immobile, as far as practical.)

FIGURE 98-1. Clinical signs of envenomation. A, Snake biting thumb (brown snake, *Pseudonaja affinis*). **B,** Bite and scratch marks on thumb, with minimal local reaction (brown snake, *Pseudonaja textilis*). **C,** Python bite with large number of teeth marks (nonvenomous). **D,** Reaction in the first few hours to a bite from a Russell viper (*Daboia siamensis*). Blue discoloration from early hemorrhagic blister formation. **E,** Local oozing and ecchymosis (puff adder, *Bitis arietans*). **F,** Local swelling of bitten hand (mulga snake, *Pseudechis australis*). **G,** Developing skin damage around bite site (jararaca, *Bothrops jararaca*). **H,** Developing skin necrosis around bite site (Russell viper, *Daboia siamensis*), with blue discoloration from bruising/bleeding into the soft tissues. **I,** Extensive full-thickness necrosis days post-bite (Russell viper, *Daboia siamensis*). **J,** Blood ooze from around IV site indicative of active coagulopathy (inland taipan, *Oxyuranus microlepidotus*). **K,** Extensive bruising in bitten limb indicative of coagulopathy (green pit viper, *Trimeresurus albolabris*). **L,** Massive bruising distant from bite site indicative of severe coagulopathy (Russell viper, *Daboia siamensis*). **M,** Chemosis indicative of developing capillary leak syndrome (Russell viper, *Daboia siamensis*). **N,** Incomplete bilateral ptosis indicative of early developing neurotoxic flaccid paralysis (tiger snake, *Notechis scutatus*). **O,** Incomplete bilateral ptosis plus lateral ophthalmoplegia indicative of progressing neurotoxic flaccid paralysis (death adder, *Acanthophis antarcticus*). **P,** Fixed dilated pupils indicative of progressive neurotoxic flaccid paralysis in snakebite, not intracranial pathology (tiger snake, *Notechis scutatus*). **Q,** Complete snakebite neurotoxic flaccid paralysis requiring intubation and ventilation (taipan, *Oxyuranus scutullatus*). **R,** Myoglobinuria indicative of severe systemic rhabdomyolysis (mulga snake, *Pseudechis australis*). **S,** Widow spider bite with central blanching and surrounding erythema (red back spider, *Latrodectus hasseltii*). **T,** Widespread diaphoresis secondary to widow spider bite (red back spider, *Latrodectus hasseltii*). (All images copyright © Prof. Julian White; reproduced with permission.)

or anaphylaxis (Chapter 233). Skin testing for sensitivity to antivenom, a dangerous and unreliable practice, is no longer recommended in the United States. Non–IgE-mediated reactions, which are nonspecific and related to the rate of infusion, are usually easily managed by slowing or stopping the infusion, treating with H_1 and H_2 receptor antagonists (e.g., diphenhydramine, 25 to 50 mg IV, and ranitidine 25 to 50 mg IV) as needed, and restarting the infusion at a slower rate. IgE-mediated reactions are usually seen in patients who previously have been exposed to antivenom or components from the source animal. IgE-mediated reactions, which are usually more severe, require cessation of the infusion, treatment with H_1 and H_2 receptor antagonists (as noted earlier), and possibly the addition of epinephrine (see Chapter 233).

Type 3 hypersensitivity reactions ("serum sickness"), with rash, fever, myalgia, and arthralgias, may be seen 5 to 21 days following antivenom treatment (Chapter 230). These effects are usually easily managed with H_1 and H_2 receptor antagonists (see earlier for dosing recommendations), analgesia, and temperature control (acetaminophen, 1 g every 6 hours as needed); oral glucocorticoids (e.g., prednisone, 5 to 60 mg per day) are helpful if other treatments do not relieve signs or symptoms.

When the identity of the animal is unknown, particularly for venomous snakes, a characteristic clinical picture may indicate the most likely culprit. This process can be enhanced using diagnostic algorithms, which are available for Australia and parts of Asia (e.g., see http://www.toxinology.com or https://apps.who.int/bloodproducts/snakeantivenoms/database/).

TABLE 98-2 A FUNCTIONAL CLASSIFICATION OF SELECTED MAJOR VENOM EFFECTS IMPACTING HUMANS AND SELECTED ANIMAL GROUPS IN WHICH ACTIVITY MAY BE PRESENT

TOXIN ACTIVITY AND TARGET SITE	CLINICAL EFFECTS	PRINCIPAL CLINICAL MANIFESTATIONS	ANIMAL GROUPS
Paralytic neurotoxicity	Progressive descending or ascending flaccid paralysis (may be presynaptic, postsynaptic, or intrasynaptic [e.g., fasciculins])	Descending type: initial cranial nerve paresis commencing with bilateral ptosis, progressing to limb weakness, loss of upper airway protection, finally respiratory paralysis Ascending type: initial ataxia, progressive paralysis, finally respiratory paralysis	• Some snakes (descending) • Paralysis ticks (ascending) • Blue-ringed octopus (descending) • Some cone snails (descending)
Excitatory neurotoxicity	Rapid development of neuroexcitation	Local pain, sweating, autonomic/catecholamine storm effects, cardiotoxicity, pulmonary edema	• Some scorpions • Some spiders • Some jellyfish
Myotoxicity	Progressive systemic damage of skeletal muscles throughout body OR locally adjacent to bite site	Systemic: muscle pain, weakness, tenderness, grossly elevated blood creatine kinase, myoglobinuria; potential secondary acute kidney injury and hyperkalemic cardiac toxicity Local: local pain, swelling, potential compartment syndrome	• Some snakes
Hemostasis: procoagulant or anticoagulant/antiplatelet	Activation and/or consumption of clotting components, or inhibition of clotting	Varies depending on toxin target: consumption of fibrinogen and/or platelets causing bleeding tendency, *OR* inhibition of hemostasis causing bleeding tendency, *OR* formation of thrombi with embolic infarction	• Some snakes • Iranian scorpion (*Hemiscorpius*) • *Lonomia* caterpillars
Hemorrhagins: blood vessel wall	Direct damage to vessel wall allowing increased vascular permeability	Local swelling, bruising, bleeding Systemic vascular damage, capillary leak syndrome	• Some snakes
Cardiotoxins	Direct or indirect cardiac damage	Acute cardiac collapse or insufficiency	• Some snakes • Some scorpions • Some spiders • Box jellyfish
Nephrotoxins	Direct or indirect renal damage	Acute kidney injury; varies from mild rise in blood creatinine to full anuric renal failure	• Some snakes • Massed bee/wasp stings
Local necrotoxins	Progressive local skin/tissue injury	Skin discoloration, may progress to blister formation *AND/OR* skin necrosis and/or necrosis of underlying tissues	• Some snakes • Iranian scorpion (*Hemiscorpius*) • Recluse spiders • Some jellyfish • Stingrays
Allergy-stimulating toxins	Can induce acute allergic response, usually on subsequent bites/stings	Varies from local immune reaction (swelling, erythema, pruritus) through to full anaphylaxis	• Potentially all venomous animals • Particular problem for bees, wasps, and stinging ants

SPECIFIC ENVENOMATION SYNDROMES

SNAKES

Snakes are the most important global cause of human envenomation.[5] Venom composition varies not only between genera and species but also can vary between individuals of the same species and even within a given individual over time.

CLINICAL MANIFESTATIONS

The rate of dry bites varies among snake species, as do the average fang length, venom volume, venom toxicity, and range of clinical effects seen with envenomation (see www.toxinology.com or https://apps.who.int/bloodproducts/snakeantivenoms/database/ and E-Table 98-1). Some African and Asian cobra species have specially evolved fangs that allow them to spit a tightly direct stream of venom forward up to 2 to 3 m away. They specifically aim for the eyes, where the venom causes instant severe pain, blepharospasm, and temporary blindness, thereby incapacitating the victim and allowing the snake to escape. Venom spit ophthalmia requires prompt, copious irrigation, followed by inspection for corneal injury. Venom spit ophthalmia can result in permanent blindness, but it does not cause systemic envenomation and does not require antivenom.

Neurotoxic Paralysis

Pre- and postsynaptic snake venom neurotoxins target the neuromuscular junction and cause a progressive descending flaccid paralysis. In the United States, neurotoxic snakebite is often associated with coral snake bites (elapids), but some rattlesnake species also cause neurotoxicity. Once damaged by presynaptic neurotoxins, the axon must regrow, a process that can take days to weeks. It is critical that the earliest signs of developing paralysis be detected and antivenom given prior to more extensive damage, which antivenom cannot reverse. In contrast, postsynaptic neurotoxins bind to the acetylcholine receptor on the muscle end plate at the neuromuscular junction, external to the cell, so antivenom may reverse this type of paralysis.

Myotoxicity

Some snake venoms contain myotoxins that target muscle, either systemically (mainly skeletal muscle) or locally in the adjacent bitten limb. The former can cause severe progressive myotoxicity, often peaking more than 24 hours postbite, with muscle pain and rhabdomyolysis, as well as with occasionally massive elevations of serum creatine kinase levels (>100,000 IU/L), and myoglobinuria; acute kidney injury and hyperkalemic cardiotoxicity (see Chapter 99) may ensue. Local myotoxicity contributes to tissue injury in the bitten limb.

Coagulopathy

A consumptive coagulopathy reduces fibrinogen levels and may result in bleeding, but venoms also may inhibit coagulation or interfere with platelet function. Some species also have hemorrhagins that damage blood vessels, thereby allowing extravasation of blood, swelling, and the potential for local necrosis or shock. The Martinique viper and related species of *Bothrops* have procoagulant toxins that cause thrombosis, thereby resulting in embolic infarction (e.g., brain, heart, lungs).

Local Tissue Injury

Many snake venoms cause significant tissue injury at and adjacent to the bite site. The resulting necrosis, fluid shift, and secondary shock can be the most medically important effect of the bite. Secondary infection is mainly from streptococcus and staphylococcus species, but gram-negative organisms, mainly Enterobacteriaceae and enterococci, are common in South Africa. Prophylactic treatment with amoxicillin clavulanate is not effective in preventing secondary infection.

Other Envenomation Effects

Russell viper venom can cause direct nephrotoxicity and acute kidney injury (Chapter 106). The same species may cause hypopituitarism owing to anterior pituitary infarction (Chapter 205) and may also cause severe capillary leak syndrome. A number of other snake species may cause secondary acute

kidney injury (Chapter 106), which is usually reversible, but rarely produces irreversible renal cortical necrosis.

SNAKEBITE TREATMENT IN PARTICULAR REGIONS

NORTH AMERICA

In the United States, an estimated 6000 to 8000 venomous snakebites occur per year. Pit vipers (i.e., Viperidae, subfamily Crotalinae, which includes rattlesnakes of the *Crotalus* and *Sistrurus* genera, and *Agkistrodon* species, which include the copperhead and cottonmouth) comprise the vast majority of bites (E-Fig. 98-2). Coral snakes, the only native elapid (mainly *Micrurus* species), are responsible for fewer than 100 bites per year. Approximately 50 non-native snake envenomations occur per year, primarily in private collections and zoos.

Viperid Bites

Ready availability of species-specific antivenom to viperids native to this region and a highly developed health care system has resulted in fewer than 10 deaths per year. Because the viperid antivenoms (a Fab antivenom, CroFab™ and a F(ab′)$_2$ antivenom, Anavip™) are effective against all North American viperid snake species and because differentiation from coral, nonvenomous, and non-native snakebites is usually clear from description and context, the snake does not need to be identified. In the United States, expert assistance can be obtained through regional poison centers (1-800-222-1222).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Envenomation occurs in approximately 80% of viperid bites, invariably with tissue injury that manifests as proximal progression of edema, ecchymosis, and occasionally tissue loss.[6] Pain is variable but is often severe. Swelling may be difficult to appreciate in certain areas of the body (e.g., the thigh), and patients should be observed for 8 to 12 hours to be certain that no local signs of envenomation are developing. Subcutaneous, circumferential extremity swelling may reach the elastic limits of the skin, thereby resulting in increased tissue pressures. Extravascular fluid loss from extensive edema may compromise circulating blood volume and cause hypotension or shock.

Hematologic effects, including thrombocytopenia, hypofibrinogenemia, or prolongation of INR and partial thromboplastin time (PTT), may occur, singly or in combination, usually beginning within 1 to 2 hours after the bite and peaking several hours later. Bleeding is more likely to occur and be more severe with rattlesnake bites but can also occur with copperhead and cottonmouth envenomations. Other systemic effects, including nausea, vomiting, diaphoresis, hypotension, and muscle fasciculation, may also occur. Muscle fasciculation and weakness may be seen with Mojave (*C. sculpturatus*), Southern Pacific (*C. helleri*), and other species; they rarely progress to respiratory compromise but may cause increased serum levels of creatine kinase. Rattlesnake envenomations are typically more severe than copperhead or cottonmouth envenomations. Elevation, antivenom, and mannitol (20% mannitol, 1 to 2 g/kg intravenously over 1 to 2 hours) reduce local tissue pressures. Fasciotomy is generally neither indicated nor beneficial.

TREATMENT

Jewelry and tight-fitting clothing should be removed, the bitten body part should be loosely splinted, and standard wound care should be applied. Immobilization of the bitten body part at the level of the heart is recommended. Aggressive but appropriately monitored resuscitation with normal saline infusion may be needed, guided by signs of shock (Chapter 92).

Antivenom treatment is usually initiated for any evidence of local envenomation, especially in patients with worsening significant thrombocytopenia (<100,000/μL) or hypofibrinogenemia (<100 mg/dL). When antivenom is indicated, it should be initiated as soon as possible after the bite. Isolated prolongation of the INR usually does not require antivenom, but significant prolongation (>6) may be a marker for profound hypofibrinogenemia.

Two antivenoms are available in the United States. One is ovine Fab, the other an equine Fab2. Both have been approved for use in all types of crotalid snakebites (rattlesnake, copperhead snake, water moccasin), and both begin with an initial infusion to achieve control followed by additional doses as indicated by signs and symptoms.

For the Fab antivenom, a typical initial dose is 4 to 6 vials, over 1 hour, with additional doses of 4 to 6 vials as needed for progressive or worsening symptoms or signs. Following initial control, maintenance doses of 2 vials over 1 hour (infused slowly over the first 10 minutes) are given every 6 hours for three additional doses. Local effects and coagulation factors should be measured after treatment, predischarge, and about 4 to 8 days later (Table 98-3).[A2]

F(ab′)2 antivenom starts with an initial infusion of 10 vials over 1 hour, followed by 10 additional vials to achieve initial control. If further doses are needed based on signs and symptoms, 4 vial boluses are administered. Maintenance doses are not needed for persistent local control. Late hematologic abnormalities are substantially less with F(ab′)2 than with Fab.[A3] Patients should be monitored for local effects and coagulation factors after treatment, predischarge, and about 4 to 8 days later (Table 98-3).[7]

Complete resolution and return of function may require several weeks or months. Copperhead and water moccasin bites usually do not require additional antivenom after initial control is achieved. Rarely, additional antivenom is required for persistent, recurrent, or late-onset coagulopathy.

Type 1 hypersensitivity reactions to antivenom are uncommon, usually mild, and rate related. When they occur, antivenom should be stopped. H_1 (e.g., starting with diphenhydramine, 25 to 50 mg IV every 4 to 6 hours, maximum daily dose 400 mg) and H_2 receptor antagonists (e.g., starting with cimetidine, 300 mg IV every 6 to 8 hours, maximum daily dose 2400 mg), and beta-adrenergic agents (e.g., albuterol by inhalation) should be titrated for reactive airway symptoms. Epinephrine may be given as needed for symptoms and signs of anaphylaxis. If antivenom is still thought to be needed, it can be tried at an infusion rate between one half and one tenth the initial rate, depending on the speed and severity of the initial reaction. A type 3 hypersensitivity reaction ("serum sickness"), usually mild and managed symptomatically with diphenhydramine (25 to 50 mg orally every 6 hours with or without prednisone, 5 to 60 mg orally daily for 5 days), may develop in 5 to 15% of patients treated with antivenom between 5 and 21 days post-treatment. The F(ab′)$_2$ antivenom has similar rates of hypersensitivity reactions.

Infection is uncommon, and prophylactic antibiotics are not indicated to prevent infection. The inflammatory effects of venom (erythema, warmth, lymphangitic erythema) may mimic infection after the first 24 hours, and antibiotics may reasonably be given at that time or if frank necrosis develops. The spectrum of organisms in snakebite, when infection does occur, appears to be similar to that in other contaminated wounds, mainly streptococcus and staphylococcus, but organisms may vary by geographic location.

Coral Snake Bites

Because of their smaller size and short fangs, coral snakes (Elapid snakes) cause an envenomation in only about 50% of bites. Local effects in coral snake envenomation are variable—pain and swelling occur in less than 50% of cases, so their absence cannot exclude envenomation.

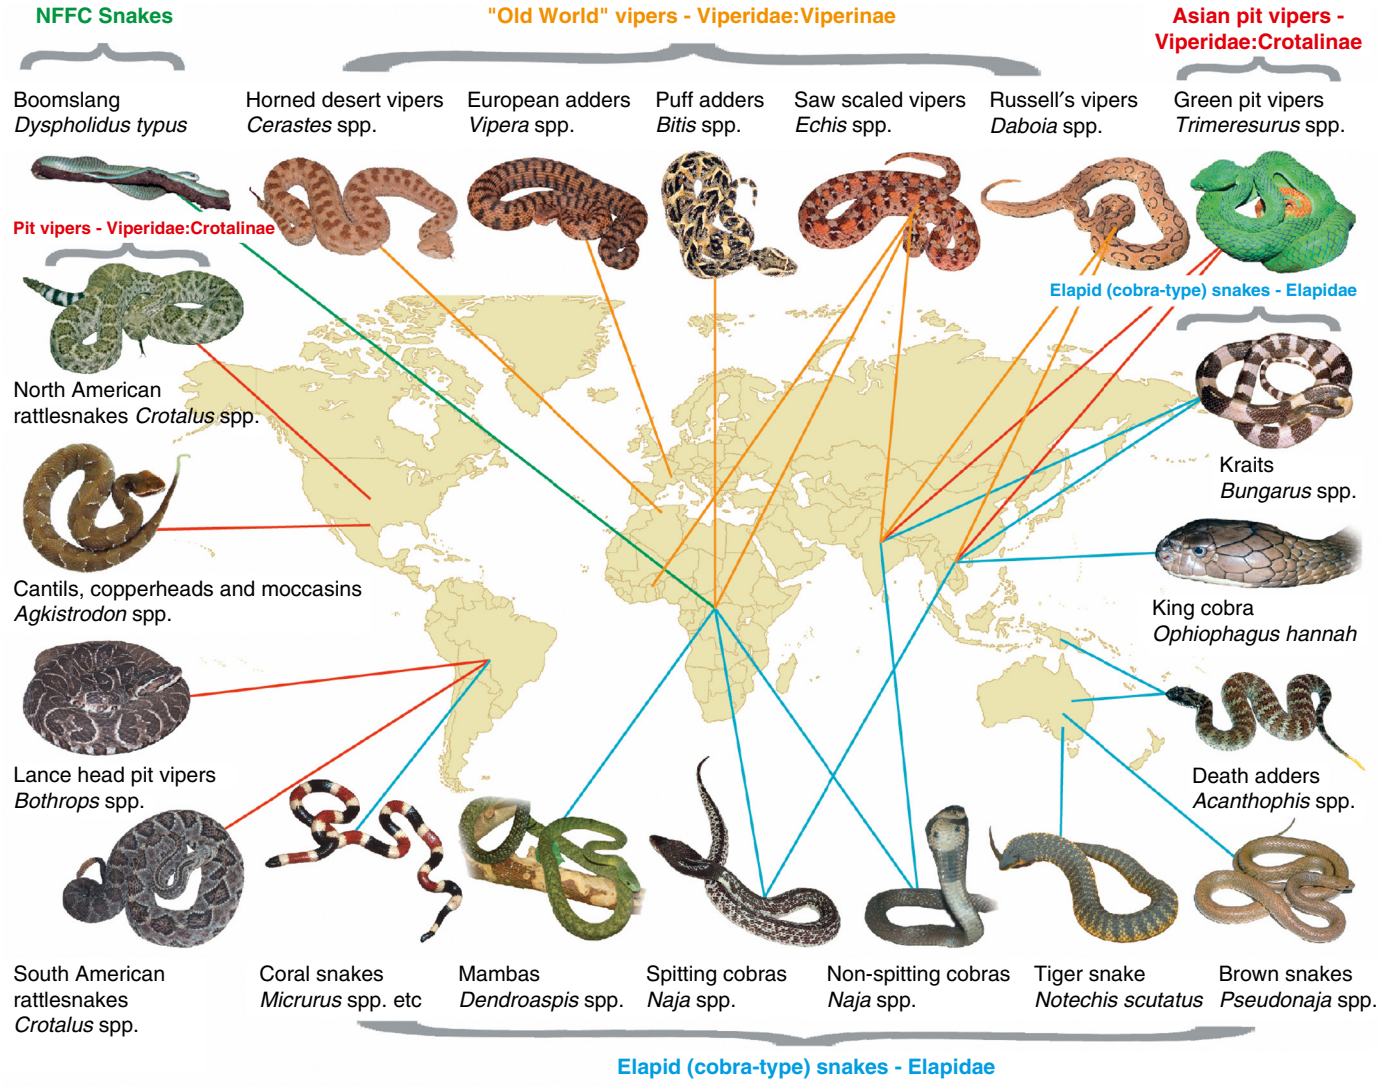
Approximately 40% of patients will have local tissue edema, but necrosis is unusual. Systemic effects may include euphoria, perioral paresthesia, hypersalivation, nausea, and vomiting. Neurologic effects include progressive, descending paralysis, beginning with bulbar muscles (ptosis, diplopia, dysphagia). Respiratory muscles may be involved and cause ventilatory insufficiency and death. Symptoms may be delayed in onset but progress rapidly once bulbar muscle symptoms have begun. No routine laboratory monitoring is needed. An effective antivenom is available for North American coral snake envenomation at https://www.pfizer.com/products/product-detail/north_american_coral_snake_antivenin. Hematologic effects do not occur.

TREATMENT

A pressure-immobilization bandage or blood pressure cuff inflated to impede lymphatic flow (upper extremity: 50 mm Hg; lower extremity: 70 mm Hg) may be considered if the transport time will be long or there will be a considerable delay in administering antivenom. The pressure-immobilization technique is not recommended for North American crotaline snakebites, but it may be useful for North American coral snake bites. Antivenom can be administered in cases with likely envenomation (e.g., evidence of fang penetration and prolonged contact time) before neurologic effects are seen. Alternatively, treatment can be withheld unless and until neurologic signs appear if patients are observed very closely for 24 hours.

MEXICO, CENTRAL AND SOUTH AMERICA

Snake envenomation causes more morbidity and mortality in Mexico, Central America, and South America than in North America. The viperids of major importance include species of the *Bothrops, Crotalus*, and *Lachesis* genera (see E-Table 98-1). *Bothrops* spp, which are the predominant cause of medically significant snakebite throughout most of South and Central America, can cause local tissue swelling, blistering, necrosis, fluid shifts, and systemic effects such as coagulopathy. A number of larger *Micrurus* (coral snake) species can produce neurotoxicity, which manifests as a descending paralysis that can result in respiratory compromise and arrest. Coral snake envenomations are



E-FIGURE 98-2. Global representation of venomous snakes. Only a few selected species of medical significance are illustrated. spp = species. (Diagram and all images copyright © Prof. Julian White; reproduced with permission.)

TABLE 98-3 LABORATORY INVESTIGATIONS FOR NORTH AMERICAN CROTALINAE BITES

Baseline tests:
- Platelet count, fibrinogen level, INR, PTT
- CK, if signs of muscle injury, fasciculation, or elevated tissue pressures

Follow-up tests:
- Platelet count, fibrinogen level, INR after the initial dose of antivenom
- Add D-dimer × 1
- Platelet count, fibrinogen level, and INR after each antivenom dose given for hematologic indications
- Predischarge fibrinogen level, INR
- Platelet count, fibrinogen level, INR at 4 and 8 days after envenomation
- Repeat as needed if values severely abnormal or worsening trend

CK = creatine kinase; INR = international normalized ratio; PTT = partial thromboplastin time.

assessed and managed similarly to North American coral snake envenomations. Appropriate antivenoms are available for most species at http://apps.who.int/bloodproducts/snakeantivenoms/database/snakeframeset.html.

Other viperid pit-viper genera (including *Agkistrodon, Atropoides, Bothriechis, Cerrophidion, Ophryacus,* and *Porthidium*), particularly in Central America, can cause significant envenomation similar to *Bothrops* spp. Compared with North American rattlesnakes, South American rattlesnakes (*Crotalus* spp) typically cause less swelling, blistering, and necrosis but more systemic envenomation, particularly neurotoxicity (descending paralysis), systemic rhabdomyolysis with secondary renal damage, and procoagulant coagulopathy.

EUROPE

The medically important European snakes are the native vipers, mostly in Southern Europe and the Balkans, but also in parts of Scandinavia and in the United Kingdom. Several major species can cause severe, even lethal, envenomation, especially in children.

Local swelling can be extensive with fluid shifts and secondary shock, particularly in children. Coagulopathy may develop with bleeding and extensive bruising. Cardiac problems and even acute kidney injury have been reported. The venom of some populations of vipers, particularly *Vipera ammodytes* and *V. aspis*, contains neurotoxins that can cause paralytic effects, primarily to the cranial nerves such as ptosis.

Significant adder/viper bites in Europe warrant antivenom.[8] The dose depends on the type of antivenom, the type of snake, and the degree of severity of envenomation. Acute and ongoing fluid management is important. Poison centers are available in several countries and should be utilized where available.

ASIA

Asia is home to many venomous vipers (including pit vipers) and elapids, with sea snakes in coastal marine waters (see E-Table 98-1). Snakebite and its consequences are more common in Asia than anywhere else in the world, with snakebites predominantly an occupational disease of rural workers. Contributing explanations include the diversity of snake fauna, the size of the human population, and the extent of rural exposure without access to good health care. In India alone, at least 45,000 people die annually following snakebites. In adjacent river delta regions of Bangladesh, snakebites are the second most common cause of death during flooding events—less than drowning but more than all infectious and other diseases. In Myanmar, snakebite accounts for more than 70% of all cases of acute kidney injury. In Sri Lanka, up to 40,000 snakebites are recorded per year.

A variety of different snake envenomation syndromes can help guide diagnosis, which relies on a targeted history and physical examination, as well as simple tests for coagulopathy (20-minute whole-blood clotting test), and kidney damage (dipstick urine test, hourly urine output measurement; E-Table 98-2).

Antivenom is the mainstay of treatment (www.toxinology.com, or https://apps.who.int/bloodproducts/snakeantivenoms/database/), but the availability and quality of the antivenom are often an issue. Because some regional antivenoms have high rates of adverse reactions, including anaphylaxis, premedication with subcutaneous epinephrine (for adults, 0.25 mL of a 1 : 1000 solution, subcutaneously) is recommended to reduce overall risk. Corticosteroids, even intravenously, are not helpful, nor is the administration of fresh frozen plasma for coagulopathy in Russell viper envenomation.[A4] The mortality after snakebites is related to delayed access to treatment and suboptimal care.[9]

AFRICA

Africa is an important global region for snakebite,[10] but epidemiologic statistics are not widely available. Examples of known risks include saw scaled viper bites in West Africa as well as puff adder bites and cobra bites throughout much of sub-Saharan Africa. In the more arid areas of North Africa, scorpion stings may surpass snakebites as the leading cause of envenomation.

Key African snake species include viperids (e.g., puff adders and relatives, saw scaled vipers, night adders, bush vipers, desert horned adders, Persian horned vipers, vipers; there are no pit vipers endemic to Africa) and elapids (e.g., cobras, some of which are spitters; coral snakes; mambas; rhinkals; desert cobras). Unique to Africa and the Middle East are the side fanged burrowing asps. A few non–front-fanged-colubrid African snakes can cause fatal envenomation (e.g., boomslang, vine snakes). Rarely the pelagic sea snake (*Pelamis platurus*) reaches East African coastal waters.

The clinical effects vary with the genus and species (see E-Table 98-1). Puff adders and their close relatives may cause local bleeding but rarely a detectable coagulopathy.

TREATMENT

Treatment principles are similar to other regions, but antivenom is unavailable or unaffordable in most of sub-Saharan Africa. When available, antivenom is useful for saw scaled viper bites, but antivenoms may not be effective for coagulopathy caused by some other *Echis* and *Cerastes* spp. In that setting, clotting replacement factor may be helpful. For the rare cases of severe coagulopathy caused by boomslang and vine snake bites, particularly for vine snake bites for which there is no antivenom, blood products and clotting factor concentrates may be useful.

Spitting cobra venom spat into the eye can cause permanent blindness if inadequately treated. Urgent copious irrigation of the affected eye(s) with water, saline, Ringer solution, buffered commercial eye wash, or other bland fluid is required, with analgesia/anesthesia as needed, followed by assessment for corneal injury and appropriate treatment. Antivenom should not be instilled into the eye. Systemic envenomation is not expected after venom spit into the eye.

AUSTRALIA AND NEW GUINEA

EPIDEMIOLOGY

All venomous snakes of medical significance in Australia and New Guinea are elapids, which account for more than about 1000 annual venomous snakebites in Australia and 3300 in Papua New Guinea.[11] In Australia, up to several hundred patients will require antivenom, and two to four patients typically die each year, primarily from prehospital cardiac collapse. In Papua New Guinea, as many as 900 fatalities occur each year, most outside of the hospital system.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Each individual snake may have a distinct venom. Significant local effects are uncommon for most species, except for genus *Pseudechis*, whose bites may cause local swelling and pain, without necrosis.

The combination of systemic and local effects can be interpreted using diagnostic algorithms to help determine the type of snake and, therefore, which type of antivenom to use. (See http://www.toxinology.com or https://apps.who.int/bloodproducts/snakeantivenoms/database/.)

The venom detection kit can help determine which type of antivenom to use in a systemically envenomed patient. Laboratory tests should include coagulation studies (INR, PTT, fibrinogen, D-dimer, platelet count, whole-blood clotting time), electrolytes, serum creatinine and blood urea nitrogen levels, and creatinine kinase levels repeated serially in asymptomatic cases for at least 12 hours after the snakebite or after any symptoms or laboratory abnormalities have appeared.

TREATMENT

Antivenom for developing or established systemic envenomation is the mainstay of treatment for Australian and New Guinea snakebites. Monovalent antivenoms are preferred if the type of snake can be determined. Otherwise, a polyvalent antivenom covering all land snake species is available. Sea snakes require sea snake–specific antivenom, but if this is unavailable, tiger snake antivenom may provide some benefit. Antivenom is typically given as one vial diluted and infused intravenously over 20 to 30 minutes.

Although antivenom may neutralize circulating toxins, it cannot replenish consumed clotting factors, which should be replaced only in patients who have potentially life-threatening bleeding despite antivenom. For patients who develop microangiopathic hemolytic anemia (Chapter 146) with intravascular hemolysis, thrombocytopenia, and acute kidney injury, platelet infusions and dialysis may be required. Plasmapheresis is not of proven benefit.

E-TABLE 98-2 WORLD HEALTH ORGANIZATION SYNDROMES FOR SOUTHEAST ASIAN SNAKEBITE

SYNDROME	PRIMARY EFFECT	ADDITIONAL EFFECTS	ADDITIONAL EFFECTS	ADDITIONAL EFFECTS	ADDITIONAL EFFECTS	LIKELY SNAKE
1	Local effects	Coagulopathy/bleeding				Viper bite
2	*Local effects*	*Coagulopathy/bleeding*	*Shock or AKI*			Russell viper
2A	Local effects	Coagulopathy/bleeding	Shock or AKI	Conjunctival edema (chemosis)	Acute pituitary insufficiency)	Russell viper (Myanmar and South India)
2B	Local effects	Coagulopathy/bleeding	Shock or AKI	Minor neurotoxicity (ptosis, external ophthalmoplegia, facial paralysis)	Dark urine (myoglobinuria)	Russell viper (Sri Lanka and South India)
3	Local effects	Neurotoxic paralysis				Cobra or king cobra
4	*Neurotoxic paralysis*	*Minimal or no local effects*				
4A	Neurotoxic paralysis	Minimal or no local effects	Bitten on land, while sleeping on the ground	With or without abdominal pain		Krait
4B	Neurotoxic paralysis	Minimal or no local effect	Bitten in the sea, estuary			Sea snake
4C	Neurotoxic paralysis	Minimal or no local effects	Bitten in Indonesia, Maluku or West Papua	Coagulopathy/ bleeding		Australian elapid
5	Paralysis	Dark urine and AKI				
5A	Paralysis	Dark urine and AKI	Bitten on land	Coagulopathy/ bleeding		Russell viper (Sri Lanka and South India)
5B	Paralysis	Dark urine and AKI	Bitten on land while sleeping indoors			Krait *B. niger, B. candidus, B. multicinctus* (Bangladesh, Thailand)
5C	Paralysis	Dark urine and AKI	Bitten in the sea, estuary	No coagulopathy/ bleeding		Sea snake

AKI = acute kidney injury.

SNAKE HANDLERS AND EXOTIC SNAKEBITE

Any person regularly exposed to venomous snakes, even without being bitten, is at risk of developing allergies to snakes or their venom, a situation accelerated by a history of past bites. Thus, snake keepers and handlers may present with major, even life-threatening anaphylactic reactions that may eclipse the effects of the envenomation itself. Similarly, some may develop allergies to antivenom. Exotic snakebites or snakebites from non-native species[12] should always result in early consultation with experts in this area (e.g., www.toxinology.com), preferably a clinical toxinologist at a regional poison center.

ARTHROPODS

SPIDERS

Data from Australia indicate that spider bites result in nearly twice as many hospital visits as do snakebites, but very few spider species harm humans (E-Fig. 98-3), and fatalities are extremely rare.

Widow spiders, principally of genus *Latrodectus*, are globally distributed and likely cause more significant bites than any other spider group. The venom contains α-latrotoxin, a potent neuroexcitatory toxin. Envenomation results in a classic syndrome, termed latrodectism, characterized by localized pain and sweating, followed in more severe cases by regional and sometimes systemic involvement, with generalized pain, sweating, hypertension, and malaise that can persist for days or longer. Fatalities occur rarely. Treatment of latrodectism is controversial. Specific antivenom was efficacious in one U.S. study but not in an Australian study. Only a minority of patients develop major latrodectism, but pain control may be difficult. An appropriate approach is to use analgesia first and to reserve antivenom for severe symptoms that do not respond adequately to conservative treatment within 2 hours.

Recluse spiders, genus *Loxosceles*, have venomous toxins that cause both local tissue damage and necrosis (necrotic arachnidism), as well as potentially lethal systemic envenoming, with intravascular hemolysis, coagulopathy, and multiorgan failure. The bite is often painless, but local necrosis slowly develops and may become extensive. However, necrotic arachnidism is often overdiagnosed in regions where the spider is not indigenous.[13] Treatment is supportive, with surgical intervention avoided if possible because early dèbridement can spread venomous effects and necrosis. A specific antivenom is available in Brazil, but evidence for its effectiveness is equivocal.

Funnel web and *mouse spiders*, which are limited to Australia, have venom that contains potent neuroexcitatory toxins and can kill humans, but most of their bites are minor. Bites are generally painful and the spider often hangs on. The patient may develop systemic envenomation rapidly (minutes), similar to a catecholamine storm, with death occurring within 60 minutes in some cases. A specific antivenom is very effective, and no known fatalities have been reported since its availability.

Armed or banana spiders, genus *Phoneutria*, are native to South America, especially Brazil, but are occasionally transported accidentally to other regions. They are large (body length of 17 to 48 mm and a leg span of 13 to 18 cm), wandering spiders whose venom contains neuroexcitatory toxins, with effects somewhat similar to latrodectism, though less severe. Pain and autonomic stimulation dominate the clinical picture, with priapism a common finding in boys. A specific antivenom is available in Brazil, where bites by this genus are one of the most common forms of spider bite. Antivenom should be reserved for the most severe cases, with other cases treated with analgesia and, where appropriate, local anesthetic agents.

The goliath tarantula, with a body length of up to 13 cm and a weight of up to 175 g, is found in upland rain forests of northern South America. It can bite humans but, if envenomation occurs, produces only mild effects similar to a wasp sting. Its urticating hairs also may produce intense mucosal irritation.

Other spider species, mostly larger spiders, can occasionally bite humans and cause variable effects such as local pain of limited duration. Treatment is supportive and symptomatic, with no antivenoms available.

SCORPIONS

Scorpions cause more worldwide cases of significant envenomation of humans than any other venomous animal group, except snakes.[14] In Mexico alone, for example, more than 300,000 scorpion stings are treated annually. *Buthid scorpion* venom is rich in peptide neuroexcitatory toxins, particularly ion channel toxins, some of which produce substantial pain. Immediate severe local pain can be followed quickly by autonomic stimulation, including sweating, tachycardia or bradycardia, hypertension, and, for some species, cardiac toxicity and pulmonary edema. A sting can be lethal in children but rarely in adults. North American bark scorpions can cause unusual features such as dystonic eye movements, athetoid limb movements, and reduced consciousness.

A few species can cause lethal effects, particularly in children, but the advent of effective antivenoms, preferably administered intravenously,[A5] has greatly reduced fatality rates. Oral prazosin (30 μg/kg/dose at 3-hour intervals until resolution of the clinical syndrome) is useful as an adjunct therapy in *Hottentotta tamulus* envenomations.[A6] Dobutamine may be helpful when scorpion envenomation leads to pulmonary edema and shock.[15]

Hemiscorpius lepturus is a scorpion found particularly in Iran, where it is responsible for severe and fatal cases. Unlike Buthid scorpions, this species has a cytotoxic venom, similar in clinical effects to *Loxosceles* spider venom. Stings cause minimal local pain, but an initially painless local necrosis develops over subsequent hours to several days, can be extensive, and may be associated with a systemic illness with potentially lethal intravascular hemolysis, coagulopathy, and multiorgan failure. An antivenom is available in Iran.

TICKS

Ticks are parasitic arachnid arthropods that feed on other animals, often with a complex life history involving multiple potential host species. A few tick species produce venom that contains paralytic neurotoxins, but the major medical significance of ticks and mites is as a vector for disease transmission (Chapter 297, 298, 303, and 324) or as a direct cause of disease.

Paralysis ticks, both hard-bodied Ixodid species and soft-bodied Argasid ticks, produce venomous saliva that can cause progressive ascending and potentially fatal flaccid paralysis. The most toxic ticks, genus *Ixodes* from Australia, have caused more fatalities than either funnel web spiders or widow spiders in that country. However, most paralysis ticks cause local irritation, sometimes a local allergic reaction, without detectable neurotoxicity. When neurotoxicity occurs, it usually starts as an ataxic gait and may progress to more generalized paralysis, including ventilatory muscle paralysis. Sometimes the paralysis can be localized, such as a Bell palsy (Chapter 388), after a tick attaches behind the ear near the seventh cranial nerve.

Treatment consists of removing all attached ticks, searching carefully in the scalp, behind and in ears, and in body folds. No antivenom is available. Patients with signs of neurotoxicity should be observed closely for 24 hours (in Australia for at least 48 hours) and provided supportive care, including mechanical ventilation if indicated.

MITES

SCABIES

Human scabies is caused by *Sarcoptes scabiei* variant *hominis*. This mite is an obligate human pathogen. Scabies, which has a worldwide prevalence that ranges from about 0.2% to 71.4%, is most common in Latin America and the Pacific regions, but all regions of the world, except Europe and the Middle East, have populations with prevalences over 10%.[16] In all parts of the world, the infection is seen much more often in children and adolescents than in adults.

PATHOBIOLOGY

After mating on the skin surface, the female mite burrows and lays eggs that hatch over 3 to 4 days. The larvae molt into adults 30 to 60 days later. Mites of all stages can penetrate the skin, and they may reach staggering proportions in immunosuppressed individuals.

CLINICAL MANIFESTATIONS

In immunocompetent adults, the infection causes severe pruritus on both affected and unaffected skin, with a symmetrical erythematous, papulovesicular eruption, especially in the interdigital web spaces, wrists, anterior axillary folds, periumbilical area, the areolae in females, and the penis and scrotum in males. In nodular scabies, patients have intensely pruritic red-brown nodules that range from 2 to 20 mm in the axillary region, groin, buttocks, and genitalia; these nodules represent hypersensitivity to mite products and do not contain mites. The mite burrow—a short serpiginous gray to white keratotic line that is 1 to 4 mm in length—is most common on the hands and feet. Crusted scabies manifests in immunosuppressed individuals as silver to white crusts on any part of the body but especially the hands and ears. Elderly patients may have subtle manifestations with mild pruritus and papules on the trunk and extremities.

DIAGNOSIS

The diagnosis is established by directly identifying mites, mite pellets, or eggs on microscopy (Fig. 98-2). The diagnosis also can be established by videodermoscopy or by using polymerase chain reaction (PCR) and enzyme-linked immunosorbent assay (ELISA) for mite products or specific immunoglobulin E (IgE).

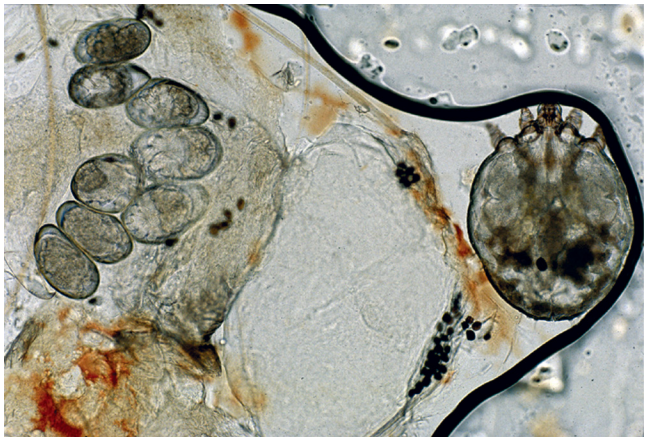

FIGURE 98-2. Scabies preparation demonstrating an adult mite, ova, and feces. (Courtesy of Dirk M. Elston, MD.)

TREATMENT AND PREVENTION

Topical options include permethrin 5% and precipitated sulfur 2 to 10% in petrolatum, benzyl benzoate 10 to 25%, monosulfiram 5 to 25%, malathion 0.5%, and esdepallethrin 0.63%. Topical crotamiton 10% is a weak antiscabic agent but an effective antipruritic; it also has antibacterial activity. Oral ivermectin (200 to 400 μg/kg given as a single dose, then repeated in 10 days) is an effective alternative to topical therapy, and mass administration of ivermectin can control scabies in endemic areas,[A7] with benefits persisting for at least 3 years.[17] Clothes and bed linens should be machine-washed at 60° C or higher followed by heated drying.

OTHER MITES

Mites are ubiquitous and frequently cause a dermatitis that can be a papular, vesicular, urticarial, or morbilliform eruption. Chigger mites, which commonly involve the lower legs, the edges of underwear, and the genitalia, can cause summer penile syndrome with tender to itchy papules of the glans and scrotum resembling a scabies infection. In Asia and South America, chigger mites are vectors for scrub typhus (Chapter 302). In urban areas, house mouse mites can transmit rickettsial pox (Chapter 302). In endemic areas, an eschar in an acutely febrile patient strongly suggests a mite-borne rickettsial infection. Most mite-induced rashes can be treated symptomatically either with topical corticosteroids or with camphor and menthol lotion.

CENTIPEDES

Centipedes are multilegged arthropods that possess pincers with fangs and associated venom glands at their head end. Human bites by some species, especially larger centipedes, can result in a locally painful reaction and sometimes broken skin, which can uncommonly lead to secondary infection. The pain is short-lived, systemic envenomation is unusual, and symptomatic treatment is rarely required, unless a secondary infection develops.

MILLIPEDES

Millipedes are multilegged arthropods that possess venom glands in their body segments. Human skin contact may result in exudation of toxins, thereby resulting in either a local irritant ache, a residual odor, or skin staining. The latter can mimic skin necrosis or bruising. No treatment is available or generally required.

LICE

Lice, which are obligate ectoparasites, cause three syndromes: *Pediculus humanus capitis* (the head louse), *Pediculus humanus* (the body louse), and *Pthirus pubis* (the crab louse).

HEAD LICE

Head lice affect 6 to 12 million people annually in the United States. Worldwide, the prevalence is much higher, especially in children ages 3 to 12 years. Transmission is via direct contact or close contact with scarves and hats.

Head lice should be suspected in a child who has pruritus of the scalp accompanied by cervical adenopathy. Nits can be seen on visual inspection, especially behind the ears. On the scalp, small bites and crusting blood are commonly seen. Definitive diagnosis requires that at least one live louse be found on the scalp.

TREATMENT

Ulesfia lotion contains benzyl alcohol to kill the louse by stunning and occluding its respiratory spiracle. Ivermectin (0.5% lotion in one 10-minute application at home) is 95% effective at 1 day, 85% effective at 7 days, and 74% effective at 14 days after treatment. For refractory infestations in children, oral ivermectin (400 μg/kg, twice at a 7-day interval) is superior to topical malathion 0.5% lotion. In epidemic settings, dimethicone is efficacious,[A8] but two applications of a shampoo-based neem extract is more ovicidal than typical dimethicone.[A9]

BODY LICE

Infestation with body lice is common among homeless people as well as in refugee situations and wars. The louse can serve as a vector for *Bartonella quintana* (which causes trench fever and endocarditis; Chapter 291), *Rickettsia prowazekii* (which causes epidemic typhus; Chapter 302), and *Borrelia recurrentis* (which causes louse-borne relapsing fever; Chapter 297).

Body lice produce a widespread rash that can be confused with allergic contact dermatitis, atopic dermatitis, a viral exanthema, or scabies. The diagnosis is made on physical examination by identifying bluish-hued maculae ceruleae (Fig. 98-3). This finding should then prompt a detailed search for body lice or nits, especially in the seams of clothing.

Lice are killed by washing and hot drying or ironing of the patient's clothing. Permethrin also can be applied to clothing but may not be necessary.

CRAB LICE

Crab louse infestation is a sexually transmitted disease, often concurrently with chlamydial (Chapter 294) or gonorrheal (Chapter 275) infection. Patients present with intense itching. Lice and nits may be found on pubic hairs and chest, abdominal, leg, and head hair. Infestation of the eyelashes can cause phthiriasis palpebrarum infection.

Treatment includes topical agents as used to treat head lice. Oral ivermectin (200 to 400 μg/kg, repeated in 10 days) is an alternative.

HEMIPTERA: BEDBUGS

Bedbugs are increasingly recognized in homes, hotels, and college campuses, and bedbugs can be introduced into buildings by birds, bats, and luggage. They hide in cracks and crevices of beds, particularly along the seams of mattresses. A bedbug is red-brown and about the size of a small tick (Fig. 98-4). Their bites, which characteristically are on the face, neck, and arms, typically present as a string of bites (Fig. 98-5). Symptomatic treatment is with topical corticosteroids (see Table 407-10), but disinfestation requires that all bedding be washed and dried in a hot setting and that the mattress and box spring be placed in a zippered plastic case.[18]

INSECTS

Insects have the largest diversity of species of any animal group, but few are venomous or medically significant. Myiasis, an ectoparasitic infestation by the dipterous larvae of flies, is commonly acquired during travel to areas of animal farming. The larvae must be surgically removed.

VENOMOUS INSECTS

Only two orders of venomous species are of major medical importance: Hymenoptera (ants, including fire ants, bees, wasps) and Lepidoptera (moths and butterflies).

Hymenoptera have a modified ovipositor apparatus that functions as a sting to inject venom produced in an intra-abdominal venom gland. Hymenopteran venom contains highly allergenic peptides, and acute allergy, particularly anaphylaxis (Chapter 233), is the major risk. Fatal anaphylaxis to bee, wasp, or ant stings causes as many or more deaths as true envenomation in most developed countries. Hymenoptera typically cause local effects such as pain, erythema, swelling, blistering, and even minor ulceration. However, massed attacks involving 500 or more stings can cause major envenomation, often characterized by hemolysis, acute renal failure, cardiac complications, and other organ failure. Treatment of systemic hymenopteran envenomation is supportive and symptomatic, commencing with urgent and rapid removal of any remaining embedded stings (honeybee mass attacks only). If an individual has a history of a significant prior type 1 hypersensitivity reaction (e.g., hypotension, airway edema), epinephrine should be carried to environments where exposure may occur. No antivenom is currently available. Any symptoms of anaphylaxis require urgent treatment (Chapter 233).

Lepidoptera larvae (caterpillars) pose a risk to humans because their hairs or spines can cause intense local skin irritation. Hairs may be removed by

FIGURE 98-3. Maculae ceruleae are bluish-red spots that represent sites where body lice have fed. (Courtesy of Dirk M. Elston, MD.)

FIGURE 98-4. Bedbugs are red-brown and about the size of small ticks (~3 mm). (Courtesy of Dirk M. Elston, MD.)

application of duct or masking tape to the exposed area. For pain after envenomation by megalopygidae (moth larvae), local anesthesia alone or combined with oral analgesics is better than analgesics alone.[19] The venom of *Lonomia* caterpillar, found in the greater Amazon basin, includes a potent procoagulant that induces a consumptive coagulopathy and can result in severe and fatal bleeding. A specific anti-*Lonomia* antivenom is available in Brazil.

MARINE ANIMALS

Minor venomous interactions with marine animals probably occur frequently, but major envenomation is far less common, and fatalities are rare.[20] Some marine envenomation-related infections may involve organisms not otherwise commonly encountered, including *Vibrio* spp, *Aeromonas* spp, *Mycobacterium marinum*, *Streptococcus iniae*, and other organisms.

Jellyfish cause envenomation using a stinging organelle (nematocyst) located on its tentacles or main body. When the trigger hair makes contact with a biologic membrane, it fires the stinging tubule, which everts and injects venom into the victim within a fraction of a second.

Fortunately, most jellyfish venom causes local pain, erythema, and mild blistering without systemic effects. However, jellyfish venom can be allergenic in some people, thereby resulting in allergic reactions when stung on a subsequent occasion.

The box jellyfish (*Chironex fleckeri* and *Malo kingi*), so named for their cube-shaped medusae, produce potent venom. Stings are generally very painful and

FIGURE 98-5. Bedbug bites are often arranged in a characteristic "breakfast, lunch, and dinner" pattern. (Courtesy of Dirk M. Elston, MD.)

may be fatal by causing cardiac arrest within 5 minutes of envenomation. Other jellyfish can also produce severe envenomation. A large jellyfish like an Australian or Pacific species may have millions of nematocysts, each able to inject venom in microseconds, with some entering capillaries and causing rapid systemic envenomation. However, most stings have smaller areas of skin contact with insufficient venom injected to cause life-threatening effects. Even small jellyfish such as the Australian irukandji can deliver a potentially lethal dose of venom.

TREATMENT

Treatment of most jellyfish stings is supportive and symptomatic, but application of hot water (no more than 45° C), preferably as a hot shower, will often provide rapid and lasting relief. The bluebottle or Portuguese-man-o-war jellyfish occurs globally. It causes local pain and welt formation and is occasionally associated with allergic reactions. Treatment is supportive and symptomatic (e.g., a hot water shower). No antivenom is available.

For box jellyfish stings, prolonged cardiopulmonary resuscitation (Chapter 50) should be provided for cardiac collapse because cardiotoxicity is likely to resolve within 60 minutes. An antivenom is available, but its effectiveness in severe cases is unclear. For less severe cases, supportive and symptomatic care is indicated. Any local tentacle track necrosis should be treated like a burn injury.

Irukandji syndrome, which is caused by a near-painless sting, is characterized by the onset of severe cramping muscle pains, notably in the back, about 15 to 60 minutes after the sting. Sweating, hypertension, and even cardiac compromise with elevated troponin levels and pulmonary edema may develop. Death is rare. No antivenom is available.

VENOMOUS STINGING FISH AND STINGRAYS

SPINY VENOMOUS FISH

Many fish species have evolved venomous spines that, upon skin puncture, release venom, which causes immediate intense local pain. Systemic effects are unusual. Treatment involves removing any residual spines from the wound. Hot water immersion (not more than 45° C) may provide adequate analgesia, but oral pain medications, including opioids (e.g., oxycodone, 5 to 15 mg orally every 4 to 6 hours) or even nerve block, may be necessary. An effective specific antivenom is available for the Australian stonefish.

VENOMOUS STINGRAYS

The sting of a venomous stingray causes intense local pain but not systemic envenomation. Treatment includes hot water immersion (no more than 45° C),[21] but parenteral analgesia (e.g., morphine, 4 to 10 mg IV every 4 hours) or a regional nerve block may be needed. For extensive wounds, exploration and removal of any residual sting debris, followed by copious irrigation, are appropriate. Stings to the abdomen or chest potentially can result in immediately lethal internal injury or fatal necrosis developing internally over a number of days. Such penetrating injuries warrant careful examination and, where appropriate, exploration and cleaning of the wound track to remove all necrotic tissue.

VENOMOUS MOLLUSKS

A few venomous *octopus species* have a potent paralytic neurotoxin, tetrodotoxin, which causes rapid (5 to 20 minutes) onset of flaccid paralysis, including

respiratory paralysis, that generally persists for a few hours. The actual bite is often painless and thus may go unrecognized. Treatment is supportive and focused on providing respiratory support until the paralysis resolves several hours later. No antivenom is available.

Cone snails can fire tiny venom-inoculated darts into prey. Humans may note instant pain or no significant pain, usually followed by the rapid onset of flaccid paralysis and, in severe cases, ventilatory paralysis. Treatment is supportive. No antivenom is available.

Sea urchins possess numerous sharp spines that can result in both a mechanical injury and a local envenomation. The result is usually intense pain without systemic effects. Retained spines can act as a nidus for secondary infection. Treatment is symptomatic (analgesia; hot water immersion at no more than 45° C), antibiotics if a secondary infection develops, and careful search for and surgical removal of embedded spines.

Many *corals* may cause cuts or abrasions and potentially a local envenomation from coral nematocysts. Fire coral cuts may cause intense immediate pain and later local skin necrosis. Coral wounds may also be contaminated by microorganisms, and coral debris can act as a nidus for infection. Although the initial injury may appear trivial, it can progress to a more significant problem if left untended. Treatment includes standard wound care, analgesia as required, and antibiotics for secondary infection.

Sea anemone stings may cause envenomation with the rapid onset of severe local pain, which may progress to vesiculation and even ulceration or necrosis. The pain may persist for hours to days or even weeks. Treatment is symptomatic and supportive.

POISONING BY MARINE ANIMALS

TETRODOTOXIN POISONING

Tetrodotoxin is a small, highly potent, nonpeptide, paralytic neurotoxin. It is produced by microorganisms and then acquired and accumulated as a venom by certain marine animals for defensive purposes (e.g., fugu fish) or offensive purposes (e.g., blue-ringed octopus). Tetrodotoxin is not destroyed by cooking, so it may remain in contaminated animals prepared as human food. Competent preparation of these fish (i.e., removal of tissues and organs with high concentrations of the toxin) may reduce, but not completely eliminate, the risk of lethal poisoning.

Mild (grade 1) poisoning causes only perioral numbness, paresthesia, and nausea. Grade 2 poisoning includes facial and tongue numbness, mild generalized paresis, incoordination, and slurred speech. More severe poisoning is defined by generalized flaccid paralysis with inability to speak, fixed dilated pupils, and respiratory compromise, often with respiratory paralysis.[22] Progression and death can occur within 60 minutes. Treatment is supportive and focused on cardiopulmonary support until the toxin degrades within a few hours.

CIGUATERA POISONING

Ciguatera is a nonpeptide, small toxin produced by dinoflagellates and concentrated up the food chain. As a result, it accumulates in larger predatory fish, without any apparent effect on them. When the larger fish are eaten by humans, however, ciguatera poisoning may occur. Cooking does not destroy the toxin. Fish such as shark, barracuda, bass, and other predatory species are predominantly involved. Ciguatera poisoning is detected only when an outbreak occurs because the fish appear healthy and taste normal.

Clinical symptoms first appear about 6 to 12 hours after eating. Gastrointestinal effects include nausea, vomiting, diarrhea, and abdominal pain. Systemic symptoms, which can be variable in onset and delayed for hours, may include myalgia, arthralgia, circumoral parasthesiae, fatigue, generalized pruritus, headaches, and abnormal sensitivity to temperature. These effects can persist for days to months and are exacerbated in some patients by consumption of alcohol or any subsequent fish meal.[23] Fatalities are rare and associated with acute-phase dehydration, cardiac failure, or cerebral edema.

Ciguatera is notoriously resistant to treatment, and no specific antidote is available. Mannitol (one dose of 1 g/kg, IV) has been recommended, but trial results are conflicting. Amitriptyline (e.g., 25 mg, orally twice daily) has been used with anecdotal success. Indomethacin (25 mg orally three times daily) may assist with arthralgias.

PALYTOXIN POISONING

Palytoxin poisoning is similar to ciguatera poisoning, except the toxin is produced by zoanthid corals in the Pacific and Mediterranean. A recent problem in the Mediterranean is that massive dinoflagellate blooms can release sea spume (aerosolized palytoxin), which exposes humans onshore, thereby resulting in skin irritation, dyspnea, and airway obstruction. Some beaches and even seaside communities have been closed during intense spume events. Cleaning of tropical aquaria can also result in the aerosolysed release of palytoxin and subsequent poisoning. Treatment is symptomatic and supportive.

SHELLFISH POISONING

Shellfish poisoning can result from the contamination of shellfish fisheries by toxin-producing blooms of dinoflagellates.

Paralytic shellfish toxins are saxitoxin and gonyautoxins. Numbness (of fingertips, lips, tongue), abdominal pain, and nausea develop 30 to 120 minutes after ingestion, followed by progressive flaccid paralysis that may extend to full respiratory paralysis. Patients also may have vertigo, ataxia, transient blindness, headache, and back pain. No specific treatment is available. Management is symptomatic and supportive. Fatalities have occurred.

Neurotoxic shellfish poisoning is caused by brevetoxin, which particularly affects clams and oysters. Clinical manifestations seen several hours after ingestion include gastrointestinal effects (nausea, vomiting, diarrhea, abdominal pain) followed by paresthesias and incoordination but not paralysis. The poisoning is generally a self-limiting nonfatal disease treated with symptomatic and supportive care.

Amnesic shellfish poisoning is caused by domoic acid, which accumulates predominantly in mussels. Gastrointestinal effects begin 6 or more hours after ingestion, but days to weeks later some patients develop encephalopathy, delirium, permanent memory loss, and, less commonly, hypotension, increased pulmonary secretions, cardiac dysrhythmias, hemiplegia, seizures, and coma. Fatalities occur. Treatment is symptomatic and supportive.

Diarrheic shellfish poisoning is caused by polycyclic ethers such as okadaic acid derivatives, which stimulate excessive intraintestinal fluid accumulation. Patients present hours after ingestion with severe gastrointestinal effects, which can persist for days, and dehydration. Symptoms may mimic those of bacterial contaminants (e.g., vibrio parahaemolyticus [Chapter 278] and norovirus [Chapter 350]). Fatalities rarely occur. Treatment is symptomatic and supportive.

Scombroid poisoning is caused by histamine, which is produced by the degradation of histidine in dead fish that are poorly stored. Scombroid is a food processing/storage problem rather than a true toxin-based disease. Clinically it presents within 1 hour of ingestion with a rash, flushing, tachycardia, and, in more severe cases, headache, gastrointestinal symptoms, bronchospasm, hypotension, angioedema, and airway compromise. It usually resolves spontaneously in 6 to 12 hours or, at most, 36 hours. Fatalities have been reported. Treatment includes use of antihistamines (see Table 404-3), beta-2 androgenic inhalers (e.g., albuterol as needed), corticosteroids (see Chapter 28), and intramuscular epinephrine (0.25 mL of a 1 : 1000 solution).

99 RHABDOMYOLYSIS

FRANCIS G. O'CONNOR AND PATRICIA A. DEUSTER

DEFINITION

Rhabdomyolysis, an acute, potentially fatal clinical syndrome, reflects the dissolution and disintegration of striated muscle, with the release of muscle cell contents into the systemic circulation.[1] Myoglobinemia and myoglobinuria are common sequelae. Other substances released from affected muscle cells (e.g., calcium, potassium) can cause systemic effects. Prerenal azotemia, complicated by the toxicity of free myoglobin on the renal tubules, may lead to acute kidney injury (Chapter 106), which exacerbates other metabolic abnormalities. At the extreme, arrhythmias, caused by the release of intracellular potassium and organic acids, coupled with hypocalcemia may be fatal.

EPIDEMIOLOGY

In the absence of a widely accepted laboratory definition or clinical diagnostic criteria, the true incidence of rhabdomyolysis is unclear, but about 26,000 hospitalized cases are seen each year in the United States. The U.S. military also reports over 500 annual cases of exertional rhabdomyolysis.[2] Among patients with rhabdomyolysis, anywhere from 13 to 67% may develop acute kidney injury, which accounts for 5 to 10% of all cases of acute kidney failure in the United States. Moreover, acute kidney injury secondary to rhabdomyolysis is independently associated with both longer hospitalizations and higher mortality.[3]

Rhabdomyolysis is a complex and multifactorial clinical disorder, with multiple potential inherited and acquired causes (Table 99-1).[4] In urban adults, abuse of alcohol and other drugs, muscle compression, and status epilepticus are common causes of rhabdomyolysis. Various viral infections, including influenza A and B, herpes simplex, adenovirus, echovirus, human immunodeficiency virus, cytomegalovirus, and most recently severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which causes coronavirus disease 2019 (COVID-19), can cause rhabdomyolysis. In pediatric patients, the most common cause is trauma, followed by nonketotic hyperosmolar coma, viral myositis, dystonia, and malignant hyperthermia. However, exertional rhabdomyolysis from repetitive exercise is also a concern in young athletes. Importantly, children and adolescents with recurrent rhabdomyolysis are increasingly being recognized as possibly having inherited metabolic disorders.

Drugs and Intoxications

Among intoxications, the most frequent illegal drug-associated causes are cocaine and heroin (Chapter 365), with nearly 20% of cocaine overdoses complicated by rhabdomyolysis. Other recreational drugs, such as "bath salts" (of which methylenedioxypyrovalerone is the primary ingredient) and synthetic cannabinoids (or "spice"), have been associated with rhabdomyolysis. Other substances that can induce rhabdomyolysis include ethanol (Chapter 364), amphetamines, phenylalkylamine derivatives, antipsychotics, caffeine, and statins.[5] Up to 10% of patients taking statins (Chapter 190) may experience myalgias, but reported rates of statin-induced rhabdomyolysis range from 0 to 2.2 cases per 1000 person-years,[6] with cerivastatin being associated with the highest rates. Statins can also induce an autoimmune anti-HMG-CoA antibody myopathy with proximal muscle weakness and profound creatine kinase elevations. Dietary supplements, in particular those with combinations of stimulants, have also been associated with exertional rhabdomyolysis. Rhabdomyolysis can also be seen when severe hyponatremia is rapidly corrected.

Exertional Rhabdomyolysis

Rhabdomyolysis can be a consequence of exertion in sports (e.g., baseball, football, track, wrestling, endurance sports[7]), military, and recreational exercise settings, and especially with high-intensity, resistance-exercise training. For example, in one series of patients with rhabdomyolysis (defined as a creatine kinase [CK] level of greater than 25,000 units/L), 35% of patients had exertional rhabdomyolysis, with most of them related to high-intensity resistance training. In another series, 35 of 225,000 emergency department visits to an urban tertiary care center were for exertional rhabdomyolysis; the average CK level was 40,000 U/L, but no patient developed acute kidney injury.

According to data from the military, the incidence rate for exertional rhabdomyolysis is higher among Black, non-Hispanic men (60.0 cases per 100,000 person-years) than for all other ethnic groups. Additionally, individuals with sickle cell trait have a slightly higher risk of exertional rhabdomyolysis than those without sickle cell trait, although their subsequent clinical courses are not different.[8] Consistent risk factors for exertional rhabdomyolysis are low levels of physical fitness and early introduction of high-intensity repetitive exercises (e.g., squats, push-ups, sit-ups). Multiple case reports in athletes and the military identify both over-motivation and leadership (e.g., drill sergeant, coach, trainer) as important risk factors. Although most cases are self-limited, with no long-term evidence of kidney or muscle injury, patients who demonstrate systemic signs, generalized clinical findings, or acute kidney injury may have an underlying metabolic myopathy. Importantly, 25% of all heatstroke cases in the military between 1980 and 2000 were associated with exertional rhabdomyolysis; acute kidney injury developed in 33%.

The extreme exertion characteristics of military service carry over to the population of correctional inmates and civil servant first responders. Unsupervised repetitive exercise in prison populations can lead to exertional rhabdomyolysis. Among New York City firefighters, 32 of 16,506 candidates (0.2%) were hospitalized for exertional rhabdomyolysis after a physical fitness test, with 4 requiring hemodialysis. In a group of 50 prospective police officers from Massachusetts, 13 trainees were hospitalized with exertional rhabdomyolysis and had CK levels higher than 32,000 U/L; 6 required dialysis, and 1 died 44 days later as a result of complications of exertional rhabdomyolysis, heatstroke, and kidney and hepatic failure.

PATHOBIOLOGY

Pathophysiology

The final common pathway for all cases of rhabdomyolysis is from direct or indirect injury or destruction of muscle cells, with displacement of their intracellular contents into extracellular fluid, the circulation, or both (E-Fig. 99-1).

TABLE 99-1 INHERITED AND ACQUIRED CAUSES OF RHABDOMYOLYSIS

INHERITED	ACQUIRED
Glycolytic/glycogenolytic (e.g., McArdle disease [myophosphorylase deficiency])	Exertion (e.g., exercise, status epilepticus, delirium, electrical shock, status asthmaticus, cardiopulmonary resuscitation; see also Table 99-2)
Fatty acid oxidation (e.g., carnitine palmitoyltransferase II deficiency)	Crush (e.g., external weight, prolonged immobility, bariatric surgery)
Krebs cycle (e.g., aconitase deficiency)	Ischemia (e.g., arterial occlusion, compartment syndrome, sickle cell disease, disseminated intravascular coagulation)
Pentose phosphate pathway (e.g., glucose-6-phosphate dehydrogenase deficiency)	Extremes of body temperature (e.g., fever, exertional heatstroke, burns, malignant hyperthermia, hypothermia, lightning)
Purine nucleotide cycle (e.g., myoadenylate deaminase deficiency)	Metabolic (e.g., hypokalemia, hypernatremia or hyponatremia, hypophosphatemia, pancreatitis, diabetic ketoacidosis, renal tubular acidosis, hyperthyroidism or hypothyroidism, nonketotic hyperosmolar states)
Mitochondrial respiratory chain (e.g., succinate dehydrogenase deficiency)	Drugs or toxins (e.g., anticholinergics, amphetamines, antihistamines, arsenic, ethanol, opiates, statins, cocaine, succinylcholine, halothane, corticosteroids, cyclosporine, itraconazole, phenothiazines, bath salts, synthetic cannabinoids)
Malignant hyperthermia susceptibility (e.g., familial malignant hyperthermia [*RYR1*] mutations, myotonic dystrophy, Duchenne and Becker dystrophies)	Infections (e.g., Epstein-Barr virus, human immunodeficiency virus, herpes simplex, influenza A and B, *Borrelia burgdorferi*, tetanus)
Other (e.g., familial recurrent myoglobinuria)	Inflammatory and autoimmune disorders (e.g., polymyositis, dermatomyositis)

ABSTRACT

Rhabdomyolysis, which is an acute and potentially fatal clinical syndrome, reflects the dissolution and disintegration of striated muscle, with the release of muscle cell contents into the systemic circulation. Myoglobinemia and myoglobinuria are common sequelae. Other substances released from affected muscle cells (e.g., calcium, potassium) can cause systemic effects. Prerenal azotemia, complicated by the toxicity of free myoglobin on the renal tubules, may lead to acute kidney injury, which exacerbates other metabolic abnormalities. At the extreme, arrhythmias, caused by the release of intracellular potassium and organic acids, coupled with hypocalcemia may be fatal.

Cell function is critically dependent on the relationship between intracellular calcium (Ca^{2+}) and sodium (Na^{+}) concentrations. Sarcolemmal Na^{+},K^{+}-ATPase regulates extracellular Ca^{2+} concentrations by exchanging Na^{+} for Ca^{2+} across the sarcolemma. A low intracellular Na^{+} concentration creates a gradient that actively results in efflux of Ca^{2+} as it is exchanged for Na^{+} ions. This process maintains intracellular Ca^{2+} levels at several orders of magnitude lower than extracellular Ca^{2+}.

When the cell is subjected to mechanical stress, stretch-activated channels in the sarcolemma can open and cause an influx of Na^{+} and Ca^{2+}. With excessive intracellular Ca^{2+}, several pathologic processes begin: persistent contraction of myofibers, depletion of adenosine triphosphate (ATP), production of free radicals, activation of vasoactive molecules, release of proteases, and, ultimately, cell death. Cell death is followed by an invasion of neutrophils, which amplify the damage by further release of proteases and increased production of free radicals. Rather than simple necrosis, a self-sustaining, inflammatory myolytic reaction develops. The activation of complement is a key contributor to the acute kidney injury.[9]

Rhabdomyolysis can be further complicated by reperfusion injury and compartment syndrome. In reperfusion injury, restoration of vascular flow after a prolonged period of ischemia results in the delivery of activated neutrophils in combination with an abundance of oxygen, which contributes to the development of highly reactive free radicals. Because most muscle groups are contained within rigid fascial compartments, rhabdomyolysis can quickly precipitate a secondary acute compartment syndrome. The swelling associated with traumatized tissue can also increase intracompartmental pressure and provoke additional damage by compromising both venous and arterial blood flow. Thus, compartment syndrome can also result in rhabdomyolysis.

Inherited and Acquired Rhabdomyolysis

Rhabdomyolysis can be classified as inherited or acquired (see Table 99-1).

Inherited Rhabdomyolysis

Patients who have recurrent episodes of high levels of CK in the blood triggered by low levels of stress or exertion should be evaluated for a metabolic myopathy. A number of pathways leading to the formation of ATP can be disrupted by genetic defects (e.g., inherited disorders of glycogenolysis, glycolysis, and lipid and purine metabolism).[10] In one series of 77 patients who underwent biopsy for idiopathic myoglobinuria, 47% were found to have enzymatic defects; the most common disorders were deficiencies of carnitine palmitoyltransferase II[11] and myophosphorylase. Mutations in the ryanodine receptor 1 gene also can cause rhabdomyolysis.[12] Carnitine palmitoyltransferase, acid maltase, and lipin deficiencies are other common causes of rhabdomyolysis. Malignant hyperthermia (Chapters 400 and 402) is a potentially fatal, heterogeneous, pharmacogenetic disorder that can be triggered by volatile anesthetics in predisposed individuals. When a susceptible patient is exposed to a triggering anesthetic agent, excessive release of Ca^{2+} into the myoplasm leads to a hypermetabolic state manifested by hypercapnia, tachycardia, and metabolic acidosis. A genetic predisposition to malignant hyperthermia may be linked to a predisposition to exertional rhabdomyolysis and exercise-induced heat injury via mutations in the ryanodine receptor 1 gene, but this association has not been proved.

Acquired Rhabdomyolysis

Drugs and Toxins

Drugs and toxins, also common causes of rhabdomyolysis, operate through a number of mechanisms, including direct membrane toxicity (e.g., herbicides), indirect metabolic derangements (e.g., anticholinergics), ischemia (e.g., cocaine), and agitation (e.g., hemlock). The most commonly cited drugs precipitating rhabdomyolysis are alcohol, statins, cocaine, amphetamines, and antipsychotics (phenothiazines), although new designer street drugs (known as spice and bath salts) are also implicated. Alcohol can induce rhabdomyolysis through a combination of mechanisms, including immobilization, direct myotoxicity, and electrolyte abnormalities. Statins, which inhibit 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, can be directly myotoxic and appear to trigger sustained increases in intracellular Ca^{2+}. Although the precise mechanisms underlying statin-induced myopathy are currently incompletely understood, it can be aggravated by the concomitant administration of cytochrome P-450 3A4 inhibitors (e.g., itraconazole, erythromycin, cyclosporine, danazol) and fibrates, as well as by physical exercise, excessive alcohol intake, and preexisting comorbid medical conditions. Amphetamines and phenothiazines may lead to a clinical picture of rhabdomyolysis through the serotonin syndrome (Chapter 402) and the neuroleptic malignant syndrome (Chapter 386), respectively. The mechanism whereby bath salts lead to rhabdomyolysis may be direct muscle toxicity, severe hyperthermia, or electrolyte disorders.

Infections

Both viral and bacterial infections can trigger rhabdomyolysis. Either cellular invasion or generation of various toxins may precipitate infection-induced rhabdomyolysis. Influenza A and B (Chapter 332) are the most common viral causes, followed by human immunodeficiency virus (Chapter 355), coxsackievirus (Chapter 349), and Epstein-Barr virus (Chapter 348). SARS-CoV-2 infection (Chapter 336) also can be associated with myositis and rhabdomyolysis.[14] The most common bacterial organisms that induce rhabdomyolysis are *Legionella* species (Chapter 290), followed by *Francisella tularensis* (Chapter 287) and *Streptococcus pneumoniae* (Chapter 268). Acute kidney injury develops in approximately 57% (33 to 100%) and 34% (0 to 100%) of bacterial and viral cases of rhabdomyolysis, respectively.

Trauma

Trauma is the most common cause of rhabdomyolysis. Wars, natural disasters, and traffic and occupational accidents are frequent causes of trauma-induced "crush injury syndrome" (Chapter 97). Other less frequent causes of trauma- or compression-induced rhabdomyolysis include struggling against restraints, direct blows, child abuse, torture, prolonged immobilization (e.g., anesthesia, coma, drug- or alcohol-induced stupor), and bariatric and other forms of surgery. The primary mechanism of crush syndrome and compression-induced rhabdomyolysis is reperfusion of damaged tissue after a period of ischemia.

Muscle breakdown occurs in response to strenuous exercise in fit and unfit individuals, particularly eccentrically based activities (lengthening contractions, such as lowering a weight). However, it is important to note that muscle breakdown in response to exercise is expected and physiologic, whereas exertional rhabdomyolysis is pathophysiologic. Persons may present with delayed-onset muscle soreness 1 to 3 days after a bout of moderate to strenuous exercise. Key findings distinguishing exertional rhabdomyolysis from physiologic muscle breakdown and/or delayed-onset muscle soreness include (1) pain out of proportion to what one would normally expect; (2) muscle swelling; (3) significant limitation in active and passive range of motion; and (4) the presence of cola-colored urine.

External rhabdomyolysis can be triggered by exertion in combination with prolonged heat exposure (Chapter 95) and altitude, as well as by the use of medications (e.g., anticholinergics) or dietary supplements (e.g., ephedra, caffeine). It can range from a minor clinical event to a catastrophic collapse and death; underlying mechanisms may be mechanical or metabolic in nature, but all are associated with elevated myoplasmic Ca^{2+} concentrations.

A number of underlying genetic polymorphisms and inherited disorders are associated with exertional rhabdomyolysis (Table 99-2). Multiple mutations in the carnitine palmitoyl-transferase II and myophosphorylase genes have been found, and although each mutation has been associated with exercise-induced myoglobinuria, the mutations alone may not explain

TABLE 99-2 GENETIC MUTATIONS/VARIANTS ASSOCIATED WITH EXERTIONAL RHABDOMYOLYSIS

GENE	
Ryanodine receptor 1	*RyR1*

Mitochondrial DNA	*MT-CO2*

the clinical episodes. Mutations and variants in the ryanodine receptor 1 (*RYR1*) gene, which are common in malignant hyperthermia (Chapter 400), have also been found in persons with external rhabdomyolysis. Other single-nucleotide polymorphisms associated with severe exertional rhabdomyolysis are found in the genes encoding CK muscle isoform (*CKMM* NcoI), α-actinin-3 (*ACTN3* R577X), or myosin light chain kinase (*MYLK* C37885A). However, data are insufficient to use these or other variants to predict an individual's clinical susceptibility to infection-, toxin-, exertion-, or drug-induced rhabdomyolysis.

CLINICAL MANIFESTATIONS

The classic manifestations of rhabdomyolysis include acute myalgia and pigmenturia as a result of myoglobinuria in association with elevated serum muscle enzymes (CK in particular). Many clinical features are nonspecific, and the course and initial signs, symptoms, and laboratory abnormalities are clearly dependent on the underlying cause and severity of the event.[13]

Rhabdomyolysis can be accompanied by both local and systemic features. Local features, generally noted in the area of the traumatized muscle groups, can occur within hours of the trauma and include muscle pain, tenderness, and swelling. Systemic features include tea-colored urine, chills, fever, and malaise. In extreme cases, patients complain of nausea and vomiting and demonstrate confusion, agitation, or delirium. Whenever systemic features such as chills, fever, malaise, or generalized muscle involvement are observed, an underlying metabolic myopathy should be considered.

Clinical findings may also include compartment syndrome, which can occur in muscle groups encased by fascia, especially the lower leg, forearm, and thigh muscle groups. Pain with muscle group passive stretching and sensory abnormalities caused by nerve compression are early manifestations of compartment syndrome; the loss of a pulse as a result of vascular compromise is a later finding. If compartment syndrome is not addressed by surgical decompression within 6 to 8 hours, irreversible ischemic muscle and nerve damage may occur.

Laboratory findings are related to the degree of muscle involvement. Early findings include elevated blood levels of CK, myoglobin, potassium, urea, and phosphorus. CK levels typically peak 2 to 5 days after the initial insult; levels of 15,000 to 20,000 U/L are more likely to be associated with acute kidney injury than lower levels, particularly when it is "crush injury syndrome." Hypocalcemia, caused by the influx and deposition of Ca^{2+} in damaged muscle tissue, may accompany rhabdomyolysis. Also, an anion-gap metabolic acidosis may develop because of the release of organic acids from damaged muscle. With resolution of rhabdomyolysis, sequestered Ca^{2+} may be released back into the circulation and cause hypercalcemia.

DIAGNOSIS

Creatine Kinase Levels

A diagnosis of rhabdomyolysis is made when there is clinical evidence of myonecrosis and release into the systemic circulation of muscle cell contents, including myoglobin, creatinine, CK, organic acids, potassium, aldolase, lactate dehydrogenase, and hydroxybutyrate dehydrogenase. The skeletal muscle subtype CK-MM is abundantly present in skeletal muscle and released as a result of muscle destruction. Serum levels exceeding 100,000 U/L are not uncommon with rhabdomyolysis. Because CK remains in the circulation longer than myoglobin and can be detected easily and efficiently, it is the most frequently used marker to diagnose rhabdomyolysis. No universally accepted clinical or laboratory definition of rhabdomyolysis currently exists, but CK elevations ranging from more than 5 times to more than 50 times the upper limits of normal, as well as varying requirements for serum creatinine elevation, have been proposed. Importantly, sex, ethnicity, and baseline physical activity levels all affect individual baseline CK levels. For example, African American males and young athletic men have the highest baseline CK levels, whereas non–African American women have the lowest. Thus, modifying factors such as sex, ethnicity, and physical fitness must be considered when CK is used for the diagnosis of rhabdomyolysis. In general, CK levels in excess of at least five times normal, in combination with the appropriate clinical presentation, are accepted as evidence of muscle breakdown, which may be consistent with a diagnosis of rhabdomyolysis.

Myoglobin Testing

Because myoglobinuria does not occur in the absence of rhabdomyolysis, myoglobin should be the most specific marker of rhabdomyolysis. However, testing for serum or urine myoglobin is problematic and not always consistent. Because myoglobin is normally bound to plasma globulins, only a small fraction of the myoglobin that is released into the circulation reaches the glomeruli. In the presence of severe muscle damage, blood levels of myoglobin overwhelm the binding capacity of the circulating proteins, so free myoglobin reaches the glomeruli and eventually the renal tubules. Elevations in serum myoglobin occur before the rise in serum CK, but the elimination kinetics of serum myoglobin are more rapid than that of CK, which makes the often evanescent rise in serum myoglobin a less reliable marker of muscle injury. Furthermore, the liver can quickly metabolize myoglobin.

Because most laboratories will perform urine myoglobin testing no more often than once per day, urine myoglobin is neither a timely nor accurate predictor of acute kidney injury. Nevertheless, urine screening for rhabdomyolysis may be performed by dipstick. The orthotoluidine portion of urine dipsticks turns blue in the presence of hemoglobin or myoglobin, so if the urine sediment does not contain erythrocytes, one can assume, in the appropriate clinical setting, that a positive dipstick reading reflects the presence of myoglobin.

Other Laboratory Tests

Other associated laboratory findings in acute rhabdomyolysis can include hypocalcemia, hyperkalemia, hyperphosphatemia, metabolic (lactic) acidosis, thrombocytopenia, and disseminated intravascular coagulation. Muscle biopsy is not required to make a diagnosis of rhabdomyolysis, but it can be confirmatory, especially in cases of recurrent rhabdomyolysis or when the diagnosis is not clear. Histopathologic evaluation usually demonstrates muscle necrosis, loss of the cell nucleus, and muscle stria with the absence of inflammatory cells.

Differential Diagnosis

The clinical findings of acutely swollen muscles or muscle weakness (or both) with reddish-brown urine are not always the result of rhabdomyolysis, and the examining clinician must be careful to scrutinize all information. The differential diagnosis includes disorders that may indirectly affect myocytes, such as Guillain-Barré syndrome and periodic paralysis. Guillain-Barré syndrome (Chapter 388) differs from rhabdomyolysis in that it is characterized as a fulminant polyneuropathy, usually after an antecedent viral infection. Periodic paralysis (Chapter 389) is frequently associated with transient electrolyte disturbances and distinguished from rhabdomyolysis in that most cases follow periods of rest or sleep.

Myoglobinuria causes the urine to be reddish brown, but tea-colored (or cola-colored) urine does not necessarily indicate the presence of myoglobin. Other conditions associated with discoloration of urine include hemoglobinuria from hemolysis, intrinsic renal disease, porphyria, acute glomerulonephritis, "athletic pseudonephritis," and external factors such as ingestion of beets and various drugs (e.g., phenytoin, rifampin) or dietary supplements (riboflavin, or vitamin B_2).

The diagnosis of rhabdomyolysis is complete when the clinician determines the cause. This step, although it is frequently established during the history and physical examination, may require further diagnostic assessment after initiating clinical treatment during the acute phase. Individuals with recurrent rhabdomyolysis, a positive family history of rhabdomyolysis or malignant hyperthermia, low exercise tolerance, no apparent cause, or a fulminant form of rhabdomyolysis appear to warrant further testing.

Testing may include a nonischemic forearm test, which involves isometric exercise at 70% of maximal voluntary contraction for 30 seconds under nonischemic conditions; electromyography; more in-depth blood tests for muscle enzymes (e.g., mitochondrial myopathies [Chapter 389], fatty acid transport defects [Chapter 389], glycogen storage diseases [Chapter 191], diseases associated with myoglobinuria); muscle biopsy to investigate specific metabolic myopathies and other enzyme or genetic defects; or any combination of such testing. The forearm exercise test may help identify metabolic and genetic causes of rhabdomyolysis. Patients who have had an episode of malignant hyperthermia or exertional heat illness may be candidates for a caffeine halothane contracture test, which evaluates the force produced by biopsied muscle samples after separate exposures to caffeine, halothane, and caffeine/halothane in the laboratory (Chapter 400).

PREVENTION

Approaches for preventing rhabdomyolysis induced by infections, medications, and toxins may emerge in the future, but no definitive guidelines currently can be presented. Rhabdomyolysis secondary to heat stress or exercise is best prevented by adhering to recommended guidelines for acclimatization and exercise progression. To prevent further muscle injury, blood flow to ischemic areas must be promptly restored to minimize ischemia-reperfusion damage.

TREATMENT

Treatment of rhabdomyolysis begins with a careful history and physical examination to identify and manage any underlying illness. Vital signs, urine output, and serial electrolyte and CK levels should be obtained as soon as possible. Patients require aggressive early management to preserve renal function (Table 99-3).[15,16] Careful observation and treatment of potential early and late complications are critical, and intensive care monitoring may be required.[17]

Hydration

Hydration is the cornerstone of preserving kidney function in patients with rhabdomyolysis, and delaying fluid administration for more than 6 hours increases the risk for acute kidney injury. Inpatient hydration is indicated for victims of collapse, trauma, or exertional heat injury, as well as for patients who have moderate early symptoms; more than mild elevations in CK; or abnormal serum levels of creatinine, potassium, calcium, phosphate, or bicarbonate. In adults, the target urine output is 300 mL/hr for at least 24 hours to prevent acute kidney injury. Hydration is accomplished by the aggressive administration of isotonic intravenous fluids at a rate that results in a urine output of 200 to 300 mL/hour until CK levels begin to decline. If fluid resuscitation fails to correct intractable hyperkalemia and acidosis, renal replacement therapy should be considered (Chapter 106). By comparison, adults with mild symptoms and serum CK levels less than 3000 U/L are considered to be at low risk and may be treated as outpatients with vigorous oral hydration, limited physical activity, and careful follow-up.

Specific Therapeutic Measures

Alkalinization of the urine decreases cast formation, minimizes the toxic effects of myoglobin on the renal tubules, inhibits lipid peroxidation, and decreases the risk for hyperkalemia. However, bicarbonate therapy can cause calcium to precipitate in the soft tissues and contribute to a hyperosmolar state. Mannitol is an osmotic diuretic, volume expander, and free radical scavenger, but it should be used only after adequate kidney function is established and must be used with great caution in patients with marginal cardiac function. To date, no convincing evidence demonstrates that adding sodium bicarbonate or mannitol is superior to fluid therapy alone.[18] Mannitol should be used only when it is needed to maintain a target urine output.

Sodium bicarbonate should be used only in patients with evidence of systemic acidosis, and mannitol should be used only when it is needed to maintain a urine output of 300 mL/hour (see Table 99-3). Deposition of calcium, which occurs early in rhabdomyolysis, is directly related to the degree of muscle destruction and to the often unnecessary therapeutic administration of calcium given to correct asymptomatic hypocalcemia. Early therapeutic reversal of hypocalcemia can worsen ectopic calcification and exacerbate the exponent hypercalcemia during the resolution phase. Accordingly, hypocalcemia should be treated only when patients develop clinical symptoms, signs of tetany, or severe hyperkalemia.

Management of Compartment Syndrome

Compartment syndrome (Chapter 97) is a well-described late complication as well as a potential cause of rhabdomyolysis. Compartment syndrome can occur as a direct consequence of muscle injury associated with increased vascular permeability, aggressive fluid resuscitation, or restoration of reperfusion. Compartment syndrome should be suspected when the muscles are tense and swollen, previously declining CK levels start to rise, or neurovascular compromise occurs. In these cases, compartment pressures should be measured; if pressures exceed 30 mm Hg, prompt fasciotomy should be considered. However, because late fasciotomy (>12 hours after the onset of symptoms) can convert a closed injury into an open wound and thereby increase the risk of uncontrollable infection, late fasciotomy is relatively contraindicated.

Management of Crush Injury

For victims of crush injury (Chapter 97), aggressive on-site hydration with intravenous normal saline is recommended. For massive damage, amputation of the extremity may be required to protect the patient's overall health. The Mangled Extremity Severity Score can identify nonsalvageable extremities on the basis of the degree of skeletal and soft tissue injury, the patient's blood pressure, the presence of a detectable pulse, and age (see http://www.mdcalc.com/mangled-extremity-severity-score-mess-score/).

Malignant Hyperthermia

Rhabdomyolysis caused by malignant hyperthermia (Chapter 400) requires rapid diagnosis and aggressive management. Anesthetics should be discontinued, and the patient should be treated with dantrolene sodium, 2.5 to 4 mg/kg intravenously, followed by about 1 mg/kg every 4 hours for up to 48 hours to avoid recrudescence.

TABLE 99-3 STEPS IN THE PREVENTION AND TREATMENT OF RHABDOMYOLYSIS-INDUCED ACUTE KIDNEY INJURY

Check for extracellular volume status, central venous pressure, and urine output.*
Measure serum creatine kinase levels. Measurement of other muscle enzymes (myoglobin, aldolase, lactate dehydrogenase, alanine aminotransferase, aspartate aminotransferase) adds little information relevant to diagnosis or management.
Measure levels of plasma and urine creatinine, potassium, and sodium; blood urea nitrogen; total and ionized calcium, magnesium, and phosphorus; and uric acid and albumin. Evaluate acid-base status, blood cell count, and coagulation.
Perform a urine dipstick test and examine the urine sediment.
Identify and discontinue nephrotoxic and myotoxic medications.
Initiate volume repletion with IV normal saline promptly at a rate of approximately 400 mL/hr (200-1000 mL/hr, depending on the patient size, setting, and severity) and monitor the clinical course or central venous pressure.
Target urine output of approximately 3 mL/kg body weight/hr (200-300 mL/hr).
Maintain volume repletion until myoglobinuria is cleared (as evidenced by clear urine or urine dipstick test that is negative for blood).
Consider IV bicarbonate therapy for severe rhabdomyolysis. Check urine pH: if it is <6.5, alternate each liter of normal saline with 1 L 5% dextrose or 0.45% saline plus 100 mmol bicarbonate (2 ampules). Avoid potassium- and lactate-containing solutions.
Consider treatment with IV mannitol only if needed to maintain target urine output. If mannitol is utilized, 50 mL of 20 percent mannitol (1 to 2 g/kg per day [total, 120 g], given at a rate of 5 g per hour) should be added to each liter of fluid. Check for plasma osmolality and calculate the plasma osmolal gap (Chapter 106). Discontinue if diuresis (>20 mL/hr) is not established within a few hours.
Check serum potassium and calcium levels frequently; identify and manage metabolic abnormalities.
Correct hypocalcemia (Chapter 227) only if symptomatic (e.g., tetany, seizures) or severe hyperkalemia occurs.
Hyperkalemia should be treated with standard medical management (Chapter 103). Consider renal replacement therapy for resistant hyperkalemia (>6.5 mmol/L) that is symptomatic (as assessed by electrocardiography), rapidly rising serum potassium levels, oliguria (<0.5 mL of urine/kg/hr for 12 hours), anuria, volume overload, or resistant metabolic acidosis (pH < 7.1).
Investigate and treat the cause of rhabdomyolysis.

*In the case of crush syndrome (e.g., earthquake, building collapse, bariatric surgery), institute aggressive volume repletion promptly before evacuating the patient if creatine kinase level is >15,000 U/L.

IV = intravenous.

Modified from Bosch X, Poch E, Grau JM. Rhabdomyolysis and acute kidney injury. *N Engl J Med.* 2009;361:62-72.

PROGNOSIS

The most serious consequence of rhabdomyolysis is acute kidney injury, which occurs in up to 67% of all cases, regardless of cause. Predictors of the risk of needing renal replacement therapy or death in patients with rhabdomyolysis include age older than 50 years; a higher initial serum potassium level; initial serum creatinine level of 1.4 mg/dL or higher; initial serum calcium level below 7.5 mg/dL; initial serum phosphate level above 4.0 mg/dL[19]; initial serum bicarbonate level below 1 mEq/L; and a cause other than syncope, seizures, exercise, statins, or myositis (E-Table 99-1).

Long-term decline in renal function is best correlated with the serum myoglobin level.[20] A higher initial creatinine level but not a higher initial creatine kinase level also predicts acute kidney injury and mortality. Event rates range from 0% in patients with none of these criteria to 20% or more in patients with four or more criteria. For compartment syndrome, a poor prognosis is associated with an ischemic period lasting longer than 6 hours.

The prognosis of patients with rhabdomyolysis improves markedly when treatment is started soon after the diagnosis is made. With mild episodes, the prognosis is customarily excellent, and the patient can typically resume usual activities within several weeks after CK levels have normalized. However, some patients do not return to normal and continue to experience extreme fatigue and muscle pain on exertion. These patients require additional testing (nonischemic forearm test, electromyography, muscle disease enzyme panel, muscle biopsy; Chapter 389) to determine whether an underlying metabolic myopathy exists. The results of these tests will help determine future recommendations, but the patient's tolerance and response to light and more strenuous exercise are important factors. Most authorities agree that statin-induced rhabdomyolysis is an indication for discontinuation of their use.

- Rhabdomyolysis NOT caused by seizure, syncope, exercise, statins, or myositis:
  - 3 points.

INTERPRETATION

MCMAHON SCORE	RISK GROUP	RECOMMENDATION
<6	Low risk	Usual care (3% risk of death or acute kidney injury requiring renal replacement therapy)
≥6*	Not low risk	Initiate renal protective therapy including high-volume intravenous fluid resuscitation to achieve a urine output of 1-2 mL/kg/hr (about 50% risk of death or acute kidney injury requiring renal replacement therapy at scores ≥10)

*The McMahon score predicts mortality or acute kidney injury in patients with rhabdomyolysis. The score should be used in patients ages 18 years or older with rhabdomyolysis (creatine kinase [CK] level greater than 5000 U/L within 72 hours of admission). The score should not be used in patients with preexisting end-stage renal disease or an elevated CK secondary to a myocardial infarction.

100 APPROACH TO THE PATIENT WITH RENAL DISEASE

ALI G. GHARAVI AND DONALD W. LANDRY

The prominent functions of the kidney include the excretion of nitrogenous waste; the regulated excretion of water, sodium, potassium, calcium, magnesium, phosphate, and acid; and the synthesis of a variety of hormones, including 1,25-dihydroxyvitamin D, erythropoietin, and renin. The kidney's elaboration of a protein-free and cell-free ultrafiltrate is uniquely responsible for the excretion of nitrogenous wastes. The approach to the patient with renal disease is largely focused on disordered ultrafiltration and not on defects in the isolated renal tubular processing of individual ions, molecules, water, or acids. A patient may, for example, present with an isolated defect in renal acid excretion (Chapter 104), but in this case the "approach to the patient" is framed for the evaluation of metabolic acidosis, an abnormality for which the kidney is only one among the many causes in a broad differential diagnosis. In contrast, acute kidney injury (Chapter 106) and chronic kidney disease (Chapter 116) refer specifically and exclusively to defects in the filtration function of the kidney. In the context of a diminished magnitude of filtration, many of the other individual functions of the kidney (e.g., hormone synthesis, electrolyte homeostasis) may fail as well.

Primary diseases of the tubules, such as acute tubular necrosis (Chapter 106) and tubulointerstitial disease (Chapter 108), also impair the rate of glomerular filtration and cause acute kidney injury and chronic kidney disease. In contrast, an impairment in ultrafiltration may, in early chronic kidney disease, be reflected solely in a decreased *quality* of glomerular filtration (e.g., the presence of albuminuria) rather than in a decreased *quantity* of filtrate with increased concentrations of nitrogenous waste. Similarly, the glomerular filtration rate (GFR) may be normal in nephrotic syndrome despite ultrafiltration defects that result in massive proteinuria. Defects in the filter can also allow passage of cells, such as red blood cells (RBCs), as is seen in the acute nephritic syndrome (Chapter 107), with or without heavy proteinuria. The paradox of glomerular hematuria without albuminuria is also possible. For example, in mild forms of immunoglobulin A (IgA) nephropathy (Chapter 107), relatively few defects in the glomerular filter will permit a detectable number of RBCs per high-power field in the urine despite a urine albumin level that still remains within normal limits (Fig. 100-1).

In this context, this chapter considers the approach to the patient with acute kidney injury, glomerular syndromes (nephrotic vs. nephritic), tubulointerstitial disease, vasculitis and vascular diseases of the kidney, papillary necrosis, and chronic kidney disease.

PATHOBIOLOGY

The approximately 2 million renal glomeruli normally filter about 180 L/day. The renal glomerulus is not simply a filter but rather a size- and charge-dependent ultrafilter that impedes not only cells but also proteins larger than 60 kD from entering the ultrafiltrate. Smaller proteins are variably filtered at the glomerulus and endocytosed in the proximal tubule so that the protein concentration of the urine is normally low. Kidney disease reflects a failure in the quantity or quality of the glomerular ultrafiltrate.

The normal GFR may decline in hours to days in acute kidney injury or during months to years in chronic kidney disease. An acute decline in glomerular filtration is the necessary and sufficient condition for the diagnosis of acute kidney injury, but abnormal urinary findings can assist with elucidating the etiology of the injury. Proteinuria, ranging from microscopic to nephrotic range (Chapter 107), and urinary findings, from a few cells per microscopic high-power field to gross hematuria or pyuria, may be the only evidence of the earliest stages of chronic kidney disease. As chronic kidney disease advances, the decline in the GFR progresses until dialysis or transplantation (Chapter 117) is required to forestall or to treat the syndrome of uremia.

DIAGNOSIS

Measuring Kidney Function

Although the most accurate method of evaluating kidney function is a formal measurement of GFR with iothalamate, iohexol, or similar markers, these

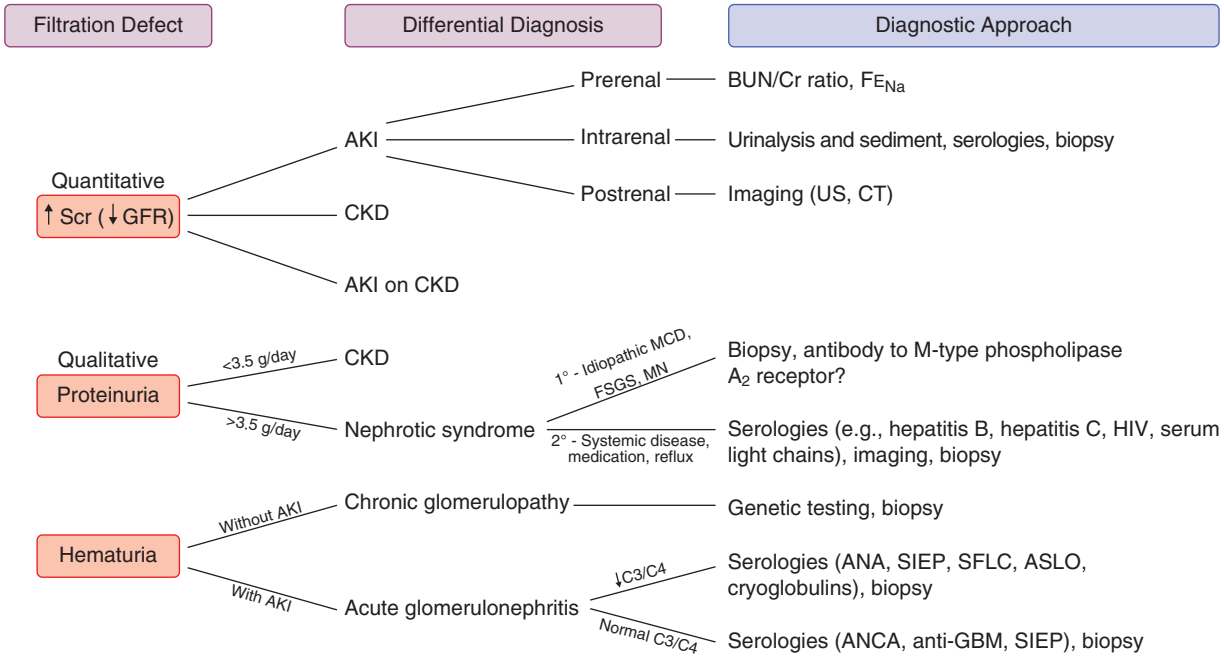

FIGURE 100-1. Overview of approach to kidney disease. Quantitative defects in filtration, manifested by elevated serum creatinine (Scr) and reduced glomerular filtration rate (GFR), should lead to a query into acute kidney injury (AKI) versus chronic kidney disease (CKD). AKI, in turn, is generally divided into prerenal, postrenal, and intrinsic causes. Qualitative defects in filtration, manifested by proteinuria or hematuria, can occur in the absence of changes in GFR and often require biopsy for diagnosis. Proteinuria of more than 3.5 g/day signals nephrotic syndrome, which may be idiopathic or secondary to systemic diseases, such as hepatitis B or C, human immunodeficiency virus (HIV) infection, or diabetes. Glomerular hematuria without AKI is consistent with a chronic glomerulopathy, such as IgA nephropathy, or familial diseases, such as thin basement membranes disease. When hematuria accompanies AKI, acute glomerulonephritis should be suspected and can diagnostically be divided into low-complement glomerulonephritides (immune complex–mediated lesions such as lupus nephritis, postinfectious glomerulonephritis, and cryoglobulinemic glomerulonephritis) and normocomplementemic glomerulonephritides (classically seen in the rapidly progressive glomerulonephropathies due to antineutrophil cytoplasmic antibody [ANCA] and anti–glomerular basement membrane [anti-GBM] antibody). ANA = antinuclear antibody; ASLO = antistreptolysin O; BUN = blood urea nitrogen; Cr = creatinine; CT = computed tomography; MCD = minimal change disease; Fe_{Na} = fractional excretion of sodium; FSGS = focal segmental glomerulosclerosis; MN = membranous nephropathy; SFLC = serum free light chain; SIEP = serum immunoelectrophoresis; US, ultrasonography.

ABSTRACT

The kidneys mediate critical homeostatic functions via excretion of nitrogenous waste and regulated excretion of water, sodium, potassium, calcium, magnesium, phosphate, and acid. The kidney is comprised of about 1 million functional nephrons, and the primary mechanism for excretion is the production of a protein-free and cell-free ultrafiltrate at the vascular origin of the nephron, which is the glomerulus. Renal failure, which refers specifically to a defect in the filtration function, might first be uncovered by abnormalities in blood levels of urea nitrogen, creatinine, and electrolytes. Impaired sodium and water handling in acute kidney injury also may produce symptoms of volume overload, such as edema from decreased urine output. The approach to the patient with renal failure begins by distinguishing acute from chronic processes. Acute renal failure is subdivided into prerenal, intrarenal, and postrenal causes. Prerenal causes include processes that compromise blood flow to the glomerulus. Intrarenal insults (e.g., glomerulonephritis, acute tubular necrosis, and acute interstitial nephritis) affect the kidney's vasculature, tubules, glomeruli, or interstitium. Postrenal causes can obstruct urine flow at any site within the urinary tract. Acute renal failure usually can be distinguished from chronic renal failure by analyzing the urine for protein, infection, and the presence of abnormal cells, as well as by assessing the trajectory of the serum creatinine level over time. Imaging with ultrasound or computerized tomography may identify the presence of postrenal causes, which commonly result in hydronephrosis. Disorders of water and electrolytes may reflect a defect in renal filtration or tubular function, but they may also be caused by primary gastrointestinal, cardiovascular, or endocrine abnormalities.

glomerulonephritis

tests are too expensive and time-consuming to be recommended for routine clinical practice. Currently, the most common methods used to estimate GFR are the serum creatinine concentration, the calculated creatinine clearance, and estimation equations based on serum creatinine.

Serum creatinine is, to a first approximation, neither secreted nor reabsorbed, so the amount appearing in the urine per unit time is a measure of the amount that was filtered at the glomerulus during that period. As a result, the rate of creatinine clearance is a reasonably close estimate of the GFR. A decrement in the GFR diminishes creatinine clearance but has no immediate effect on creatinine production by muscle; as a result, the serum creatinine concentration rises. The change in serum creatinine over time indicates the tempo of the renal disease and can distinguish acute injury from chronic kidney disease. The routine use of serum creatinine alone to infer GFR is ill-advised because of the differing rates of creatinine production among individuals, mainly related to variations in muscle mass. Women and the elderly can have deceptively low serum creatinine levels despite significant declines in GFR. In addition, the inverse relationship between GFR and serum creatinine (Fig. 100-2) has important and potentially easily overlooked clinical implications. An initial small absolute rise in creatinine usually reflects a marked fall in GFR, whereas seemingly large changes in the serum creatinine level in patients with more advanced chronic kidney disease (CKD) may reflect minor changes in GFR.

Approach to Diagnosis

The routine screening of asymptomatic adults without risk factors for kidney disease is not recommended. Most patients are diagnosed because other conditions lead to tests of kidney function.

Some kidney diseases may have clinical manifestations in their early stages (e.g., edema in the nephrotic syndrome [Chapter 107] or rash in IgA vasculitis [Chapter 249]). However, because of the kidney's large functional reserve, only significant impairments of kidney function result in clinical manifestations. Advanced renal failure (Chapter 116) is associated with anorexia, abnormal taste, nausea, vomiting, fatigue, sleep difficulties, and shortness of breath from volume overload. Physical examination and laboratory tests reveal malnutrition, hypertension, hypervolemia, anemia, hyperlipidemia, and bone disease. More advanced kidney disease results in the syndrome of uremia, which can manifest as impaired cognition, pericarditis, life threatening hyperkalemia, and acidosis, thereby necessitating renal replacement therapy (Chapter 117).

The serum creatinine level or cystatin C level to estimate and GFR plus additional tests (e.g., a formal 24-hour urine collection to measure creatinine clearance and proteinuria) can confirm the diagnosis of kidney disease. Calculation of creatinine clearance from a 24-hour urine collection can be cumbersome for patients and is prone to error because of inaccurate urine collection. To measure the creatine clearance accurately, the patient must be instructed to discard the first morning urine before initiating the collection and to conclude the collection by including the next morning void. The formula for calculating creatinine clearance is as follows:

$$CCr = (\text{urine Cr} \times V)/(\text{plasma Cr})$$

where *CCr* is creatinine clearance, *urine Cr* is urine creatinine concentration, *V* is urine flow rate, and *plasma Cr* is plasma creatinine. The normal value for GFR ranges from 120 to 140 mL/min/1.73 m^2.

Because of the logistical and practical limitations of a 24-hour urine collection for direct measurement of the GFR, several equations have been developed to estimate GFR based on the serum creatinine or cystatin C level[1–3] and levels of albuminuria (Table 116-2). Although useful for staging CKD, these estimating equations have limitations, particularly in the elderly and at the extremes in the distribution (Chapter 116).[4] For example, physiologic, age-related decline in the GFR in older individuals must be distinguished from a true reduction in the GFR due to kidney disease. All calculations of GFR assume that the patient is in a steady state (Table 100-1), and so values will be inaccurate in situations in which kidney function is changing rapidly (e.g., in acute kidney injury; Chapter 106). The creatinine clearance also overestimates GFR by about 10% owing to tubular secretion of creatinine. The calculations can be further influenced by drugs or conditions (i.e., the nephrotic syndrome or sickle cell disease) that can alter the secretion of creatinine. Cystatin C may provide a more accurate and prognostic measurement of GFR in patients whose creatinine levels are in the upper end of the normal range,[5] but it has not replaced estimated GFR measurements for most clinical purposes.

Urinalysis

Urinalysis can be a very useful test, although it can also be over-ordered in low-risk, asymptomatic individuals. The normal color of the urine is derived from urochromes, which are pigments excreted in the urine. Abnormal color or appearance of the urine may be explained by many conditions (Table 100-2). The basic analysis of the urine sample involves measurements with commercially available dipsticks or microscopic analyses.

Urine Dipstick

The *specific gravity* of the urine generally is related linearly with osmolality. However, it can be raised by the presence of molecules with relatively high molecular weight, such as glucose or contrast dye. A fixed specific gravity of 1.010, so-called isosthenuria, is characteristic of chronic kidney disease (Chapter 117).

Urine pH typically is 5 as a result of daily net acid excretion. An alkaline pH often is noted after meals, when an "alkaline tide" to balance gastric acid excretion increases urine pH. A high urine pH also is seen in patients who are on a vegetarian diet. An exceptionally high urine pH is indicative of an infection with a urea-splitting organism, such as *Proteus* species (Chapter 263). An inappropriately high urine pH in the setting of systemic non–anion gap metabolic acidosis may be seen in certain forms of renal tubular acidosis (Chapter 104). In a proximal renal tubular acidosis, the urine pH is high until the tubular reabsorption threshold for bicarbonate, which is abnormally low, is reached. At this point, the urine pH decreases to 5. In distal renal tubular acidosis, the inability to create a sufficient gradient for hydrogen ions results in a urine pH that is always higher than 5.5. In type 4 renal tubular acidosis, the urine pH is often 5, and the urine net charge is often positive, thereby confirming the

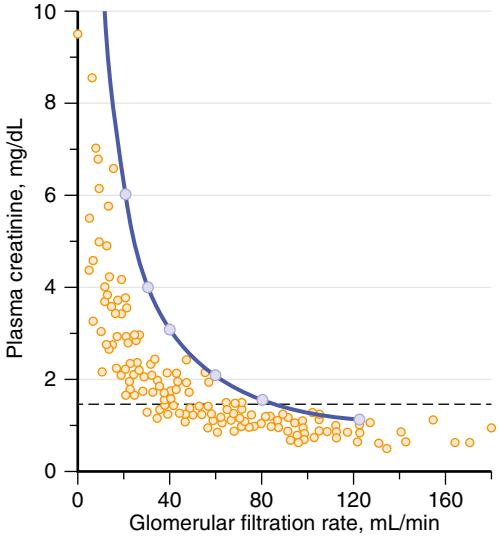

FIGURE 100-2. Relationship between plasma creatinine and glomerular filtration rate measured by inulin clearance in 171 patients (*circles*). The *continuous line* reflects the idealized relationship between these parameters if creatinine were excreted solely by glomerular filtration; the *dashed line* represents an upper limit of "normal" for the creatinine concentration of 1.4 mg/dL. (Redrawn from Shemesh O, Golbetz H, Kriss JP, et al. Limitations of creatinine as a filtration marker in glomerulopathic patients. *Kidney Int.* 1985;28:830-838.)

TABLE 100-1 CONSIDERATIONS FOR INTERPRETATION OF GFR VALUES

ASSUMPTIONS
Assumption of steady state
Assumption of complete 24-hour urine collection
FACTORS THAT ALTER CREATININE PRODUCTION OR SECRETION
Drugs that reduce creatinine secretion (cimetidine, trimethoprim, poly adenosine diphosphate-ribose polymerase inhibitors, tyrosine kinase inhibitors)
Diet (high protein meals can temporarily increase serum creatinine)
Muscle mass (higher muscle mass associated with increased production)
Rhabdomyolysis (increased release due to muscle injury)
Nephrotic syndrome and sickle cell disease (increased secretion)

GFR = glomerular filtration rate.

TABLE 100-2 MACROSCOPIC APPEARANCE OF URINE

APPEARANCE	CAUSE
Milky	Acid urine: urate crystals Alkaline urine: insoluble phosphates Infection: pus Spermatozoa Chyluria
Smoky pink	Hematuria (>0.54 mL blood/L urine)
Foamy	Proteinuria
Blue or green	*Pseudomonas* urinary tract infection Bilirubin Methylene blue
Pink or red	Aniline dyes in sweets Porphyrins (on standing) Blood, hemoglobin, myoglobin Drugs: phenindione, phenolphthalein Anthocyaninuria (beetroot, "beeturia")
Orange	Drugs: anthraquinones (laxatives), rifampicin Urobilinogenuria
Yellow	Mepacrine Conjugated bilirubin Phenacetin Riboflavin
Brown or black	Melanin (on standing) Myoglobin (on standing) Alkaptonuria
Green or black	Phenol Lysol
Brown	Drugs: phenazopyridine, furazolidone, L-dopa, niridazole Hemoglobin and myoglobin (on standing) Bilirubin

absence of significant amounts of ammonium in the urine; this defect, which is most often present in patients with diabetic kidney disease, is exacerbated by the accompanying hyperkalemia.

Glucose in the urine is detected by an assay using dipsticks impregnated with the enzyme glucose oxidase. Glycosuria, which is seen in diabetes mellitus (Chapter 210), when pregnancy causes the tubular threshold for glucose reabsorption to change, and in tubular diseases that affect the proximal convoluted tubule and cause tubular glycosuria, is an independent risk factor for mortality. Evidence for pan–proximal tubular dysfunction (e.g., glycosuria, aminoaciduria, phosphaturia) indicates that Fanconi syndrome is present.

The dipstick for *protein* is a sensitive assay based on color change induced by the presence of proteins at a given pH. It is most sensitive to the presence of albumin[6] and is much less sensitive to other proteins, such as the light chains of Bence Jones protein (Chapter 173). The presence of 1+ protein correlates with about 30 mg/dL of albuminuria, and 3+ protein correlates with more than 500 mg/dL of proteinuria. Because the dipstick is not a quantitative measurement, small amounts of proteinuria in an oliguric patient may give the false appearance of high-grade proteinuria. The excretion of abnormal quantities of albumin below the level detectable by the urine dipstick is called *microalbuminuria*. Normal albumin excretion, which is less than 30 mg/day, is best detected by radioimmunoassay or enzyme immunoassay. Microalbuminuria is the earliest clinically detectable stage of diabetic nephropathy (Chapter 109). Proteinuria of increasing severity is associated with a more rapid decline in the GFR, regardless of the GFR and even after acute kidney injury,[7] except in minimal change disease (Chapter 107).

The dipstick for *heme* uses the peroxidase-like activity of hemoglobin and myoglobin molecules to detect the presence of heme pigment. The reaction occurs on exposure to hemoglobin, myoglobin, or intact RBCs. Urine dipstick testing is very sensitive (97%) and reasonably specific (75%) for the detection of hematuria. The presence of myoglobin, which is found in patients with rhabdomyolysis (Chapter 99), or free hemoglobin, which is seen in patients with intravascular hemolytic anemias (Chapter 147), is suspected if the heme reaction is intensely positive and there is a paucity of cellular elements in the sediment. Since RBCs lyse rapidly on storage, especially in a hypotonic urine, their absence on routine analysis of the urinary sediment is likely to provide false reassurance in the presence of a positive dipstick. Persistent, isolated, asymptomatic, microscopic hematuria is an independently significant risk factor for the subsequent development of end-stage renal disease (Chapter 116). Although gross asymptomatic hematuria is associated with cancer in 8 to 25% of cases, only about 2.5% of patients with dipstick-positive hematuria have cancer, including less than 0.5% of people under age 50 years.

The dipstick detection of *leukocytes* depends on the presence of leukocyte esterase. Leukocyte esterase is usually present in infections (Chapter 263) and in inflammatory conditions. When positive, it is reasonable to proceed directly to a urine culture without requiring confirmation of leukocytes on a microscopic examination of the urine.[8,9]

Urine Sediment

RBCs, white blood cells (WBCs), tubular cells, transitional cells, and squamous epithelial cells may be seen in the urine.[10] Casts are formed in tubules, may contain cells or cellular debris, or may be acellular.

Hematuria

RBCs may originate from intrarenal vessels, glomeruli, tubules, or anywhere in the urogenital tract (Fig. 100-3). Dysmorphic RBCs are cells that have been deformed by transit through the glomerulus and through the medullary interstitium, as opposed to RBCs from the remainder of the genitourinary tract (Figs. 100-4 and 100-5); these cells are often lysed and less refractile than nonglomerular RBCs. Dysmorphic RBCs often fragment with poikilocytosis and with blebs, forming so-called "Mickey Mouse" RBCs. Phase contrast microscopy aids in the identification of dysmorphic RBCs. The presence of a majority of dysmorphic RBCs in a urine sediment points to a glomerular origin of the hematuria. The presence of RBC casts is often conclusive evidence for the presence of glomerulonephritis.

In asymptomatic individuals with three or more RBCs per high-powered field in a properly collected urine specimen, formal evaluation of the lower and upper urinary tract is commonly indicated, regardless of whether or not patients are taking anticoagulants,[11] if infection, menstruation, and vigorous exercise can be excluded as causes. Lower urinary tract evaluation by cystoscopy should be performed in patients over age 35 years or with risk factors for urinary tract malignancies. Upper tract evaluation usually is performed by computed tomography (CT) or magnetic resonance (MR) imaging urography.[12] Findings suggestive of intrinsic parenchymal renal disease (dysmorphic RBCs, RBC casts, proteinuria, cellular casts) require nephrologic evaluation but do not preclude the need for a urologic evaluation.

Pyuria

WBCs are seen most commonly in bacterial urinary tract infections, but some patients with evident pyuria will have negative urine cultures. Infectious causes of sterile pyuria include tuberculosis (Chapter 299), gonorrhea (Chapter 275), chlamydia (Chapter 294), mycoplasma (Chapter 293) and ureaplasma (Chapter 293, 263, and 264), genital herpes (Chapter 345), trichomoniasis (Chapter 324), fungal infections (Chapter 307), and schistosomiasis (Chapter 326). Even when bacteriuria is confirmed, asymptomatic patients rarely require treatment (Chapter 263).[13,14]

WBCs also can be seen in acute interstitial nephritis, infections with *Legionella* (Chapter 290) and *Leptospira* (Chapter 298) species, allergic interstitial nephritis (Chapter 108), atheroembolic diseases (Chapter 110), granulomatous diseases such as sarcoidosis (Chapter 83), IgG4-related interstitial nephritis, and tubulointerstitial nephritis and uveitis syndrome (Table 100-3). Mononuclear cells often appear with transplant rejection. Tubular cells, which are seen in many conditions involving tubulointerstitial diseases, also are seen in ischemic and nephrotoxic injury, such as with myeloma kidney (Chapter 173) or cast nephropathy. Eosinophils require special stains, with the Giemsa stain being much less sensitive than the Hansel stain (Chapter 108). Urine eosinophils classically are seen in allergic interstitial nephritis (Chapter 108), but they also are seen in atheroembolic disease (Chapter 110), prostatitis (Chapter 114), and vasculitis.

Casts and Crystals

Casts, which are formed in tubules, are characterized by the arrangement of the cells in a clearly formed matrix composed of Tamm-Horsfall protein. Because casts are formed in the renal parenchyma, they may give a clue to the origin of accompanying cellular elements.

Hyaline casts are composed of Tamm-Horsfall proteins that are formed normally and are seen in increased numbers after exercise (Fig. 100-6). *Granular casts* are degenerated tubular cell casts that are seen in the setting of tubular

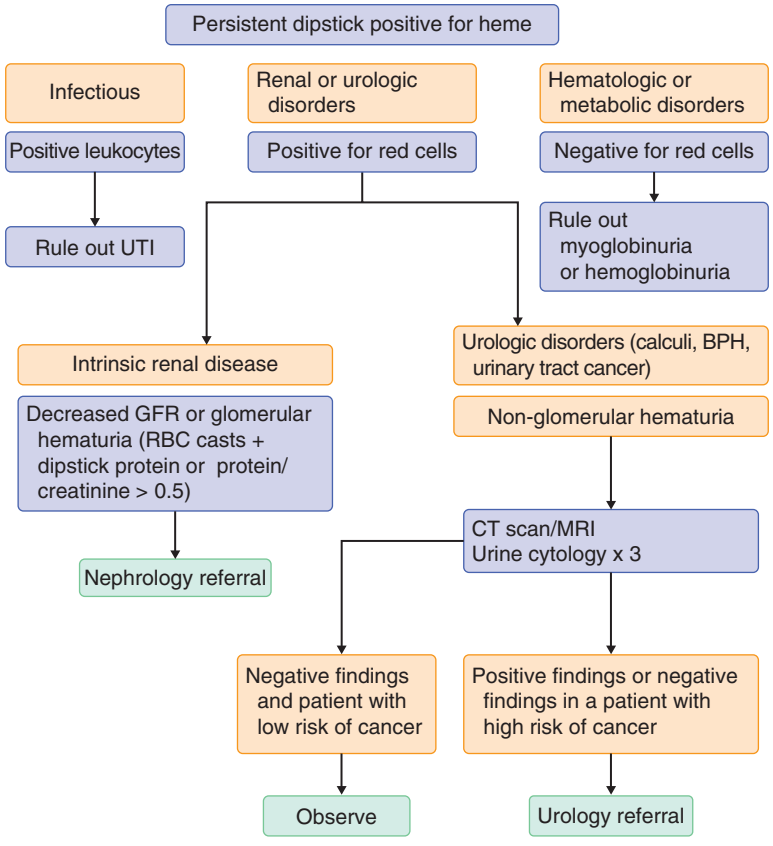

FIGURE 100-3. Algorithm for the evaluation of asymptomatic hematuria. BPH = benign prostatic hyperplasia; CT = computed tomography; GFR = glomerular filtration rate; MRI = magnetic resonance imaging; RBC = red blood cell; UTI = urinary tract infection. (Modified from Cohen RA, Brown RS. Microscopic hematuria. *N Engl J Med*. 2003;348:2330-2338.)

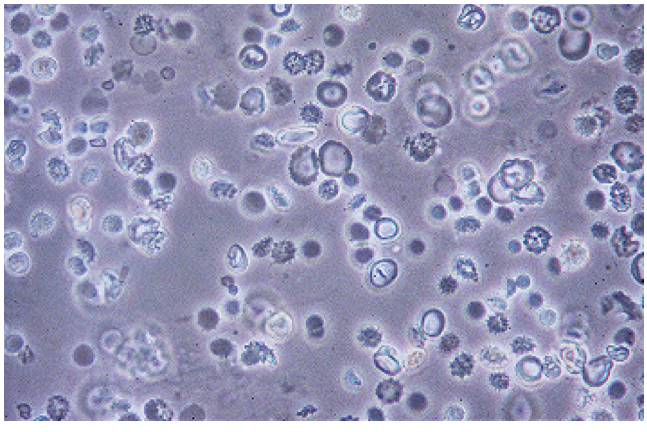

FIGURE 100-4. Dysmorphic erythrocytes. These dysmorphic erythrocytes vary in size, shape, and hemoglobin content and reflect glomerular bleeding. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

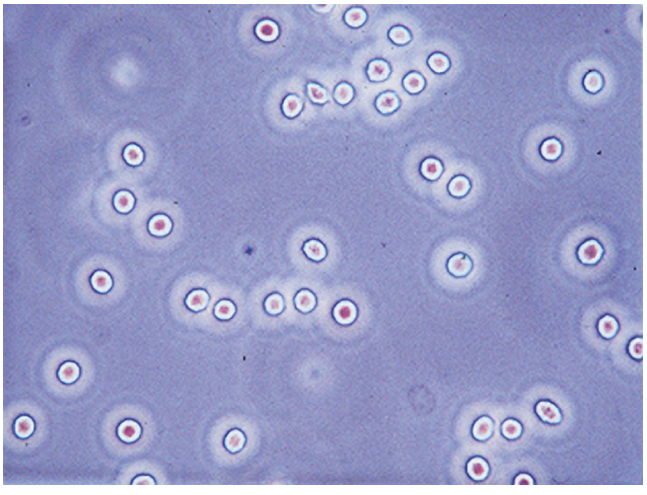

FIGURE 100-5. Isomorphic erythrocytes. These erythrocytes are similar in size, shape, and hemoglobin content. Isomorphic cells reflect nonglomerular bleeding from lesions such as calculi and papillomas or hemorrhage from cysts in polycystic renal disease. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

injury (Fig. 100-7). *Pigmented granular casts* are seen in rhabdomyolysis (Chapter 99) with myoglobinuria or, rarely, hemoglobinuria. *RBC casts* (Fig. 100-8) are rarely seen in allergic interstitial nephritis and diabetic nephropathy, but they are frequently seen in acute glomerulonephritis (Chapter 107). The presence of RBC casts in a patient with microscopic hematuria can narrow the focus of the evaluation to a glomerular lesion. *WBC casts* are seen commonly in pyelonephritis (Chapter 263) and in acute and chronic nonbacterial infections. They also are seen in other conditions in which WBCs are associated with parenchymal renal processes, such as allergic interstitial nephritis (Chapter 108), atheroembolic diseases (Chapter 110), and granulomatous diseases such as sarcoidosis (Chapter 83). Rarely, WBC casts can be a dominant feature of many diseases that traditionally are thought of as glomerular diseases, such as lupus nephritis (Chapter 245) and antineutrophil cytoplasmic antibody (ANCA)–associated glomerulonephritis (Chapter 249). *Tubular cell casts* are seen with any acute tubular injury and are the dominant cellular casts in ischemic acute tubular necrosis (Chapter 106). They also can be seen with nephrotoxic injury, such as with aminoglycosides and cisplatin. Some casts may contain both leukocytes and tubule cells.

Crystals can be a normal finding in the urine or serve as clues to pathophysiologic processes. Certain crystals, such as the hexagonal crystals seen with cystinuria (Chapter 111), are always abnormal (Fig. 100-9). Others, such as the octahedral calcium oxalate crystals (Fig. 100-10), may be a normal finding or may be evidence for ethylene glycol intoxication (Chapter 96). Coffin lid–shaped triple phosphate crystals, which are composed of ammonium magnesium phosphate (Fig. 100-11), are seen in urinary tract infections with urea-splitting organisms (Chapter 263). Uric acid crystals, sodium urate

TABLE 100-3 CAUSES OF STERILE PYURIA

INFECTIOUS
Current use of antibiotics
Past treated urinary tract infection (within past 2 weeks)
Tuberculosis (Chapter 299)
Gonorrhea (Chapter 275) and chlamydia (Chapter 294)
Mycoplasma and ureaplasma (Chapter 293)
Genital herpes (Chapter 345)

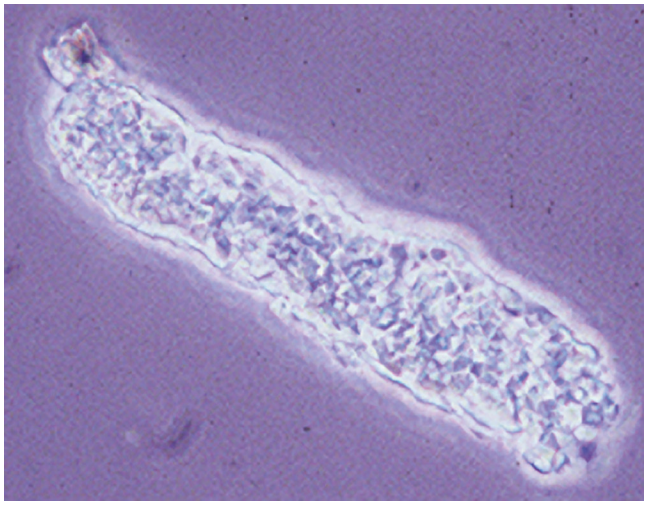

FIGURE 100-7. Number and type of granules and their density in the cast vary in different casts. The presence of erythrocytes in this cast may mean that the granules are derived partly from disrupted erythrocytes. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

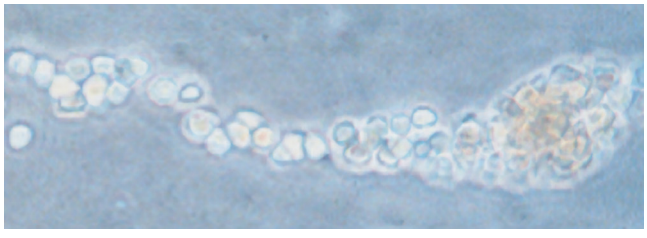

FIGURE 100-8. A cast composed entirely of erythrocytes reflects heavy hematuria and active glomerular disease. Crescentic nephritis is likely to be present if erythrocyte cast density is greater than 100/mL. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

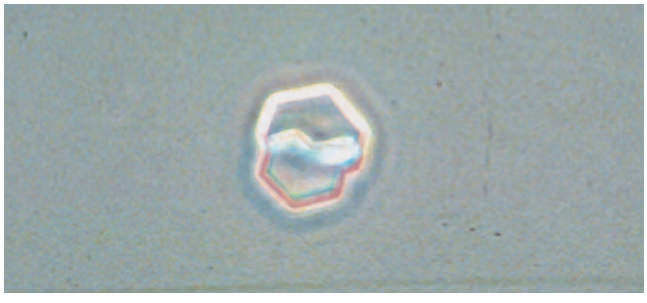

FIGURE 100-9. Typical hexagonal cystine crystal. A single crystal provides a definitive diagnosis of cystinuria. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

crystals (Fig. 100-12), and calcium phosphate amorphous crystals are common and do not usually have pathologic significance.

Other Elements

Bacteria may be seen in the urine sediment. A spun urine sediment may show rods or cocci in chains, but bacteria are identified best by Gram staining of the urine sediment. Budding yeast forms (which are highly refractile), trichomonads, and spermatozoa also may be seen in the urinary sediment.

Disorders of Electrolytes

The kidneys mediate the homeostatic balance of a variety of electrolytes. Electrolyte disorders may accompany renal failure or may reflect isolated defects in tubular function or specific defects in ion transporters. The functional integrity of the renal tubules can be assessed by calculating the fractional excretion of an electrolyte *X*.

$$FE = \frac{(urine_X)/(plasma_X)}{(urine_{Cr})/(plasma_{Cr})} \times 100 = \frac{(urine_X) \times (plasma_{Cr})}{(urine_{Cr}) \times (plasma_X)} \times 100$$

Imbalances in renal sodium and water handling can lead to extracellular volume depletion or to the formation of edema (Chapter 102). Potassium homeostasis is regulated primarily at the distal nephron, but dietary intake, transcellular shifts, and gastrointestinal losses also contribute to balance (Fig. 100-13; Chapter 103). Calcium homeostasis is regulated by the actions of parathyroid hormone, calcitonin, and vitamin D on bone, intestine, kidney, and parathyroid tissue. Although Ca^{++} is also filtered and excreted by the kidney, the important role of these hormones generally places disorders of hypocalcemia and hypercalcemia within endocrinology (Chapter 227). Magnesium deficiency (Chapter 105) may be caused by decreased intake (either orally or by impaired intestinal absorption) or by increased losses via the gastrointestinal tract, kidneys, or skin. Conversely, hypermagnesemia

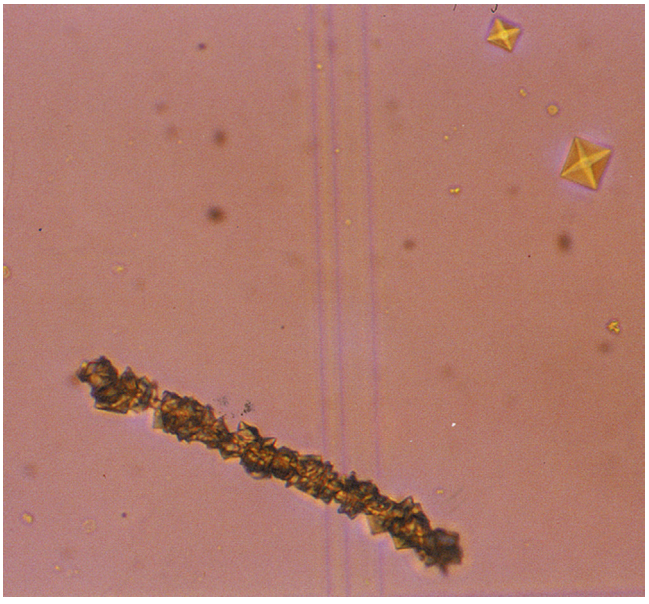

FIGURE 100-10. Oxalate crystals. A pseudocast of calcium oxalate crystals accompanied by crystals of calcium oxalate dehydrate. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

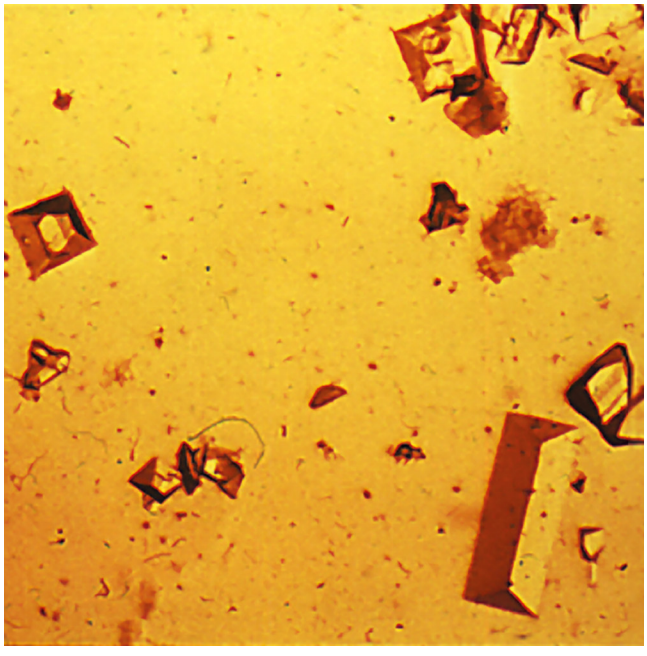

FIGURE 100-11. Coffin lid crystals of magnesium ammonium phosphate (struvite). (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

(Chapter 105) can rarely occur in individuals with a normal GFR when the rate of intake exceeds capacity of renal clearance (e.g., excessive use of Mg^{++}-based antacids or large parenteral doses given for preeclampsia). Similar to potassium, hyperphosphatemia (Chapter 105) can arise from reduced excretion (primarily chronic kidney disease), excessive intake, or redistribution of cellular phosphorus. Hypophosphatemia also can be caused by shifts into the intracellular compartment, or may occur from malnutrition or from renal losses. High urine phosphorus in the setting of hypophosphatemia suggests a renal tubule defect, hyperparathyroidism (Chapter 227), or a form of rickets (Chapter 226) and can be assessed by determining the fractional excretion.

SPECIFIC RENAL SYNDROMES

This chapter considers the approach to the patient with acute kidney injury (Chapter 106), glomerular syndromes (nephrotic vs. nephritic; Chapter 107), tubulointerstitial disease (Chapter 108), vasculitis and vascular diseases of the kidney (Chapter 110), papillary necrosis, and chronic kidney disease (Chapter 116).

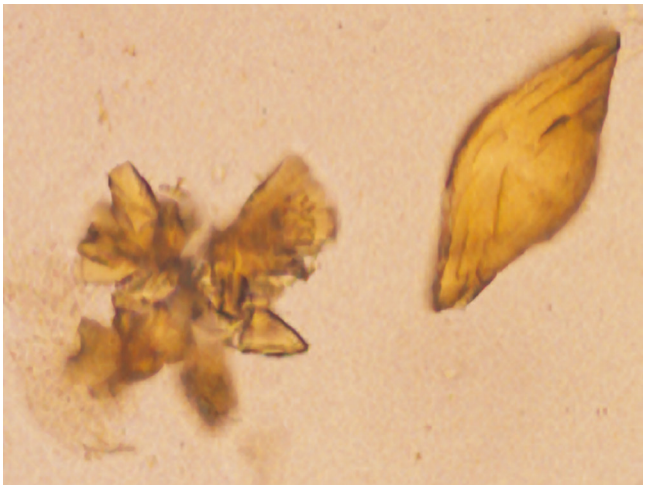

FIGURE 100-12. Urate crystals. Complex crystals suggestive of acute urate nephropathy or urate nephrolithiasis. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

ACUTE KIDNEY INJURY

Acute kidney injury (Chapter 106) is a syndrome in which glomerular filtration declines during a period of hours to days. The serum creatinine level is elevated in both acute and chronic kidney disease, but an actively rising serum creatinine level confirms an acute or acute-on-chronic insult to kidney function. As a blood filtration organ, the kidney is susceptible to an acute compromise of renal arterial perfusion (Chapter 110), such as prerenal kidney injury, or blockage in urine outflow, such as urinary obstruction due to benign prostatic hypertrophy (Chapter 114). Thus, the patient with acute renal failure is best approached by evaluation for prerenal, renal, and postrenal causes. The intrarenal causes of acute kidney injury include acute tubular necrosis (Chapter 106), acute interstitial nephritis (Chapter 108), acute glomerulonephritis (Chapter 107), and acute vasculitis and vascular disease (Chapters 107, 110 and 249). The careful and systematic evaluation of the patient should start with a thorough history and physical examination, which should be followed by selected laboratory tests and often an imaging test, such as renal ultrasonography. Most cases of acute renal failure in the hospital have hemodynamic or toxic causes, so prerenal azotemia and acute tubular necrosis must be considered carefully and distinguished from one another.

DIAGNOSIS

Laboratory Testing

The normal concentration of blood urea nitrogen (BUN), which is a product of protein catabolism, is about 10-fold higher than the creatinine concentration. Because the BUN-to-creatinine ratio commonly rises with arterial underfilling, BUN typically is used as a marker of effective volume status. Classically, the BUN-to-creatinine ratio will be higher than 15 to 20 in prerenal azotemia but 10 or close to it in acute tubular necrosis. However, the BUN concentration (and hence its ratio to creatinine concentration) may be inappropriately high in other circumstances, such as with high protein intake, gastrointestinal bleeding, or the use of steroids or tetracyclines. The BUN concentration and its ratio to creatinine concentration may be low in patients who have a poor dietary intake of protein, malnutrition, or liver disease.

The excretion of sodium in the setting of oliguria and acute kidney injury (Chapter 106) often gives insight into the appropriateness of tubular function. The fractional excretion of sodium (FE_{Na}) is calculated as follows:

$$FE_{Na} = (urine_{Na}/plasma_{Na})/(urine_{Cr}/plasma_{Cr}) \times 100$$

where *Na* is the sodium concentration (in mmol/L) and *Cr* is the creatinine concentration (in mmol/L or mg/dL). In the setting of oliguria, FE_{Na} below 1% often denotes prerenal azotemia, whereas FE_{Na} above 1% suggests intrinsic renal damage. Although this measurement is generally useful, FE_{Na} below 1% may be seen without evidence of a prerenal component, including contrast nephropathy (Chapter 106), hepatorenal syndrome (Chapter 139), obstructive

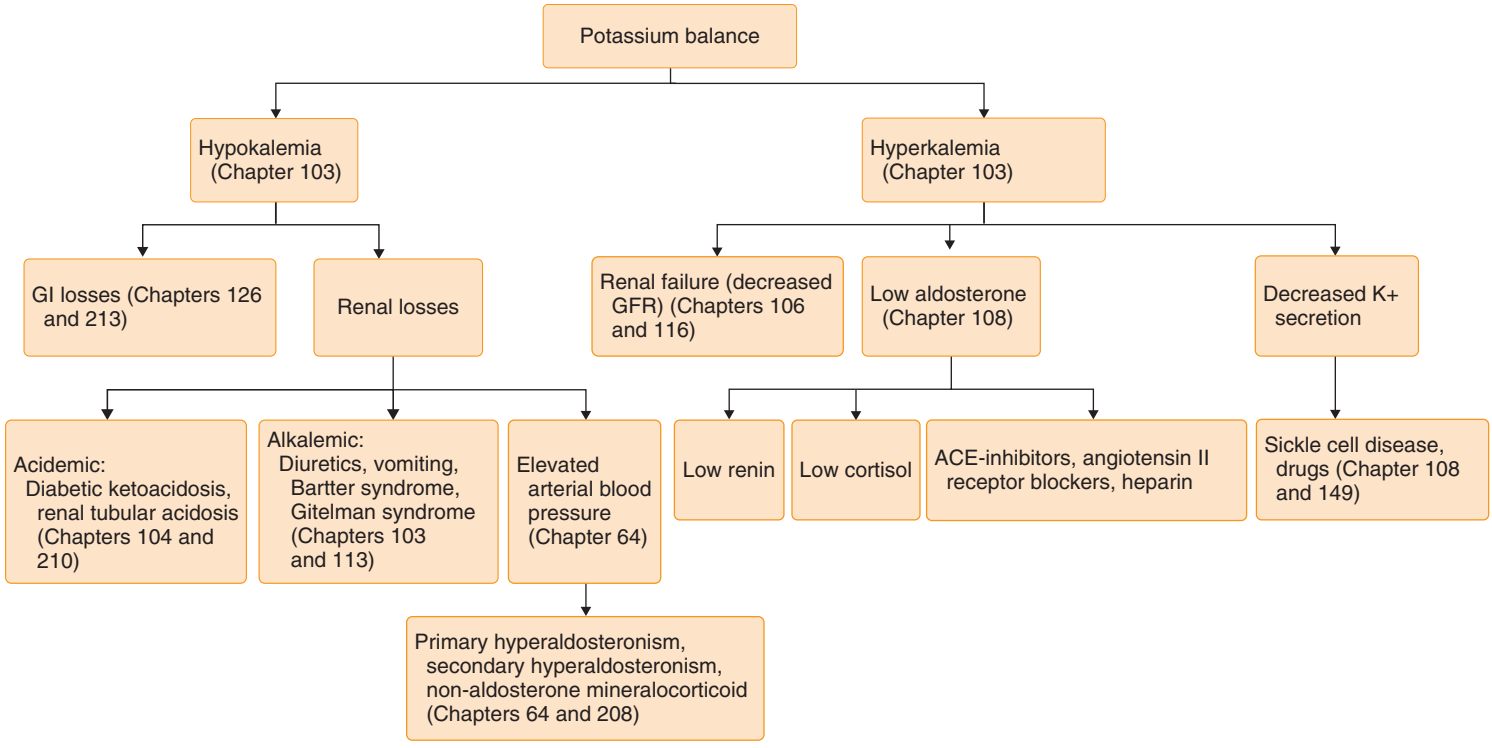

FIGURE 100-13. Regulation of potassium balance. ACE = angiotensin-converting enzyme; AKI = acute kidney injury; GI = gastrointestinal.

uropathy (Chapter 114), interstitial nephritis (Chapter 108), glomerulonephritis (Chapter 107), and rhabdomyolysis (Chapter 99). Conversely, a high FE_{Na} can be seen in cases in which there is a prerenal component, including diuretic use, adrenal insufficiency (Chapter 208), cerebral salt wasting, and salt-wasting nephropathy (Chapter 102). The FE_{Na} must be evaluated in the context of the clinical situation because it can be low or high in a normal patient or in a patient with chronic kidney disease. Ultimately, a patient's volume status is best evaluated at the bedside and should not be deduced solely from a measurement of electrolytes.

Imaging

Ultrasonography, which is the most commonly used renal imaging study (Fig. 100-14),[15] provides reliable information about obstruction, kidney size, presence of masses, and renal echotexture. Ultrasonography has only a 90% sensitivity for the detection of hydronephrosis and hence is not sufficient to exclude obstruction (Chapter 114) with certainty. In addition, its inability to detect stones in the ureters and bladder limits its utility in the evaluation for kidney stones (Chapter 111). Ultrasonography can detect vascular disease, and Doppler imaging permits evaluation of the renal vessels with resistive indices. Resistive indices are crucial in ascribing renal dysfunction to the detected vascular disease (Chapter 110). A high resistive index reflects parenchymal disease with scarring and indicates that intervention on the vascular disease itself is unlikely to improve renal function.

A CT scan stone protocol to assess the kidneys, ureters, and bladder is the study of choice for detecting kidney stones (Chapter 111) because of its ability to detect all types of stones, nonobstructing stones, and stones in the ureters (Fig. 100-15). Masses in the kidney can be evaluated with either contrast CT or a renal ultrasound examination. CT angiography with iodinated contrast material can assess possible renal artery stenosis (Chapter 110) with an accuracy comparable to that of MR angiography.

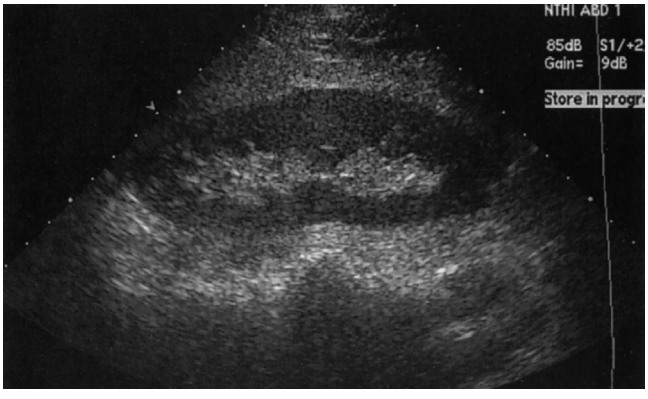

FIGURE 100-14. Normal findings on sagittal renal ultrasound. The cortex is hypoechoic compared with the echogenic fat containing the renal sinus. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

GLOMERULAR SYNDROMES: NEPHROTIC VERSUS NEPHRITIC

The nephrotic syndrome (Chapter 107) is characterized by the presence of proteinuria of more than 3.5 g/day/1.73 m^2, with accompanying edema, hypertension, and hyperlipidemia. Other consequences include a predisposition to infection and hypercoagulability. In general, the diseases associated with nephrotic syndrome do not cause acute kidney injury, although acute kidney injury may be seen with minimal change disease, human immunodeficiency virus (HIV)–associated nephropathy, and bilateral renal vein thrombosis (Chapter 110). The causes of primary idiopathic nephrotic syndrome, in decreasing order of prevalence, are focal and segmental glomerulosclerosis, membranous nephropathy, minimal change disease, and membranoproliferative glomerulonephritis. Membranous nephropathy has been associated with antibodies to the M-type phospholipase A_2 receptor. Secondary causes of the nephrotic syndrome include diabetic nephropathy (Chapter 109), amyloidosis (Chapter 174), and membranous lupus nephritis (Chapters 107 and 245).

The acute nephritic syndrome is an uncommon but dramatic presentation of an acute glomerulonephritis (Chapter 107). The hallmark of the acute nephritic syndrome is the presence of dysmorphic RBCs and RBC casts, but their absence does not exclude the syndrome. The acute nephritic syndrome can be caused by any of the rapidly progressive glomerulonephropathies with ANCA-associated vasculitis (granulomatosis with polyangiitis, microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis), anti–glomerular basement membrane (anti-GBM) glomerulonephritis, and immune complex–mediated glomerulonephritis (including systemic lupus erythematosus, cryoglobulinemia, postinfectious glomerulonephritis, endocarditis, IgA nephropathy, and IgA vasculitis). The rapid decline in renal function often warrants urgent and usually inpatient evaluation.

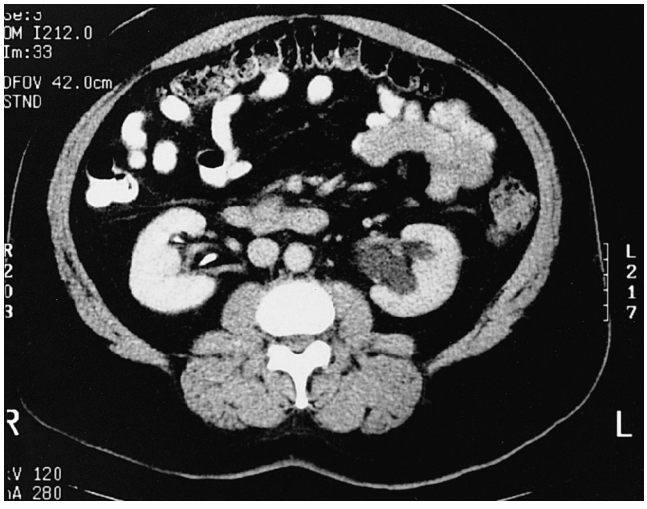

FIGURE 100-15. Delayed excretion in the left kidney secondary to a distal calculus. Contrast-enhanced computed tomography scan shows dilated left renal pelvis. (From Johnson RJ, Feehally J. *Comprehensive Clinical Nephrology*. London: Mosby; 2000.)

DIAGNOSIS

Laboratory Testing

Proteinuria (as albuminuria) of more than 3.5 g in 24 hours generally indicates glomerular disease (Chapter 107). Lesser quantities do not preclude glomerular disease, and electrophoresis gives valuable insight into the composition of the proteinuria (Chapter 173). On occasion, overflow proteinuria of a low-molecular-weight protein, such as light chains in Bence Jones proteinuria, can be higher than 3.5 g/day without any of the manifestations or implications of the nephrotic syndrome; a urine protein electrophoresis study is important in making the distinction. A comparison of the microalbumin-to-creatinine ratio with the protein-to-creatinine ratio will give an insight into the presence of Bence Jones protein because of the absence of albuminuria despite significant proteinuria. Collection must be done by discarding the first morning void and collecting all urine output for the next 24 hours, including the first morning void the next day.

The 24-hour urine collection for protein excretion is cumbersome and subject to inaccuracies. Instead, a spot urine sample for protein and creatinine can be used to estimate the amount of protein excreted. A protein-to-creatinine ratio of 3 translates to a 24-hour protein excretion of about 3 g. The ratio is most accurate when the first morning urine collection is used and may be inaccurate in patients with orthostatic proteinuria.

The evaluation of proteinuric renal dysfunction, particularly when glomerular diseases are suspected, should follow a stepwise progression from noninvasive serologic evaluation to a definitive or confirmatory diagnostic evaluation, such as a renal biopsy. Sometimes an expeditious diagnosis is needed, and a biopsy may be done relatively early in the evaluation.

Serologies

An *antinuclear antibody* (ANA) titer can be useful to evaluate glomerular disease in either nephrotic or nephritic presentations. A high ANA titer (e.g., 1 : 320), especially if it is accompanied by a more specific finding such as anti–double-stranded DNA antibody or anti-Smith antibody, can be highly specific for the diagnosis of lupus nephritis (Chapter 245), which usually requires a renal biopsy. Lower titers (e.g., 1 : 80 or 1 : 40) are nonspecific.

A *rheumatoid factor* titer will usually be elevated in patients with rheumatoid arthritis (Chapter 243), but vasculitis is a relatively late and rare event. Rheumatoid factor can be detected in some forms of cryoglobulinemia (Chapter 173); for example, IgM and occasionally IgG, which is present in type II and type III cryoglobulinemia, has rheumatoid factor activity. Rheumatoid factor also can be seen as a nonspecific finding in bacterial endocarditis (Chapter 61) and systemic vasculitis (Chapter 249).

The levels of *complement* components C3 and C4 and the 50% hemolyzing dose of complement (CH_{50}) usually are measured to evaluate suspected rapidly progressive glomerulonephritis (Chapter 107). Complement levels are usually low in active systemic lupus erythematosus (Chapter 245), post-streptococcal glomerulonephritis (Chapter 107), endocarditis (Chapter 61), membranoproliferative glomerulonephritis, cryoglobulinemia (Chapter 173), shunt nephritis with infection of a ventriculoatrial shunt, and glomerulonephritis associated with visceral abscesses. A particularly depressed C4 compared with C3 should raise the suspicion of cryoglobulinemia.

Serum immunoelectrophoresis will detect elevated polyclonal IgA levels in about 50% of cases of IgA nephropathy (Chapter 107) and IgA vasculitis (Chapter 107). Polyclonal elevation of IgG may occur in a variety of systemic diseases and is a nonspecific finding. The presence of a monoclonal protein in the serum should raise the suspicion for a monoclonal gammopathy–associated disease (Chapter 173). The differential diagnosis includes monoclonal gammopathy of uncertain significance, myeloma kidney, lymphomas (Chapter 171), amyloidosis (Chapter 174), light chain deposition disease, heavy chain deposition disease, immunotactoid glomerulonephritis, and cryoglobulinemia. These conditions, with the exception of monoclonal gammopathy of undetermined significance, have been collectively called monoclonal gammopathy of renal significance when they affect the kidney. The concentration of the monoclonal protein is higher when the diagnosis of multiple myeloma is made, but even small quantities of Bence Jones proteins in the serum can have clinical significance.

A *urine immunoelectrophoresis* always should be obtained if myeloma is suspected. Because a substantial fraction of multiple myelomas can have no heavy chain excretion and small quantities of light chains may be difficult to detect by serum immunoelectrophoresis, a urine immune electrophoresis test for Bence Jones protein should be obtained. In light chain myeloma, patients may have Bence Jones proteinuria even in the absence of an M component in the serum immunoelectrophoresis. Bence Jones proteinuria may be present in myeloma kidney, amyloidosis, light chain deposition disease, lymphoma, or, occasionally, monoclonal gammopathy of uncertain significance. However, some patients with systemic AL (light chain) amyloidosis have a normal serum immunoelectrophoresis and no Bence Jones proteinuria (Chapter 173). More sensitive assays for serum free light chains and an assessment of the ratio of κ to λ lights chains increase the sensitivity for detection of monoclonal gammopathies.

The *antineutrophil cytoplasmic antibody* (ANCA) assay has allowed earlier and more definitive recognition of vasculitic causes of rapidly progressive glomerulonephritis (Chapter 249), especially granulomatosis with polyangiitis, microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis, when it is confirmed by enzyme-linked immunosorbent assay. The antibodies cause two different patterns of staining: perinuclear staining (p-ANCA) and cytoplasmic staining (c-ANCA). Both antigens actually have a cytoplasmic distribution, and the perinuclear staining pattern is an artifact of the fixation method. In most cases, the antigen for p-ANCA is myeloperoxidase (MPO), whereas the antigen for c-ANCA is proteinase 3 (PR3). Anti-MPO antibodies are associated with microscopic polyangiitis, idiopathic crescentic glomerulonephritis, or Churg-Strauss syndrome (eosinophilic granulomatosis with polyangiitis; Chapter 249). Anti-PR3 antibodies often correlate with the classic disease of granulomatosis with polyangiitis (formerly known as Wegener granulomatosis) (Chapter 249).

Anti–glomerular basement membrane (anti-GBM) antibodies are autoantibodies to the Goodpasture antigen (Chapter 107), which resides in a domain of the α chain of type 4 collagen. An early and accurate diagnosis of Goodpasture syndrome can be made by immunofluorescence and confirmed by Western blot analysis. Anti-GBM antibody staining also may occur in the presence of a positive ANCA. In these cases, the theory is that exposure of the Goodpasture antigen, as a result of the glomerular injury, leads to anti-GBM antibody formation as a secondary process.

Cryoglobulins (Chapter 173) are thermolabile immunoglobulins. They are a single monoclonal type in type I cryoglobulinemia. In type II and type III cryoglobulinemia, however, the mixture of immunoglobulins includes one with rheumatoid factor activity against IgG. Type I and type II cryoglobulins are more likely to be associated with clinical disease, especially at higher titers. Type III cryoglobulinemia is often of less clinical significance. Type I cryoglobulinemia is seen with Waldenström macroglobulinemia and multiple myeloma (Chapter 173); type II with hepatitis C infection (Chapters 134 and 135), Sjögren syndrome (Chapter 247), lymphomas (Chapters 171 and 172), and systemic lupus erythematosus (Chapter 245); and type III with hepatitis C (Chapters 134 and 135), chronic infections, and inflammatory conditions. When cryoglobulinemia is associated with hepatitis C, the hepatitis C virus (HCV) RNA is concentrated in the cryoprecipitate as the antigen; the diagnosis can be made by an RNA assay of the cryoprecipitate at 37° C.

Membranous nephropathy is associated with chronic hepatitis B infection with hepatitis B surface antigenemia (Chapter 135). Classic polyarteritis nodosa (Chapter 249) occasionally is seen with chronic hepatitis B infection, often with surface antigenemia and hepatitis B e antigenemia. M-type phospholipase

A_2 receptor antibodies also have been detected as autoantibodies in about 70% of cases idiopathic membranous nephropathy and have diagnostic value. Antibodies to the thrombospondin type-1 domain-containing 7 A protein are detected in another 5 to 10% of cases.

Hepatitis C serology is associated with a variety of renal diseases, including cryoglobulinemia, membranoproliferative glomerulonephritis, and membranous nephropathy. The evaluation may include the antibody test and an assay for HCV RNA. On occasion, the HCV RNA analysis may have to be conducted on the cryoprecipitate at 37° C.

HIV-associated nephropathy (Chapter 107) is associated with nephrotic syndrome and acute kidney injury. In the appropriate clinical setting, HIV serology and viral titers are warranted tests for both clinical syndromes.

Streptococcal infection can be confirmed as the cause of postinfectious glomerulonephritis (Chapter 107) with an anti-DNase or antistreptolysin O assay. Acute and convalescent serology assays are used to confirm recent infection.

The erythrocyte sedimentation rate (ESR) is a relatively nonspecific test in the evaluation of renal disease. However, a high ESR often points to systemic vasculitis (Chapter 249), multiple myeloma (Chapter 173), or malignant disease as the underlying cause. However, the ESR often is elevated in the nephrotic syndrome (Chapter 107), including diabetic nephropathy (Chapter 109).

Renal Biopsy

No formal guidelines exist for the indications to perform a renal biopsy. Most nephrologists will perform a biopsy for adults with idiopathic nephrotic syndrome and for children with steroid-dependent or steroid-resistant nephrotic syndrome. In addition, acute kidney injury without an identifiable inciting cause is a clear indication for biopsy. Notably, patients with hospital-acquired kidney failure rarely meet this indication. Other abnormal clinical findings, such as gross or microscopic hematuria or subnephrotic proteinuria, often but not always lead to a kidney biopsy. Renal biopsy usually is performed percutaneously with real-time ultrasound or CT guidance. About 1 to 2% of patients without an underlying coagulopathy will develop bleeding that requires a transfusion. The transjugular approach can be used in patients in whom the risks for bleeding are high.

Genetic Testing

Inherited factors play an important role in kidney disease, and 25 to 30% of patients with CKD have a family history of nephropathy. Genetic testing can establish a genetic diagnosis in nearly 10% of patients with CKD and is useful even in patients who have had a renal biopsy.[16,17] The diagnostic yield is higher in patients who have a younger onset of disease, a family history of kidney disease, or multi-organ, syndromic features. The diagnostic yield is highest in patients with cystic kidney disorders (20 to 50%) and patients with nephrotic syndrome (5 to 25%), but full exome sequencing also has a diagnostic yield of about 20% in patients with CKD of unknown cause, thereby leading to the detection of many rare conditions spanning all major clinical categories of kidney disease (E-Fig. 100-1).[18]

TUBULOINTERSTITIAL DISEASES

Tubulointerstitial diseases (Chapter 108) vary in presentation from acute kidney injury to chronic kidney dysfunction that initially is manifested as asymptomatic mild renal insufficiency (Table 100-4). The urine sediment often contains small to moderate amounts of proteinuria, usually less than 1 g/day, as well as WBCs, RBCs, tubule cells, and WBC casts. RBC casts are rare in acute interstitial nephritis and more characteristic of glomerular disease.

TABLE 100-4 MAJOR CAUSES OF TUBULOINTERSTITIAL DISEASE

Ischemic and toxic acute tubular necrosis
Allergic interstitial nephritis
Interstitial nephritis secondary to immune complex–related collagen vascular disease, such as Sjögren disease or systemic lupus erythematosus
Granulomatous diseases: sarcoidosis, tubulointerstitial nephritis with uveitis
IgG4-related interstitial nephritis
Pigment-related tubule injury: myoglobinuria, hemoglobinuria
Hypercalcemia with nephrocalcinosis
Tubular obstruction: drugs such as indinavir, uric acid in tumor lysis syndrome
Myeloma kidney or cast nephropathy
Infection-related interstitial nephritis: *Legionella, Leptospira* species
Infiltrative diseases, such as lymphoma

Ig = immunoglobulin.

VASCULITIS AND VASCULAR DISEASES OF THE KIDNEY

Vascular diseases of the kidney can be divided into large-vessel obstruction and medium- to small-vessel diseases (Chapter 110). Renovascular disease is a common cause of hypertension, heart failure, and renal insufficiency. About 90% of renal artery stenosis is atherosclerotic in origin, with most of the remaining caused by fibromuscular dysplasia, which is more common in women 20 to 50 years of age. Medium-sized arterial vessel diseases include polyarteritis nodosa, which is seen in patients with hepatitis B (Chapters 134 and 135), HIV infection (Chapter 107), or, rarely, hepatitis C (Chapters 134 and 135). Symptoms include abdominal pain, hypertension, and mild renal insufficiency, often with a benign sediment; diagnostic findings include microaneurysms at the bifurcation of medium-sized arteries. Other diseases involving small vessels include atheroembolic disease (Chapter 110), which is seen after arteriography or surgery or, rarely, spontaneously. This syndrome typically affects the kidneys, gastrointestinal tract, and lower extremities, but it can also involve the central nervous system when the aortic arch is affected.

The thrombotic microangiopathies include hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura (Chapter 158). Thrombotic thrombocytopenic purpura is associated with an acquired inhibitor to or the congenital inherited absence of a protease that cleaves large-molecular-weight von Willebrand multimers. The hemolytic-uremic syndrome is caused by endothelial injury. In diarrhea-positive (or typical) hemolytic-uremic syndrome, the endothelial injury is induced by Shiga toxin from *Escherichia coli* O157:H7 infection. In diarrhea-negative (atypical) hemolytic-uremic syndrome, dysregulation of the alternative complement pathway is the underlying cause of endothelial injury. The antiphospholipid antibody syndrome (Chapter 67) can cause large-vessel thrombosis and stenosis as well as a thrombotic microangiopathy with proteinuria, hypertension, and renal insufficiency. Scleroderma renal crisis, which is a manifestation of systemic sclerosis (Chapter 246), often leads to an inexorable progression to end-stage renal insufficiency if untreated.

A systemic vasculitis may be manifested in a variety of ways, including skin manifestations such as petechial rash, purpura, digital gangrene, and splinter hemorrhages. Otitis, sinusitis, epistaxis, hemoptysis, and nasal septal ulcers are common manifestations of granulomatosis with polyangiitis (Chapter 249). Pulmonary hemorrhage can be a catastrophic manifestation of Goodpasture syndrome (Chapter 107), anti-GBM disease, or ANCA-associated vasculitis (Chapter 249). Abdominal pain and tenderness and gastrointestinal hemorrhage may be observed in IgA vasculitis and classic polyarteritis nodosa (Chapter 249). Neurologic symptoms may be a manifestation of vasculitis, such as microscopic polyangiitis (Chapter 249) and cryoglobulinemia (Chapter 173).

DIAGNOSIS

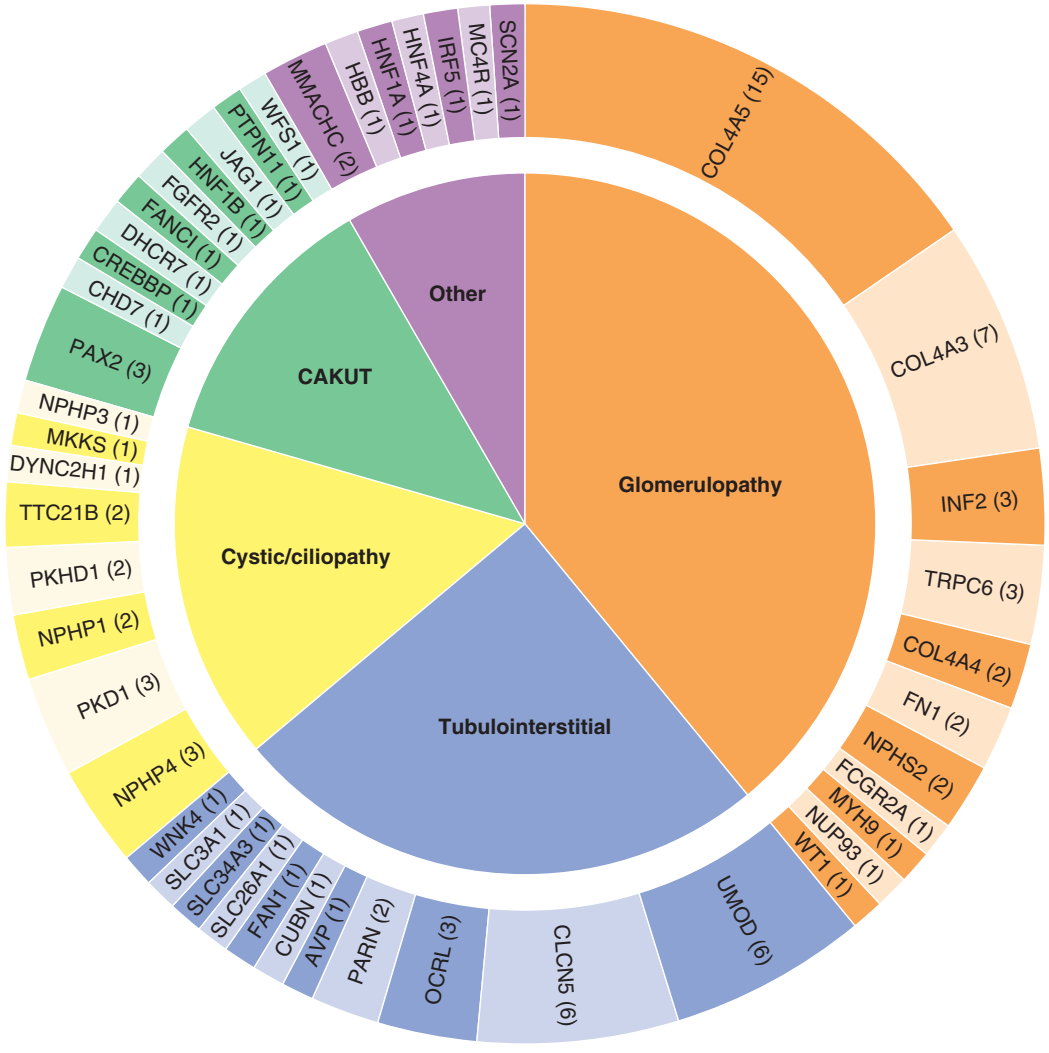
Radiologic Evaluation

Magnetic resonance imaging (MRI) with MR angiography (Fig. 100-16) is highly sensitive for detecting atherosclerotic renovascular disease (Chapter 110), but it tends to overestimate the degree of stenosis. Its accuracy in detecting fibromuscular dysplasia, however, is less well validated. MRI also can be used to evaluate renal masses. MRI does not require iodinated contrast material, but gadolinium-based contrast agents for vascular studies are associated with the syndrome of nephrogenic systemic fibrosis in patients with advanced renal failure (Chapter 246).

Renal arteriography, which is the "gold standard" in the evaluation of renal artery stenosis (Chapter 110), also is used for the evaluation of arteriovenous malformations, polyarteritis nodosa, and other vascular lesions of the kidneys. This invasive study uses iodinated contrast material and incurs a small risk for atheroembolic disease (Chapter 110). Therapeutic angioplasty and stenting can be done at the time of angiography.

PAPILLARY NECROSIS

Acute necrosis of the renal papilla is associated with sickle cell anemia (Chapter 149), analgesic nephropathy (Chapter 108), diabetic nephropathy (Chapter 109), and obstructive pyelonephritis (Chapter 263). In sickle cell disease (Chapter 149), the hypoxic and hypertonic milieu of the inner medulla promotes sickling, and chronic sickling at the vasa recta results in medullary ischemia. Massive and prolonged consumption of analgesics, particularly the combination of aspirin, caffeine, and acetaminophen, is associated with chronic interstitial nephritis and a predisposition to papillary necrosis (Chapter 108); medullary ischemia is thought to be caused by inhibition of synthesis



E-FIGURE 100-1. Diagnoses in individuals with kidney disease of unknown etiology. A review of six genome-wide studies identified 47 distinct genetic etiologies corresponding with the categories listed within the inner disc. The genes identified are represented in the outer ring, with the number of patients affected in parentheses. CAKUT = congenital anomalies of the kidneys and urinary tract. (From Hays T, Groopman EE, Gharavi AG. Genetic testing for kidney disease of unknown etiology. *Kidney Int*. 2020;98:590-600.)

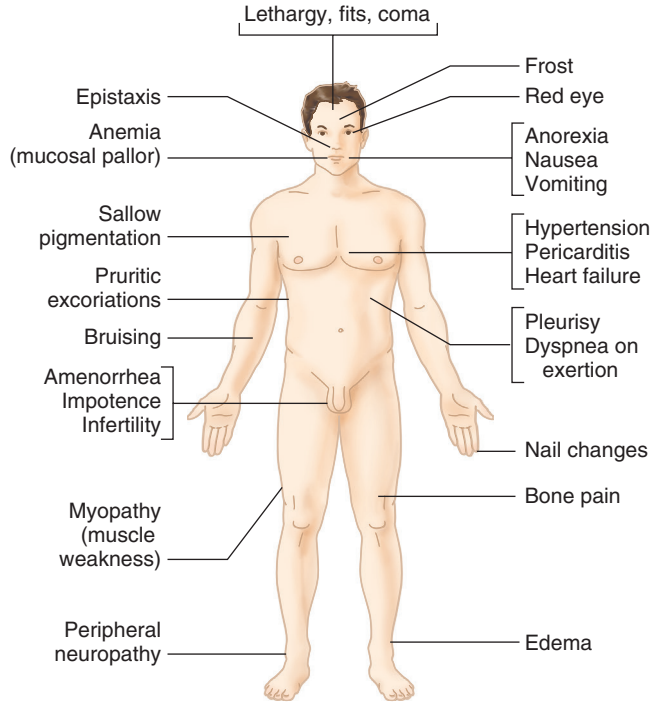

FIGURE 100-17. Common symptoms and signs of chronic renal failure. (Redrawn from Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*. 3rd ed. London: Mosby; 2003.)

of vasodilatory prostaglandins by aspirin, and direct toxicity is attributed to metabolites of phenacetin. Similarly, medullary perfusion is thought to be compromised in diabetic nephropathy (Chapter 109) and obstructive pyelonephritis (Chapter 114).

The clinical manifestations of papillary necrosis can include flank pain and hematuria. If the papilla is sloughed, obstruction may occur at the renal pelvis or ureter of the affected kidney, with referred pain migrating from the flank to the groin. A sloughed papilla may precipitate frank renal failure if the function of the contralateral kidney is impaired or if obstruction occurs at the level of the bladder or urethra.

Classically, papillary necrosis is diagnosed on an excretory pyelogram as a calyceal defect after sloughing of a papilla, but CT with contrast enhancement is as good for advanced lesions. If the necrotic papilla is retained, however, the defect will be more subtle. Transitional cell carcinoma (Chapter 182) can occur in the setting of papillary necrosis or can mimic its appearance. Obstruction, if present, must be relieved, but treatment otherwise is limited to pain control and hydration.

CHRONIC KIDNEY DISEASE

Chronic kidney disease, which is defined as either kidney damage or a GFR of less than 60 mL/min/1.73 m^2 for longer than 3 months. Kidney damage is defined as pathologic abnormalities or markers of kidney damage, including abnormalities in the composition of blood or urine or abnormalities on imaging tests. The excretion of 30 to 300 mg of albumin in a 24-hour period defines microalbuminuria. CKD is classified according to underlying cause, level of GFR, and level of albuminuria (Fig. 116-2). An estimated 12% of the adult U.S. population has abnormal albumin excretion in the urine, and the frequency increases with age. Kidney failure is defined as either a GFR of less than 15 mL/min/1.73 m^2 that is accompanied by signs and symptoms of uremia or a need for initiation of kidney replacement therapy for treatment of complications of decreased GFR (Fig. 100-17). End-stage renal disease includes all cases requiring treatment by dialysis or transplantation regardless of the level of GFR.

Patients with chronic kidney disease warrant referral to a nephrologist. Care of these patients should focus on efforts to slow disease progression, to optimize medical management, and to make a seamless transition to renal replacement therapy (Chapter 116). The care should include optimal blood pressure control, use of angiotensin-converting enzyme inhibitors and angiotensin receptor blockers if indicated, dietary counseling, careful management of calcium and phosphorus levels, control of the parathyroid hormone level, and management of anemia with the use of erythropoietin and iron supplements. Early referral for placement of access for dialysis and initiation of transplant evaluation (Chapter 117) are important components of the care of patients with chronic kidney disease.

101 STRUCTURE AND FUNCTION OF THE KIDNEYS

QAIS AL-AWQATI AND JONATHAN BARASCH

The kidney regulates the ionic composition and volume of body fluids, the excretion of nitrogenous waste, the elimination of exogenous molecules (e.g., many drugs), the synthesis of a variety of hormones (e.g., erythropoietin), and the metabolism of low-molecular-weight proteins (e.g., insulin). Befitting such an array of responsibilities, the kidney receives 25% of the cardiac output. The gross anatomy of the kidney is notable for a weight of approximately 150 g and a characteristic bean shape with approximate dimensions of 11 × 6 × 2.5 cm. On bisection, a gross structure is evident with an outer cortex and a more central medulla that narrows to multiple papillae at the apices of so-called pyramids (Fig. 101-1).

Understanding renal physiology, however, requires an appreciation of the intricate microstructure that underlies its complex functions. Although the kidney is an organ, the *nephron* is actually the organ's independent filtration unit. On average, each human kidney is composed of 1 million essentially identical nephrons. All functions of the kidney are performed by each individual nephron, and to a first approximation, all nephrons are independent of each other because they have their own innervation and blood supply.

of vasodilatory prostaglandins by aspirin, and direct toxicity is attributed to metabolites of phenacetin. Similarly, medullary perfusion is thought to be compromised in diabetic nephropathy (Chapter 109) and obstructive pyelonephritis (Chapter 114).

The clinical manifestations of papillary necrosis can include flank pain and hematuria. If the papilla is sloughed, obstruction may occur at the renal pelvis or ureter of the affected kidney, with referred pain migrating from the flank to the groin. A sloughed papilla may precipitate frank renal failure if the function of the contralateral kidney is impaired or if obstruction occurs at the level of the bladder or urethra.

Classically, papillary necrosis is diagnosed on an excretory pyelogram as a calyceal defect after sloughing of a papilla, but CT with contrast enhancement is as good for advanced lesions. If the necrotic papilla is retained, however, the defect will be more subtle. Transitional cell carcinoma (Chapter 182) can occur in the setting of papillary necrosis or can mimic its appearance. Obstruction, if present, must be relieved, but treatment otherwise is limited to pain control and hydration.

CHRONIC KIDNEY DISEASE

Chronic kidney disease, which is defined as either kidney damage or a GFR of less than 60 mL/min/1.73 m^2 for longer than 3 months. Kidney damage is defined as pathologic abnormalities or markers of kidney damage, including abnormalities in the composition of blood or urine or abnormalities on imaging tests. The excretion of 30 to 300 mg of albumin in a 24-hour period defines microalbuminuria. CKD is classified according to underlying cause, level of GFR, and level of albuminuria (Fig. 116-2). An estimated 12% of the adult U.S. population has abnormal albumin excretion in the urine, and the frequency increases with age. Kidney failure is defined as either a GFR of less than 15 mL/min/1.73 m^2 that is accompanied by signs and symptoms of uremia or a need for initiation of kidney replacement therapy for treatment of complications of decreased GFR (Fig. 100-17). End-stage renal disease includes all cases requiring treatment by dialysis or transplantation regardless of the level of GFR.

Patients with chronic kidney disease warrant referral to a nephrologist. Care of these patients should focus on efforts to slow disease progression, to optimize medical management, and to make a seamless transition to renal replacement therapy (Chapter 116). The care should include optimal blood pressure control, use of angiotensin-converting enzyme inhibitors and angiotensin receptor blockers if indicated, dietary counseling, careful management of calcium and phosphorus levels, control of the parathyroid hormone level, and management of anemia with the use of erythropoietin and iron supplements. Early referral for placement of access for dialysis and initiation of transplant evaluation (Chapter 117) are important components of the care of patients with chronic kidney disease.

101 STRUCTURE AND FUNCTION OF THE KIDNEYS

QAIS AL-AWQATI AND JONATHAN BARASCH

The kidney regulates the ionic composition and volume of body fluids, the excretion of nitrogenous waste, the elimination of exogenous molecules (e.g., many drugs), the synthesis of a variety of hormones (e.g., erythropoietin), and the metabolism of low-molecular-weight proteins (e.g., insulin). Befitting such an array of responsibilities, the kidney receives 25% of the cardiac output. The gross anatomy of the kidney is notable for a weight of approximately 150 g and a characteristic bean shape with approximate dimensions of 11 × 6 × 2.5 cm. On bisection, a gross structure is evident with an outer cortex and a more central medulla that narrows to multiple papillae at the apices of so-called pyramids (Fig. 101-1).

Understanding renal physiology, however, requires an appreciation of the intricate microstructure that underlies its complex functions. Although the kidney is an organ, the *nephron* is actually the organ's independent filtration unit. On average, each human kidney is composed of 1 million essentially identical nephrons. All functions of the kidney are performed by each individual nephron, and to a first approximation, all nephrons are independent of each other because they have their own innervation and blood supply.

ABSTRACT

The kidney is the primary organ that regulates the volume and composition of the body fluids. Each kidney contains about 1 million nephrons, each of which is composed of a filtering unit (the glomerulus) and a reabsorbing unit (the tubule, which is divided into multiple segments, including proximal, loop of Henle, and distal and collecting tubules). Filtration occurs through the interaction of the hydrostatic pressure (controlled by the balance of afferent and efferent arteriolar states of constriction) and the oncotic pressure exerted by plasma albumin. Regulation of volume of the body fluids is mediated by changes in the rates of sodium reabsorption in the tubules as mediated by the renin-angiotensin-aldosterone system and the secretion of atrial natriuretic factor. The osmolarity of the body fluids is controlled by the reabsorption and excretion of water mediated by the effect of the hormone vasopressin on water transport by the collecting tubule. Control of the pH of the body fluids is effected by the reabsorption of filtered HCO_3^- and secretion of H^+ ions into the urine. The kidney also produces two hormones: erythropoietin and $1,2(OH)_2D_3$.

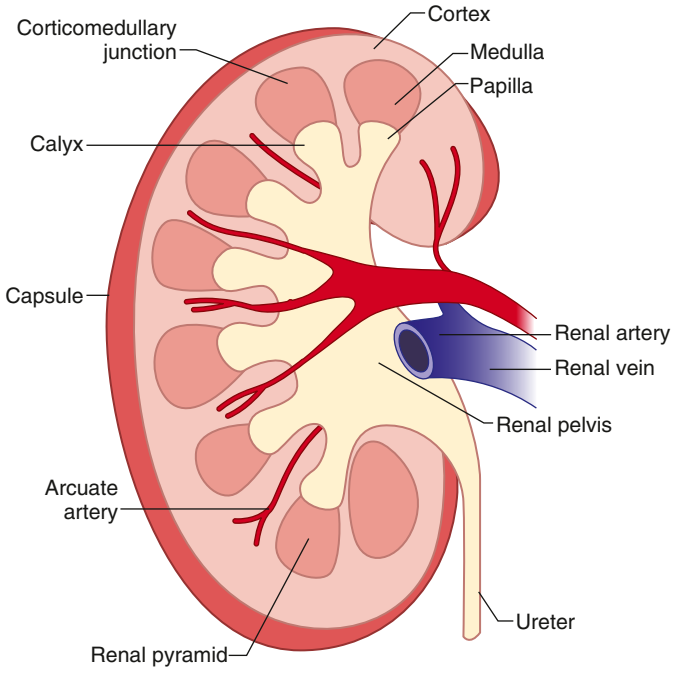

FIGURE 101-1. Sagittal section of the human kidney depicting gross anatomy and organization.

The nephron is made up of two functional subunits, the glomerulus and the tubules and ducts (Fig. 101-2). The glomerulus begins with the branching of the afferent arteriole, an end artery of the corresponding renal artery, into a tuft of capillaries. The glomerular capillaries invaginate an epithelium with the visceral epithelial cells adjacent to the capillary and the parietal epithelial cells outside this tuft. The space between the epithelial layers is the urinary space.[1] The fenestrated glomerular capillary endothelium, the intervening basement membrane, and the foot processes of the visceral epithelium, so-called podocytes, compose the glomerular filtration barrier. The balance of hydrostatic and oncotic pressures drives the extrusion of a protein-free filtrate through this barrier into the urinary space. The urinary space then leads to a series of tubules and ducts: the proximal tubule, the thin limb of the loop of Henle, the thick limb of the loop of Henle, the distal convoluted tubule, the cortical collecting duct, and the medullary collecting duct. The papillary collecting duct empties through the renal papilla into the renal pelvis and then to the ureter. The glomerular capillary bed coalesces to form the efferent arteriole, a vessel that is exquisitely sensitive to angiotensin II, and then the peritubular (proximal) capillaries. This system allows efferent arteriole constriction to regulate proximal tubule reabsorption, as described later.

The nephron regulates homeostasis by three actions. First, in the glomerulus, nephrons collectively produce as much as 120 mL/minute of an ultrafiltrate of blood. Second, different segments of the nephron change the composition of the filtrate by the transfer of nearly 99% of its components (e.g., glucose, NaCl, water) from the lumen to the blood. Third, additional electrolytes (e.g., NH_4^+, K^+, HCO_3^-) are secreted from the blood into the lumen.

To perform these functions, each nephron segment, with the exception of the connecting segment and the collecting ducts, is composed of a single epithelial cell type whose luminal or apical surface (facing the urine) and basolateral surface (facing the blood) differentially express various proteins and lipids. For example, the apical membrane often has microvilli or cilia, whereas the basolateral membrane does not. Polarized endocytosis and exocytosis are often important in the regulation of the number of transport proteins on the apical surface. In addition, epithelia are connected to one another by tight junctions, which confer a characteristic ionic permeability on the epithelial sheet. Transepithelial transport occurs largely through the cell, but transport also can occur through the tight junction (the *paracellular pathway*). For instance, sodium transport begins with entry at the luminal surface down an electrochemical gradient, whereas its exit at the basolateral surface is uphill and requires adenosine triphosphate (ATP) hydrolysis. The Na^+, K^+-ATPase is located at the basolateral surface of all epithelia, and all "active" energy-consuming transport is coupled directly or indirectly to it with the exception of H^+ transport by the H^+ATPase. Each segment has a distinct composition of channels, carriers, and ATPases, and each segment is regulated by different chemical and physical sensors, so the "final urine" contains the components that must be discarded to maintain constancy of body composition.

THE KIDNEY REGULATES EXTRACELLULAR FLUID VOLUME BY REGULATING SODIUM CONTENT

Filtration of 180 L/day of plasma containing 24,000 mEq of sodium is followed by the reabsorption of over 99% of the filtered sodium. Sodium reabsorption accounts for more than 90% of the oxygen consumed by the kidney. It is regulated by volume receptors that are located in the carotid artery and increase β-sympathetic output, which in turn releases renin, an aspartate protease from the granular cells of the juxtaglomerular apparatus, which is located near the afferent arteriole that supplies the glomerulus. Renin cleaves angiotensinogen to angiotensin I, which is then converted locally to angiotensin II. Angiotensin II binds to angiotensin receptors and constricts the efferent arteriole, thereby affecting glomerular hemodynamics. Increased hydrostatic pressure within the glomerular capillaries drives the formation of an ultrafiltrate of plasma. As filtration progresses, a protein-rich, oncotically active solution in the capillary opposes the glomerular capillary hydrostatic pressure until a pressure equilibrium is achieved before the efferent arteriole is reached. Consequently, angiotensin II may not change glomerular filtration rate (GFR) markedly, but it can increase proximal reabsorption by reducing the hydrostatic pressure and increasing the oncotic pressure in the peritubular capillaries that surround the proximal tubule in a plexus, thereby favoring reabsorption of water and solutes such as urea.

The glomerular filtrate next enters the tubules. Na^+ traverses the cell by entering the apical membrane either through a segment-specific cotransporter, counter-transporter, or sodium channel. The apical membrane of the proximal tubule contains an Na^+/H^+ (NHE3) exchanger, Na^+-coupled glucose carrier, and Na^+-coupled amino acid and phosphate cotransporter. Na^+ is then actively transported by the basolateral Na^+, K^+-ATPase into the paracellular space, thereby resulting in local hypertonicity, which causes osmosis through low-resistance tight junctions of the initial segments of the proximal tubule (E-Fig. 101-1).

In the thick ascending limb of Henle, Na^+ is absorbed by an Na-K-2Cl cotransporter. The driving force for this neutral carrier allows Na^+ and Cl^- to enter the cell, but then recycles K^+ across the apical membrane, thereby resulting in depolarization of the transepithelial membrane potential. In the distal convoluted tubule, Na^+ is absorbed by a thiazide-sensitive cotransporter, which conducts Na^+ and Cl^- in a strict 1 : 1 stoichiometry. Na^+ exits as usual by the Na^+, K^+-ATPase, but there is also a basolateral Na/Ca exchanger. In this short segment, the macula densa helps control the GFR by regulating renin release through secretion of adenosine and prostaglandins.

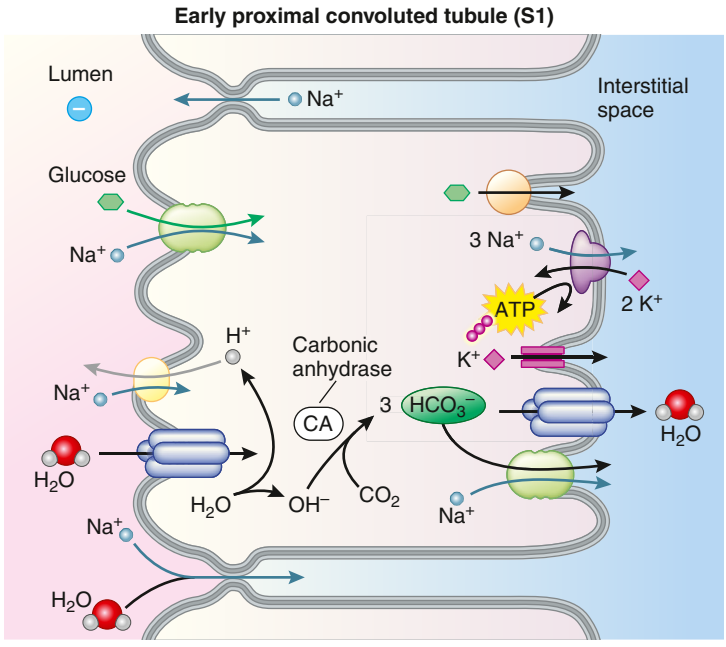
In the principal cells of the collecting duct, aldosterone, derived from the zona glomerulosa of the adrenal cortex, is the final critical regulator of Na^+ balance. Aldosterone increases reabsorption of the final 50 to 100 mEq/day of sodium remaining in the lumen by increasing the number of open sodium channels (ENaC) and by increasing the activity of the basolateral Na^+, K^+-ATPase.[2]

A number of the steps that regulate sodium reabsorption can be counteracted by atrial natriuretic peptide (ANP), which is released from the atria in response to volume overload. ANP increases filtration in the glomerulus by dilating the afferent arteriole, thereby increasing glomerular capillary pressure and lowering the oncotic pressure. In addition, ANP increases sodium excretion by inhibiting the release of renin, the production of aldosterone, and the tubular reabsorption of sodium in the terminal collecting duct.

THE KIDNEY CONTROLS BODY FLUID OSMOLARITY BY REGULATING WATER CONTENT

Water moves freely among all cells and compartments of the body via water-conducting channels called aquaporins. Osmolarity (the concentration of water) is strictly regulated to prevent cells from swelling or contracting via mechanisms that control the intake (thirst) and excretion of fluids, whereby the kidney can vary the osmolarity of urine. Channels in the thick ascending limb, distal tubule, and collecting duct absorb sodium without water to dilute the urine. The absorbed NaCl and urea provide a hyperosmotic region in the medulla, where the limited blood flow maintains an osmotic gradient. To concentrate the urine, water is removed from the filtrate by this osmotic gradient as it passes through the cortical and medullary collecting tubules.

Antidiuretic hormone (ADH), also called *vasopressin,* is a critical component of water reclamation. Changes of less than 1% in osmolarity induce cells in the neurohypophysis to shrink and, via activation of TRPV1 channels, to release ADH. In the kidney, ADH binds to the vasopressin type 2



E-FIGURE 101-1. Sodium reabsorption in the proximal tubular cell. (Figure from Boron W, Boulpaep E. *Medical Physiology*, 3rd Edition. Elsevier; 2016. Taken from Figure 35-4A.)

receptor on collecting tubules and increases water permeability by reversibly inserting a water channel, called *aquaporin 2*, in the apical membrane.[3] During states of water deprivation, the dilute urine generated by the thick ascending limb enters vasopressin-sensitive segments in the cortical collecting tubule, where the bulk of the water is absorbed into the cortex to increase the osmolarity of the urinary filtrate to 300 mOsm, equivalent to plasma osmolarity. When it then travels through the medullary collecting duct, the urine becomes concentrated as it equilibrates with the osmolarity of the medulla (Fig. 101-3).[4]

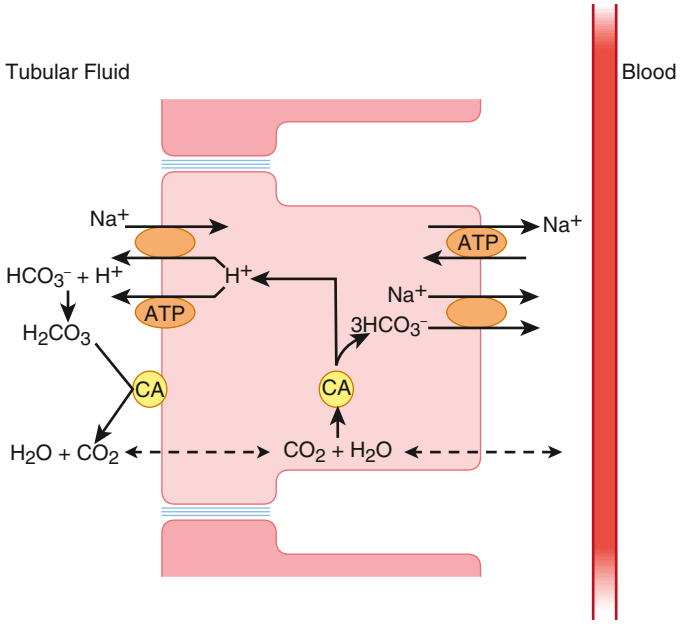
THE KIDNEY REGULATES PLASMA pH BY REGULATING HCO_3^- CONTENT

The concentration of free H^+ in the intracellular and extracellular fluids is maintained at about 40 nM (pH 7.4) by the daily excretion of acid or base in amounts equal to what is generated by dietary intake and by cellular activity. The complete oxidation of carbohydrates and fats generates approximately 15 to 20 mol/day of the volatile acid CO_2, and nonvolatile acids generated by the metabolism of protein-rich diets account for 60 to 80 mEq/day. HCO_3^- is the most important buffer because it is consumed by metabolic acid, thereby producing CO_2 that can be exhaled, and because it can be regenerated by the kidney. The overall relationship of this buffer system is described by the Henderson-Hasselbalch equation:

$$pH = pK_a + \log[HCO_3^-]/\alpha P_{CO_2}$$

where pK_a is 6.1 and α represents the solubility coefficient of P_{CO_2} (which is 0.03). Because all the body buffers (e.g., bone, intracellular proteins) are in equilibrium, changes in the concentration of HCO_3^- regulate the pH of body fluids.

The kidney reabsorbs about 5000 mEq of HCO_3^- that is filtered daily. Beyond this task, it must replace the HCO_3^- that is lost as a consequence of the production of acid by oxidative metabolism. The proximal tubule reabsorbs luminal HCO_3^- by secreting H^+ through an apical Na^+/H^+ exchanger, which is directly stimulated by angiotensin II to secrete H^+ in strict 1 : 1 exchange for Na^+, thereby mediating both sodium absorption and H^+ secretion. An H^+-ATPase is also present in the apical membrane. H^+ secretion titrates filtered HCO_3 and, catalyzed by carbonic anhydrase, converts it to CO_2 and water, thereby allowing CO_2 reabsorption. H^+ secretion leads to an excess of OH^- in the cell, where it combines with this CO_2 to produce cellular HCO_3^-, which then exits across the basolateral membrane through an Na-HCO_3^- cotransporter (E-Fig. 101-2).



E-FIGURE 101-2. Ion transport in the proximal tubule. ATP = adenosine triphosphate; CA = carbonic anhydrase.

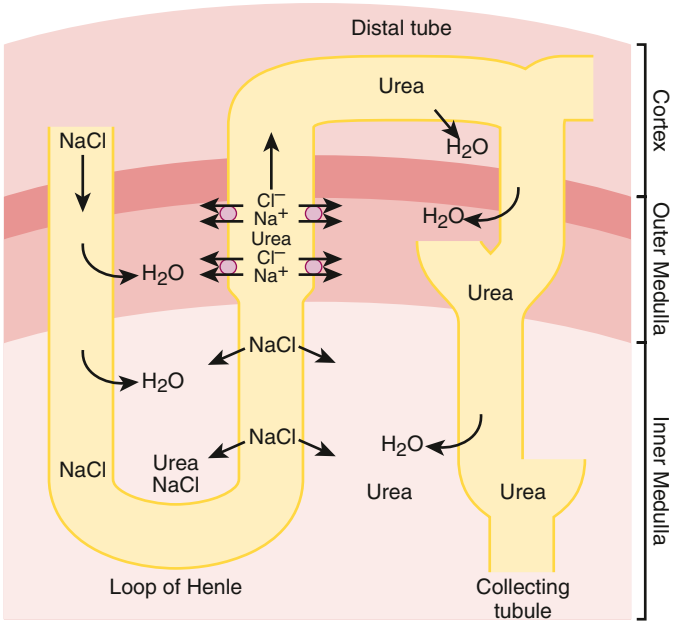


FIGURE 101-3. **Regulation of water content.**

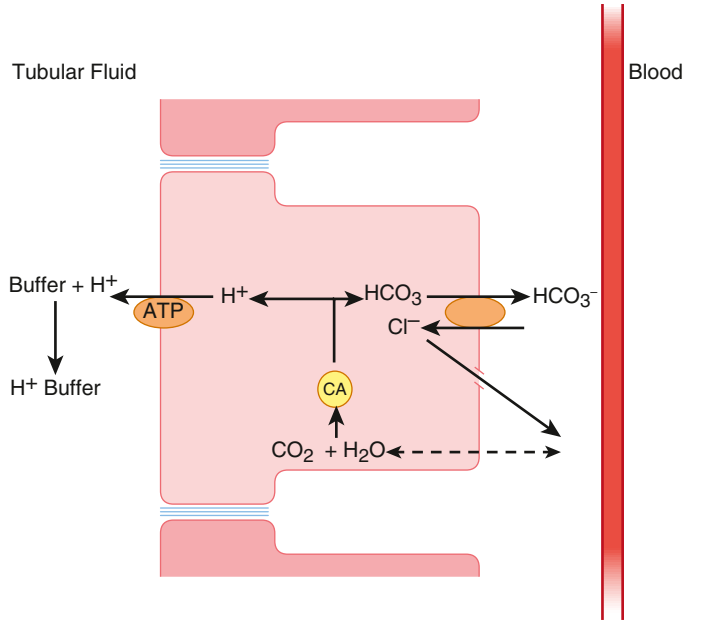

FIGURE 101-4. **Mechanism of acid secretion in the collecting duct.** ATP = adenosine triphosphate; CA = carbonic anhydrase.

Given that the proximal tubule regulates bicarbonate reabsorption, the collecting duct must produce "new" HCO_3 to replace what is lost during titration by nonvolatile acids. The cortical collecting tubules contain intercalated cells that mediate H^+ secretion (α-intercalated cell) and β-cell types that mediate the secretion of HCO_3, whereas only α cells are present in the medulla. In the α-intercalated cell, H^+ secretion is mediated by the H^+-ATPase that is delivered to the apical membrane by fusion of apical vesicles as stimulated by ambient P_{CO_2} (Fig. 101-4).

In a reaction catalyzed by carbonic anhydrase II, the excess OH^- is carboxylated by CO_2 to form HCO_3^-. HCO_3^- is subsequently transported across the basolateral surface in exchange for Cl^- by an alternately spliced form of the red cell anion exchanger (band 3). In contrast, β cells secrete HCO_3^- by an apical Cl/HCO_3 exchanger (pendrin) and a basolateral H^+-ATPase. An H^+, K^+-ATPase in the collecting tubule may also play a role in potassium absorption and perhaps in H^+ secretion.

The collecting tubule is a "tight epithelium" that can maintain electrical and concentration gradients. Secretion of H^+ reduces the pH of the filtrate; the maximal gradient is 3 pH units or 180 mV, but both the size of the pH gradient and its transepithelial membrane potential can be modified to fine-tune H^+ secretion. For example, Na^+ absorption by the principal cell hyperpolarizes the epithelium and can thus drive H^+ secretion. Aldosterone, in addition to regulating Na^+ absorption, independently can stimulate H^+ secretion; hence, it is the major hormone that stimulates acid secretion in the collecting tubule. Finally, chronic metabolic acidosis converts the β-intercalated cells into α-intercalated cells, preferentially increasing the number of acid-secreting cells and reducing the number of HCO_3^- secreting cells in this segment.

The secreted H^+ titrates urinary NH_3 and HPO_4^{2-}. NH_3, which is synthesized by the conversion of glutamine to α-ketoglutarate, is secreted into the proximal lumen. In the loop of Henle and distal segments, the protonated ammonium ion is transferred into the interstitium, from where it re-enters the nephron as ammonia gas. Once in the lumen, ammonia gas becomes reprotonated to ammonium, thus trapping a proton. The amount of NH_3 generated from glutamine increases up to four- to five-fold in the setting of metabolic acidosis. Net acid secretion is consequently urinary NH_4^+ plus titratable weak acids (such as HPO_4^{2-}) minus urinary HCO_3^-. Each of these components is regulated by the kidney.

THE KIDNEY REGULATES PLASMA POTASSIUM BY SECRETION AND THE CONTROL OF EXTRACELLULAR pH

Because the membrane potential of most cells is governed by the ratio of intracellular to extracellular potassium, the plasma potassium concentration must be tightly regulated. Most dietary potassium is pumped into the cell by the Na^+, K^+-ATPase, but about 90% of ingested potassium eventually must be excreted into the urine.[5] K^+ is filtered but is then reabsorbed by the proximal tubule and loop of Henle. K^+ is then secreted by the distal convoluted tubule and the principal cells through apical potassium inwardly rectifying (ROMK) and potassium large conductance calcium-activated (BK) channels. The gradient, in which cellular K^+ is greater than luminal K^+, drives K^+ out of the cell. Secretion is enhanced by the increased entry of K^+ into the principal cell as a result of high extracellular concentration, by metabolic alkalosis, and by aldosterone. Aldosterone increases the synthesis of Na^+, K^+-ATPase and increases the probability that the ROMK channels will be open. Aldosterone also enhances Na^+ reabsorption by ENaC, thereby hyperpolarizing the transepithelial membrane potential, which increases the driving force for potassium secretion. High urinary flow rates deliver a large volume of fluid that is essentially K^+ free, thereby providing a concentration gradient. The flow rate also activates mechanosensory flagella that lead to an increase in cell calcium, which in turn activates BK channels. Potassium reabsorption is not regulated to the same extent as sodium retention, and profound potassium depletion may be required for potassium excretion by the kidneys to be eliminated completely.

THE KIDNEY REGULATES PLASMA PO_4 AND CA^{2+} BY EXCRETION AND BY SYNTHESIZING VITAMIN D_3

The level of PO_4 critically regulates serum Ca^{2+} level. Because their plasma concentrations are close to their saturation product, at which point crystallization occurs, any significant increase in PO_4 results in precipitation of $CaPO_4$.

PO_4 concentration is regulated by glomerular filtration. Initially, about 85% is reabsorbed by the proximal tubule sodium-phosphate cotransporters NaPi-2a and NaPi-2c. Parathyroid hormone and the heteromeric receptor FGFR/Klotho, which binds fibroblast growth factor 23 (FGF23), inhibit the expression of NaPi and hence increase excretion of PO_4. Conversely, the proximal tubule generates vitamin D_3 (1,25-dihydroxycholecalciferol) by capturing 25-hydroxycholecalciferol, bound to its filterable transport protein with brush border megalin (E-Fig. 101-3), after which 1α-hydroxylation is stimulated by low Ca^{2+} and PO_4. 1,25-Vitamin D_3 inhibits parathyroid hormone and stimulates PO_4 reabsorption in gut and kidney, thereby counteracting parathyroid hormone and FGF23-Klotho. Nonetheless, Klotho signaling blocks 1,25-vitamin D_3 synthesis, thereby suggesting that it dominates the control of PO_4.[6]

The level of serum calcium is also regulated by the kidney. Approximately 60% of serum calcium is filtered, after which it is reabsorbed in the proximal tubule through the paracellular pathway. The tight junction protein claudin 2 is critical for calcium selectivity in this segment and mutations in it lead to hypercalciuria. Calcium is also absorbed paracellularly in the thick ascending limb driven by the positive membrane potential generated by the Na-K-2Cl/K recycling transporter. Mutations in the tight junction proteins claudin 14, 16 and 19, have been implicated in monogenic causes of hypercalciuria and nephrolithiasis.[7] In contrast, calcium and sodium are regulated independently in the distal convoluted tubule by parathyroid hormone and Klotho, which increase reabsorption. Phosphate and calcium metabolism is regulated by sodium reclamation, parathyroid hormone, 1,25-dihydroxycholecalciferol, and Klotho in different segments of the nephron.[8]

102 DISORDERS OF SODIUM AND WATER

QAIS AL-AWQATI AND JAI RADHAKRISHNAN

EPIDEMIOLOGY

Disturbances of water and sodium include hypovolemia, hypervolemia, hyponatremia, and hypernatremia.[1] Up to 15 to 20% of hospitalized patients may develop hyponatremia or hypernatremia. Among ambulatory individuals, these abnormalities are more common in the elderly and in patients who are treated with multiple medications. Patients may have combinations of abnormalities in extracellular osmolality and volume (Table 102-1). Hypovolemia, which can be caused by dehydration or bleeding, can cause postural symptoms (Chapter 7) or shock (Chapter 94). Common causes of fluid overload include heart failure (Chapters 45 and 46), renal dysfunction, and liver failure, commonly resulting in edema (Fig. 39-7).[2]

DISORDERS OF EXTRACELLULAR FLUID VOLUME

PATHOBIOLOGY

Control of Extracellular Fluid Volume

The regulation of circulating volume is one of the body's major homeostatic mechanisms, and perturbations in the regulation of volume can cause a number of clinical conditions that carry substantial morbidity and mortality. Water accounts for approximately 60% of body weight (Fig. 102-1). Two thirds of this water resides intracellularly, and the remainder constitutes the extracellular fluid space. The kidney regulates extracellular volume by adjusting the amount of sodium chloride it excretes. Additionally, the kidney's regulated excretion of water maintains serum osmolality within narrow limits. The kidney accomplishes this goal by balancing salt excretion with salt intake, even though the daily intake of salt is highly variable, owing to cultural, social, and personal factors.

In the steady state, the renal excretion of salt is essentially equal to the salt intake because other possible routes of salt loss from the body (e.g., sweat glands and the gastrointestinal tract) do not contribute significantly to the maintenance of salt balance. When the dietary intake of sodium is abruptly increased (Fig. 102-2), only about one half of the increment appears in the urine over the first day. The remainder of the dietary increment is retained as a positive sodium balance. On each successive day of the higher intake of sodium, a smaller fraction of the dietary increment is retained as the excretion of sodium progressively increases over 3 to 5 days to match the new intake. Weight

TABLE 102-1 PATHOGENIC PROCESSES LEADING TO DISORDERS OF BODY SODIUM AND FLUID HOMEOSTASIS

CLINICAL STATE	ECF VOLUME	BODY FLUID TONICITY	PATHOGENIC PROCESS

• Hypovolemic	↓	↑	ECF depletion Na > H_2O
• Hypervolemic	↑		ECF overload Na > H_2O
Hyponatremia			Net loss of sodium in excess of water
• Normovolemic	↔	↓	
• Hypovolemic	↓		
• Hypervolemic	↑		

ECF = extracellular fluid; H_2O = water; Na = sodium.

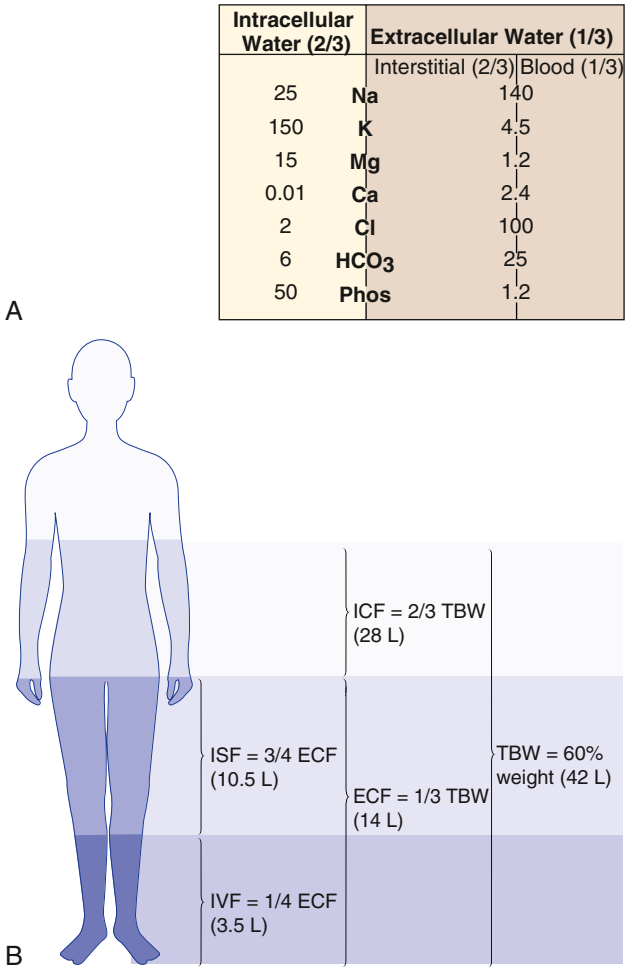

FIGURE 102-1. Composition of body fluid compartments. Schematic representation of (A) electrolyte composition of compartments in humans and (B) body fluid compartments. In A, electrolyte concentrations are in millimoles per liter; intracellular concentrations are typical values obtained from muscle. In B, shaded areas depict the approximate size of each compartment as a function of body weight. In a normally built individual, the total body water content is roughly 60% of body weight. Because adipose tissue has a low concentration of water, the relative water–to–total body weight ratio is lower in obese individuals. Relative volumes of each compartment are shown as fractions; in parentheses are shown approximate absolute volumes of the compartments (in liters) in a 70-kg adult. Ca = calcium; Cl = chloride; ECF = extracellular fluid; HCO_3 = bicarbonate; ICF = intracellular fluid; ISF = interstitial fluid; IVF = intravascular fluid; K = potassium; Mg = magnesium; Na = sodium; Phos = phosphate; TBW = total body water. (B from Verbalis JG. Body water osmolality. In: Wilkinson B, Jamison R, eds. *Textbook of Nephrology*. London: Chapman & Hall; 1997:89-94. Reproduced with permission of Hodder Arnold.)

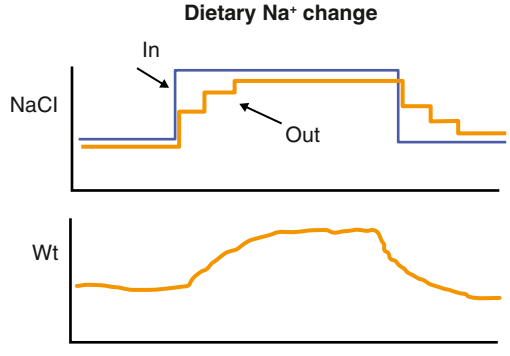

FIGURE 102-2. Time course of sodium excretion and weight change in humans following abrupt changes in daily sodium intake. Positive sodium balance continues for several days after salt intake is increased. As the volume of extracellular fluid increases, sodium excretion increases until the new lower intake of sodium is matched. It is this reduction of body sodium and extracellular fluid that provides the stimulus for diminishing the excretion of sodium. Na^+ = sodium; NaCl = sodium chloride; Wt = weight.

102 DISORDERS OF SODIUM AND WATER

QAIS AL-AWQATI AND JAI RADHAKRISHNAN

EPIDEMIOLOGY

Disturbances of water and sodium include hypovolemia, hypervolemia, hyponatremia, and hypernatremia.[1] Up to 15 to 20% of hospitalized patients may develop hyponatremia or hypernatremia. Among ambulatory individuals, these abnormalities are more common in the elderly and in patients who are treated with multiple medications. Patients may have combinations of abnormalities in extracellular osmolality and volume (Table 102-1). Hypovolemia, which can be caused by dehydration or bleeding, can cause postural symptoms (Chapter 7) or shock (Chapter 94). Common causes of fluid overload include heart failure (Chapters 45 and 46), renal dysfunction, and liver failure, commonly resulting in edema (Fig. 39-7).[2]

DISORDERS OF EXTRACELLULAR FLUID VOLUME

PATHOBIOLOGY

Control of Extracellular Fluid Volume

The regulation of circulating volume is one of the body's major homeostatic mechanisms, and perturbations in the regulation of volume can cause a number of clinical conditions that carry substantial morbidity and mortality. Water accounts for approximately 60% of body weight (Fig. 102-1). Two thirds of this water resides intracellularly, and the remainder constitutes the extracellular fluid space. The kidney regulates extracellular volume by adjusting the amount of sodium chloride it excretes. Additionally, the kidney's regulated excretion of water maintains serum osmolality within narrow limits. The kidney accomplishes this goal by balancing salt excretion with salt intake, even though the daily intake of salt is highly variable, owing to cultural, social, and personal factors.

In the steady state, the renal excretion of salt is essentially equal to the salt intake because other possible routes of salt loss from the body (e.g., sweat glands and the gastrointestinal tract) do not contribute significantly to the maintenance of salt balance. When the dietary intake of sodium is abruptly increased (Fig. 102-2), only about one half of the increment appears in the urine over the first day. The remainder of the dietary increment is retained as a positive sodium balance. On each successive day of the higher intake of sodium, a smaller fraction of the dietary increment is retained as the excretion of sodium progressively increases over 3 to 5 days to match the new intake. Weight

TABLE 102-1 PATHOGENIC PROCESSES LEADING TO DISORDERS OF BODY SODIUM AND FLUID HOMEOSTASIS

CLINICAL STATE	ECF VOLUME	BODY FLUID TONICITY	PATHOGENIC PROCESS
Normal	↔	↔	NA
Isonatremia			
• Hypovolemia	↓	↔	ECF depletion
• Hypervolemia	↑	↔	ECF overload
Hypernatremia			
• Hypovolemic	↓	↑	ECF depletion Na > H_2O
• Hypervolemic	↑		ECF overload Na > H_2O
Hyponatremia			Net loss of sodium in excess of water
• Normovolemic	↔	↓	
• Hypovolemic	↓		
• Hypervolemic	↑		

ECF = extracellular fluid; H_2O = water; Na = sodium.

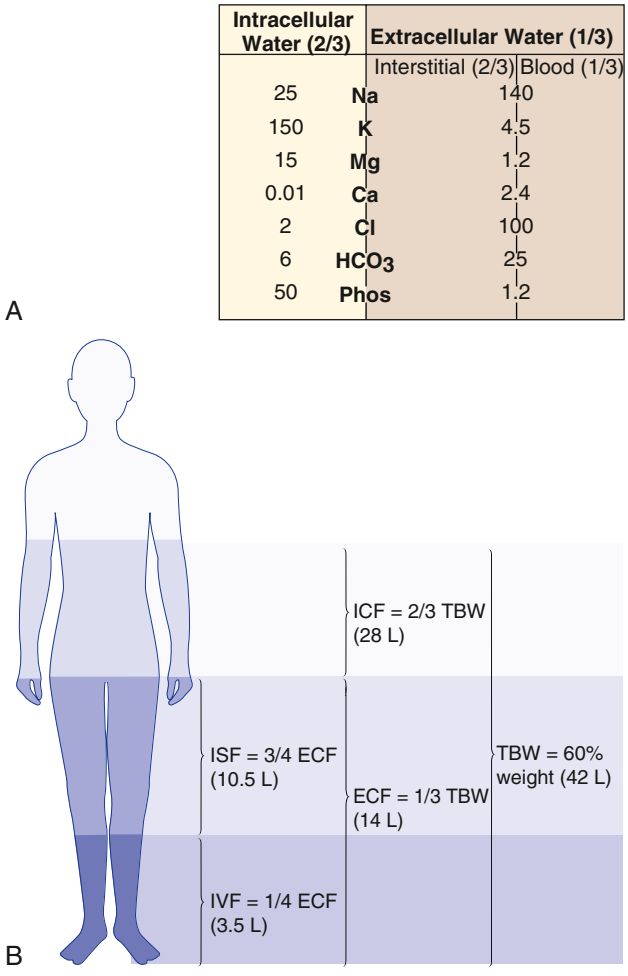

FIGURE 102-1. Composition of body fluid compartments. Schematic representation of (A) electrolyte composition of compartments in humans and (B) body fluid compartments. In A, electrolyte concentrations are in millimoles per liter; intracellular concentrations are typical values obtained from muscle. In B, shaded areas depict the approximate size of each compartment as a function of body weight. In a normally built individual, the total body water content is roughly 60% of body weight. Because adipose tissue has a low concentration of water, the relative water–to–total body weight ratio is lower in obese individuals. Relative volumes of each compartment are shown as fractions; in parentheses are shown approximate absolute volumes of the compartments (in liters) in a 70-kg adult. Ca = calcium; Cl = chloride; ECF = extracellular fluid; HCO_3 = bicarbonate; ICF = intracellular fluid; ISF = interstitial fluid; IVF = intravascular fluid; K = potassium; Mg = magnesium; Na = sodium; Phos = phosphate; TBW = total body water. (B from Verbalis JG. Body water osmolality. In: Wilkinson B, Jamison R, eds. *Textbook of Nephrology*. London: Chapman & Hall; 1997:89-94. Reproduced with permission of Hodder Arnold.)

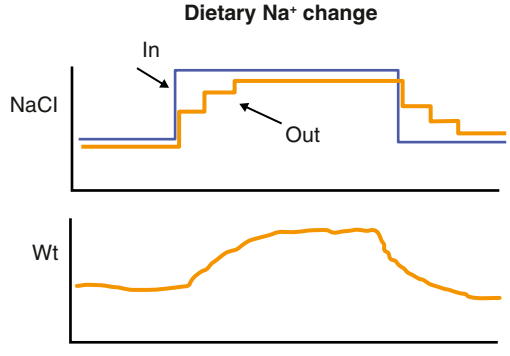

FIGURE 102-2. Time course of sodium excretion and weight change in humans following abrupt changes in daily sodium intake. Positive sodium balance continues for several days after salt intake is increased. As the volume of extracellular fluid increases, sodium excretion increases until the new lower intake of sodium is matched. It is this reduction of body sodium and extracellular fluid that provides the stimulus for diminishing the excretion of sodium. Na^+ = sodium; NaCl = sodium chloride; Wt = weight.

ABSTRACT

The kidney is the major organ that controls the content of salt and water. More than 99% of filtered sodium is reabsorbed in a manner regulated by the renin-angiotensin-aldosterone system as well as by the sympathetic nervous system and by atrial natriuretic peptides. The volume of the extracellular space (and thus the arterial blood pressure) is highly dependent on the amount of sodium reabsorbed by the kidney. Any decrease will lead to hypotension. Sodium retention leading to a large expansion of the extracellular fluid volume is one of the most common problems in medicine and results in the development of edema, which is a characteristic finding in heart failure, liver failure, and kidney diseases. However, the osmolality (tonicity) of the body fluids, as measured by the serum sodium concentration, is regulated by changes in the renal excretion of water. Reabsorption of filtered sodium generates a dilute urine, but vasopressin, which is produced by the hypothalamus, leads to insertion of water channels in the collecting duct and to the formation of concentrated urine by equilibration of urine with the hypertonic medulla. The hypothalamus also senses any decrease in the effective plasma volume, thereby leading to thirst even in the absence of hypernatremia. Clinical syndromes with an inappropriate sensing of the extracellular fluid volume include heart failure, cirrhosis, nephrotic syndrome, and the syndrome of inappropriate secretion of antidiuretic hormone.

will increase because the retained Na will obligate the retention of an amount of water sufficient to maintain iso-osmolality. This positive balance of sodium and expansion of the extracellular water compartment stimulates a progressive increase in the excretion of sodium until the higher intake is matched by excretion. An abrupt decrease in sodium intake also does not result in an immediate equal reduction in sodium excretion. Negative sodium balance will continue for several days, and extracellular volume will diminish until the new, lower sodium intake is matched by reduced sodium excretion. Similar responses are seen with the introduction of a new salt source (such as intravenous fluids) or the development of new salt losses (such as vomiting or diarrhea).

Afferent Limb Mechanisms

For a change in volume to result in a change in salt excretion, the change in extracellular volume must be sensed. Alterations in extracellular volume stimulate volume and pressure receptors that sense concomitant changes in intravascular volume, blood pressure, or distension of a particular vascular bed. The juxtaglomerular apparatus is a renal volume sensor that releases renin when the perfusion pressure is reduced. In addition to increasing circulating levels of angiotensin II (see later), stimulation of these receptors leads to alterations in the local concentration of angiotensin, which profoundly decreases salt excretion. Volume receptors in the carotid sinus and aorta increase sympathetic output in response to hypotension. The increased sympathetic tone of the renal vasculature decreases salt excretion. Renal sympathetic nerves and catecholamines released from the adrenal medulla also stimulate renin release. The atria contain secretory granules which, in response to an increase in extracellular volume, release atrial natriuretic peptide, which increases salt excretion and causes peripheral vasodilation. Activation of volume receptors located in intrahepatic sinusoids may play a role in sensing changes in volume and salt content.

Efferent Limb Mechanisms

Several of the efferent mechanisms, such as the angiotensin/renin pathway and atrial natriuretic peptide, act in part by altering glomerular hemodynamics, which in turn affects the proximal tubular reabsorption of salt and water. Glomerular filtration is driven by the balance of two opposing forces across the glomerular capillary membrane: the difference in hydrostatic pressure and the difference in colloid osmotic pressure. The normal glomerular filtrate is virtually protein-free. As the plasma courses down the glomerular capillary, the albumin concentration increases, thereby resulting in an oncotic driving force that opposes hydrostatic pressure and decreases the filtration rate. When colloid osmotic pressure increases to match hydrostatic pressure (a condition called filtration pressure equilibrium), filtration ceases.

Because the efferent arteriole is a resistance vessel, the peritubular hydrostatic pressure is lower than the glomerular capillary pressure. Further, the peritubular capillary oncotic pressure is higher than the hydrostatic pressure because protein-free fluid has been removed by filtration. This balance of hydrostatic and oncotic forces in the peritubular capillary favors tubular reabsorption of fluid from the extracellular space of the tubules back into the capillaries. In this way, changes in glomerular hemodynamics can alter tubular reabsorption by changing the peritubular capillary oncotic and hydrostatic pressures.

Changes in glomerular and peritubular hemodynamics can influence the rate of net sodium reabsorption. Reabsorption of the filtered fluid occurs by active transport of sodium from the tubular lumen into the peritubular space. The proximal tubule is quite "leaky," so it cannot maintain large gradients of concentration or electrical potential. Sodium accumulates in the intercellular space, thereby resulting in local hypertonicity. Water is subsequently drawn in by osmosis through the cells and the leaky junctions. Removal of this fluid into the peritubular capillary occurs because the peritubular capillary has a higher protein concentration and a lower hydrostatic pressure than an ordinary capillary; these forces favor reabsorption of fluid from the intercellular space.

Filtered sodium is passively reabsorbed from the tubular lumen into the epithelial cell down a concentration gradient. It is then actively transported into the lateral intercellular channel, which communicates directly with the interstitial space. If the net force for uptake into the capillary is decreased, conductive and/or geometric changes in the tight junction complex may favor increased "back leak" of fluid into the tubular lumen, thereby diminishing net reabsorption. When those forces are in the opposite direction, the leak will decrease, thereby resulting in an increase in net reabsorption.

In principle, sodium excretion could be altered by either a change in the amount filtered or a change in the amount reabsorbed. In practice, both glomerular filtration rate and tubular reabsorption must be considered in analyzing the actions of atrial natriuretic peptide and angiotensin II.

Renin-Angiotensin II—Aldosterone

Renin is released from the juxtaglomerular apparatus in response to hypotension or to extracellular volume depletion in the absence of hypotension. Adrenergic innervation also stimulates renin release in response to the same stimuli. Additionally, prostaglandins, low plasma K^+, and increased Na^+ delivery to the macula densa also stimulate renin release. Circulating renin converts angiotensinogen, which is mainly produced by the liver and secreted into the blood, to angiotensin I. Angiotensin I in turn is converted by a converting enzyme located on the surface of endothelial cells to the active hormone, angiotensin II. Angiotensin II causes peripheral vasoconstriction and decreases salt excretion in the proximal and distal tubules.[3]

Angiotensin II increases the proximal tubule reabsorption of Na^+ by constricting the efferent arteriole, which increases the filtration fraction, which increases the peritubular capillary oncotic pressure, which increases the driving force for Na^+ reabsorption from the interstitial space into the capillary and decreases the backward leak. Increased reabsorption of sodium and water will result in a higher concentration of many solutes, including urea and uric acid, which are reabsorbed at a slower rate than are sodium and water. Based on their ability to be reabsorbed, these solutes will diffuse out of the tubule to a larger extent than normal. Since that diffusion is driven by a difference in concentration, the blood urea nitrogen (BUN) level will increase to a higher level than simply predicted by the reduction in filtration rates. Indeed, the serum ratio of BUN:creatinine is frequently elevated when angiotensin levels are increased. Angiotensin II also stimulates the Na:H exchanger, thereby causing a direct increase in Na reabsorption through the cells in the proximal tubule. Angiotensin II also directly stimulates Na^+ transporters in the thick ascending limb, the distal tubule, and the early collecting tubule.

A major effect of angiotensin II on Na+ reabsorption, however, is to stimulate the release of aldosterone from the zona glomerulosa of the adrenal cortex. In the collecting tubule and late distal tubule, aldosterone leads to an increase in the number of open Na^+ (and also K^+) channels, thereby leading to increased entry of Na^+ into the cell and, consequently, increased exit at the basolateral surface via the Na^+-K^+-ATPase, which is also stimulated by aldosterone. The Na^+ absorbed under the influence of aldosterone is estimated to be 50 to 100 mEq/day, amounting to less than 0.5% of that filtered. However, because it acts on the final 50 to 100 mEq that have escaped absorption, aldosterone has a critical effect on renal salt excretion and total body sodium balance. In the absence of aldosterone, such as in primary adrenal insufficiency (Chapter 209), patients will develop negative salt balance with severe salt depletion and shock unless their intake compensates for this loss of salt.

Interaction of Angiotensin II and Prostaglandins

In the setting of decreased renal perfusion, glomerular filtration is usually preserved. This effect is mediated by two vasoactive factors, angiotensin II and prostaglandins, which have opposing effects on the renal vasculature. Angiotensin II binds to receptor subtypes 1 A in the efferent arteriole and promotes vasoconstriction. Concomitantly, the release of vasodilating prostaglandins mitigates the constriction of the afferent arterioles. This combined effect of efferent arteriolar constriction and afferent arteriolar dilation maintains intraglomerular pressure. These factors also have opposite effects on salt handling: angiotensin II releases aldosterone to promote salt absorption in the distal nephron, whereas prostaglandins inhibit salt absorption in the loop of Henle. Inhibitors of the renin-angiotensin axis and nonsteroidal anti-inflammatory drugs (NSAIDs) may produce acute declines in glomerular filtration in the setting of low renal perfusion pressures (e.g., volume depletion, heart failure, and cirrhosis). Further, NSAIDs may induce salt retention in these circumstances (Chapter 106).

Atrial Natriuretic Peptide

Atrial natriuretic peptide is a 28–amino acid peptide that is released from granule stores of the right and left atria in response to volume overload with atrial distention or after an atrial tachyarrhythmia. Atrial natriuretic peptide inhibits renin release and thus indirectly inhibits the production of angiotensin II. Second, atrial natriuretic peptide inhibits aldosterone production regardless of the presence of angiotensin II, high plasma K^+, or elevated adrenocorticotropic hormone. Third, atrial natriuretic peptide increases the glomerular filtration rate and thus increases the amount of Na^+ available for excretion. Finally, atrial natriuretic peptide directly inhibits the tubular reabsorption of Na^+ in the terminal collecting duct.

Renal Nerves

Renal nerves directly increase afferent and efferent arterial tone, and the resulting decrease in renal plasma flow and glomerular filtration rate will favor Na^+

retention. Stimulation of these nerves also leads to release of renin and angiotensin, which results in salt retention. Sympathetic neurons also are present in apposition to the proximal tubule and thick ascending limb, where their stimulation results in an increase in proximal Na^+ absorption even when the filtration rate, renin, and angiotensin levels are not measurably changed.

HYPOVOLEMIA

Hypovolemia, which is a contraction of intravascular volume, can be caused by renal and nonrenal conditions (Table 102-2).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical manifestations of hypovolemia depend on its magnitude, the rate at which it developed, and what fluid was lost.[4] A detailed history will usually reveal underlying bleeding, polyuria, gastrointestinal losses, medications, and diaphoresis. However, gradual volume loss with an intravascular volume contraction of less than 5% may be asymptomatic and associated with few physical findings. An intravascular volume contraction of 5 to 15% typically causes symptoms and signs, often including postural lightheadedness and weakness. Thirst is common as the volume loss worsens. Hemodynamic collapse (hypovolemic shock; Chapter 92) can occur with more rapid volume loss.

On physical examination, jugular venous pressure will generally be less than 5 cm H_2O in the absence of confounding factors. Findings such as reduced skin or eyeball turgor and dry mucous membranes are not reliable indicators of hypovolemia.

Relative intravascular hypovolemia also is seen with the vasodilation that typically accompanies sepsis (Chapter 94), even though no fluid has been lost outside of the body. Such patients can be critically ill, but typically they will have warm extremities unlike the cool extremities that are typical of patients in cardiogenic or true hypovolemic shock (Chapter 92). However, the diminished tissue perfusion in sepsis can reduce the level of consciousness and cause oliguria, acute kidney injury, and lactic acidosis.

In addition to oliguria with a high urine osmolality and a low urine sodium concentration (<20 mEq/L), hemoconcentration can raise the hemoglobin level unless the patient is bleeding. The BUN will rise, often out of proportion to the rise in the serum creatinine level. The serum albumin concentration often rises with gastrointestinal, urinary, or skin losses of albumin-free fluids but falls when accompanied by albumin loss (e.g., proteinuria, protein-losing enteropathy, and burns). Loss of hypotonic fluids with inadequate water ingestion or replacement results in hypernatremia. Hypokalemia with metabolic alkalosis frequently accompanies vomiting and hypovolemia induced by thiazide and loop diuretics. By comparison, diarrhea often is associated with a non–anion gap metabolic acidosis. Adrenal insufficiency is typically accompanied by hyperkalemia and mild metabolic acidosis.

An important goal is to assess volume responsiveness (i.e., the probability that the patient with suspected hypovolemia will respond to volume repletion), especially in critically ill patients in whom volume overload is equally, if not as, deleterious as volume depletion. A static assessment of intravascular volume by measuring central venous pressure or pulmonary arterial wedge pressure can be useful but does not provide a reliable measure of volume responsiveness. Dynamic techniques that more predictably indicate volume responsiveness include passive leg raising and respiratory variation in the diameter of the vena cava, pulse pressure, or left ventricular end-diastolic diameter.

TABLE 102-2 CAUSES OF ABSOLUTE AND RELATIVE HYPOVOLEMIA

RENAL
Absolute
Diuretics
Inherited sodium-wasting tubulopathies
Tubulointerstitial diseases
Partial urinary obstruction or postobstruction diuresis
Endocrine disorders (e.g., hypoaldosteronism, adrenal insufficiency)
Relative
Nephrotic syndrome
EXTRARENAL
Absolute
Bleeding
Gastrointestinal fluid loss (e.g., diarrhea, vomiting, ileostomy or colostomy secretions)
Fluid loss from skin (e.g., burns, sweat)
Respiratory fluid loss
Relative
Third space losses (e.g., sepsis, angioedema, pancreatitis, ileus, cirrhosis with ascites)

TREATMENT

Absolute Hypovolemia

The major goal in treating hypovolemia is to restore hemodynamic integrity and tissue perfusion (Chapter 92). The management approach includes treatment of the underlying disease state, assessment and replacement of the volume deficit, treating concomitant electrolyte and acid-base abnormalities, and maintaining volume in the face of continuing losses.[5]

The choice of fluid therapy includes isotonic crystalloids (0.9% and lactated Ringer solution), colloids (albumin), and packed red cells. Generally, crystalloids are used as first-line therapy. Buffered crystalloids (e.g., lactated Ringer solution or Plasmalyte-A) may have an advantage over 0.9% saline in avoiding the dilutional acidosis and the propensity to acute kidney injury that accompanies large-volume resuscitation in critically ill patients,[A1,A2] although data in critically ill patients are less clear.[A3,A4] Using albumin adds no benefit in essentially any situation other than cirrhosis (Chapter 139). Colloids such as hetastarch or dextran should not be used. In hemorrhagic shock, packed red cells are usually required to correct anemia after initial resuscitation with crystalloids.

The rate of fluid repletion depends on the severity of the volume deficit. In patients with hypovolemic shock (Chapter 92), rapid administration of a crystalloid is recommended until hemodynamic parameters are normalized. With lesser degrees of hemodynamic compromise, one or more boluses of crystalloids (e.g., 500 mL of saline followed by an assessment of the response)[A5] may be used. In uncertain situations in which avoidance of fluid overload is critical, dynamic assessment of fluid status (see Clinical Manifestations and Diagnosis) may be helpful.

For an accompanying metabolic acidosis (Chapter 104), hypertonic sodium bicarbonate can be added to half-isotonic saline or 5% dextrose to create an isotonic replacement fluid appropriate for the acid-base abnormality. Similarly, the addition of potassium chloride is indicated in patients with concomitant potassium depletion (Chapter 103).

Relative hypovolemia owing to peripheral vasodilation requires treatment of the underlying cause, such as sepsis (Chapter 94) or anaphylaxis (Chapter 233). While this treatment is being instituted, isotonic crystalloid is the mainstay of treatment until vascular resistance and capacitance are restored to normal. Such patients also may require vasopressors (Chapter 94).

HYPERVOLEMIA

Hypervolemia is an expansion primarily of extracellular volume owing to primary or secondary renal retention of sodium (Table 102-3).

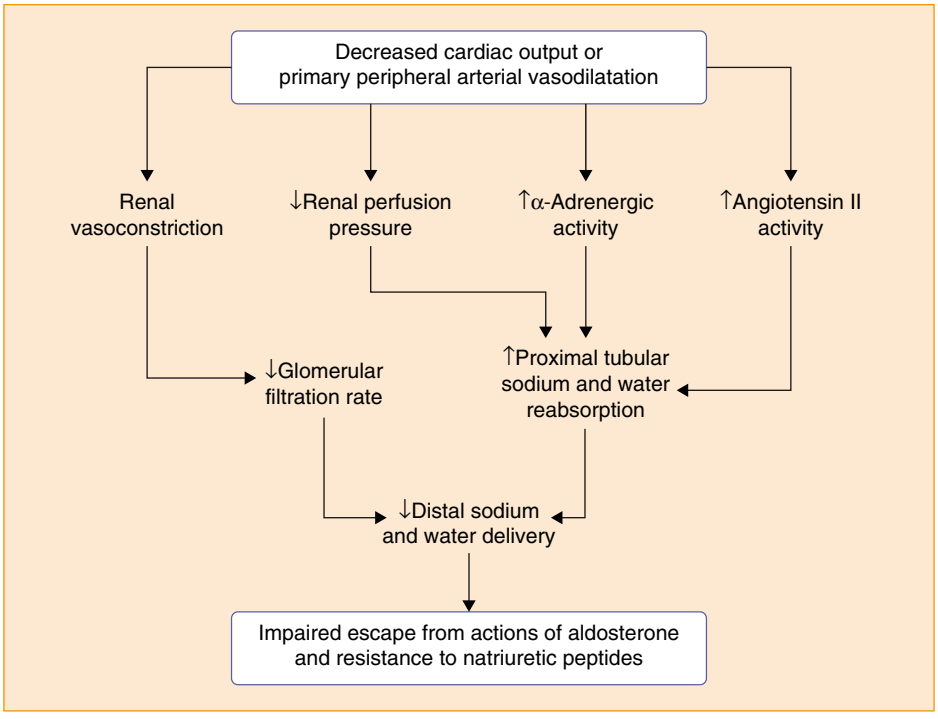
PATHOBIOLOGY

Heart Failure

With heart failure (Chapters 45 and 46), a decrease in cardiac output activates baroreceptors (E-Fig. 102-1). The result is an increase in sympathetic activity, activation of the renin-angiotensin system, and increased levels of angiotensin II. Constriction of the efferent arteriole increases the glomerular capillary hydrostatic pressure but reduces renal plasma flow. In early heart failure, the filtration rate is maintained. In severe heart failure, the filtration rate may be reduced owing to a severe decline in renal plasma flow. However, the filtration fraction is always elevated because the decline in plasma flow is always greater than the decline in the filtration rate.

TABLE 102-3 PRIMARY AND SECONDARY RENAL SODIUM-RETAINING STATES

PRIMARY
Oliguric renal failure
Chronic kidney disease
Glomerular disease, including nephrotic syndrome
Severe bilateral renovascular obstruction
Mineralocorticoid excess
Inherited sodium-retaining tubulopathies
SECONDARY
Cardiac failure
Cirrhosis
Idiopathic edema



E-FIGURE 102-1. Fluid retention in heart failure. Mechanisms by which arterial underfilling leads to diminished distal tubular sodium and water delivery, impaired aldosterone escape, and resistance to natriuretic peptide hormone. (Reproduced with permission from Schrier RW, Abraham WT. Hormones and hemodynamics in heart failure. *N Engl J Med*. 1999;341:577-585.)

The lower peritubular capillary hydrostatic pressure (owing to reduced glomerular filtration) and elevated albumin concentration (owing to the elevated filtration fraction) favor increased absorption from the proximal tubule, which is the major cause of salt retention in heart failure. Angiotensin II also stimulates aldosterone release, which in turn stimulates Na^+ absorption in the more distal nephron.

Not all patients with heart failure continue to accumulate salt. After the initial salt retention, expansion of the extracellular volume may restore cardiac output to near-normal levels, albeit with a higher-than-normal extracellular volume. In this new state, the initial compensatory mechanisms will be largely deactivated: angiotensin and aldosterone levels will decrease, as will sympathetic tone. In this new steady state, salt excretion will equal salt intake. However, if heart failure worsens, owing, for example, to further myocardial damage, the cycle will be repeated. In severe heart failure, the patient will remain in the salt-retaining, high renin-angiotensin-aldosterone state despite massive extracellular volume expansion. The pathophysiology of heart failure therefore consists of two phases. The first is a salt-retaining, high-renin, high-angiotensin, and high-aldosterone state, in which the extracellular volume will continuously expand. The second phase is characterized by a normal renin-angiotensin-aldosterone axis, a higher-than-normal extracellular fluid volume, and external salt balance.

Cirrhosis

Cirrhosis of the liver (Chapter 139) is uniformly associated with disturbances in salt excretion and the consequent development of edema and ascites. Portal hypertension leads to transudation of fluid into the abdominal cavity, with consequent intravascular volume depletion. Peripheral vasodilation also causes a decrease in the "effective plasma volume," with consequent salt retention.

In general, salt retention appears to precede the development of ascites or portal hypertension. The main stimulus is the activation of volume receptors located in intrahepatic sinusoids. This increase in pressure appears to signal the kidney to retain salt and water, thereby causing volume expansion. At a time when the kidney is retaining Na^+, the glomerular filtration rate and renal plasma flow are normal, as are plasma levels of renin and angiotensin. Although total plasma volume is increased, the capacity of the splanchnic bed is much larger in cirrhotic patients than in normal individuals. If the extra-splanchnic plasma volume is depleted or effectively depleted owing to splanchnic vasodilation and increased capacity, then the mechanism for salt retention is the same as that induced by simple extracellular volume depletion.

Ascites (Chapter 132) is not only due to portal hypertension. As cirrhosis advances, progressive portal hypertension contributes to excessive transudation of fluid into the peritoneal cavity. Further, the albumin secreted by the hepatocytes enters the lymphatic system, which delivers it to the thoracic duct and then to the blood stream. In cirrhosis, however, the disturbed architecture of the hepatic lobules causes much of the albumin to be dumped directly into the ascitic fluid. Thus, although the albumin concentration in ascitic fluid is low enough to be classified as a transudate, it is actually much higher than the albumin concentration in the extravascular fluid elsewhere in the body. In addition, when the synthetic function of the liver deteriorates and the serum albumin concentration falls, the low oncotic pressure results in transudation of fluid into the interstitial space. Volume depletion from any of these causes promotes salt retention through an increase in angiotensin II and aldosterone.

Nephrotic Syndrome and Glomerulonephritis

Immunologic injury to the glomerulus results in proteinuria and, almost uniformly, in salt retention. When the proteinuria is especially severe, nephrotic syndrome (Chapter 107) develops.

In most adults with nephrotic syndrome, the plasma volume appears to be normal or even expanded, likely because of primary salt retention by the kidney. The increased glomerular permeability that causes proteinuria in these diseases also increases the filtration of circulating proteases, which activate the epithelial Na channel (ENaC) in the collecting tubule, thereby increasing Na reabsorption independent of aldosterone. In a minority of patients (usually children), low oncotic pressure leads to intravascular volume depletion and activation of the renin-angiotensin-aldosterone system, which may stimulate sodium retention by the kidney.

In patients with glomerulonephritis, the glomerular filtration rate is reduced; because salt excretion is dependent on the adequacy of the filtered load, the inability to excrete a salt load is common in advanced glomerulonephritis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical manifestations depend on the amount and relative distribution of accumulated fluid. Particularly harmful manifestations of hypervolemia include hypertension, pulmonary congestion, pleural effusions with compromised respiratory function, congestive hepatopathy, ascites, and peripheral edema that can be severe enough to compromise skin integrity and predispose the patient to cellulitis (Chapter 408).

On physical examination, left heart failure is associated with pulmonary venous congestion as manifested by pulmonary crackles (Chapter 45), and right heart failure is associated with jugular venous distention (Fig. 39-1), peripheral edema, hepatic congestion, and even ascites (see Fig. 132-4). Pitting peripheral edema (Fig. 39-6) usually does not develop until patients have at least 3 L of excess interstitial volume. Pleural effusions usually are a manifestation of combined right and left heart failure (Chapters 45 and 46). Relative hypotension suggests more severe heart failure or even cardiogenic shock (Chapter 94). When hypotension is caused by portal hypertension (as in cirrhosis) or hypoalbuminemia, the clinical manifestations may be similar to pure right heart failure, except the jugular venous pressure will be low, not high.

Laboratory tests can provide evidence of cardiac, pulmonary, or liver disease. An elevated brain natriuretic peptide (BNP) level is seen in heart failure and other states of central venous overload. Hypoalbuminemia is seen in both cirrhosis and nephrotic syndrome, but the latter is associated with marked proteinuria (Chapter 107). An elevated serum creatinine level suggests acute or chronic renal failure, which can be intrinsic or occur with advanced heart failure (cardiorenal syndrome) or hepatic cirrhosis (hepatorenal failure).

TREATMENT

Treatment must be targeted to the underlying cause to optimize hemodynamic parameters in heart failure (Chapter 46), improve liver function (Chapter 139), or treat nephrotic syndrome (Chapter 107). The reduction of excess volume requires a negative sodium balance, which can be achieved by diuretic therapy in combination with dietary sodium restriction. If these interventions are insufficient, extracorporeal fluid removal by ultrafiltration may be required.

Diuretics

Diuretics (Table 102-4) enhance urinary excretion of sodium by inhibiting its tubular reabsorption (E-Fig. 102-2).[6,7]

Loop Diuretics

Loop diuretics are the most potent diuretics, even in patients who have relatively compromised kidney function. Loop diuretics induce the loss of sodium by inhibiting the coupled entry of Na^+, Cl^-, and K^+ in the thick ascending limb of the loop of Henle, which is responsible for the reabsorption of about 25% of filtered sodium. Loop diuretics also cause hypercalciuria and are useful in some hypercalcemic states (Chapter 227). Side effects include hypokalemia and metabolic alkalosis.

Distal Tubule Diuretics

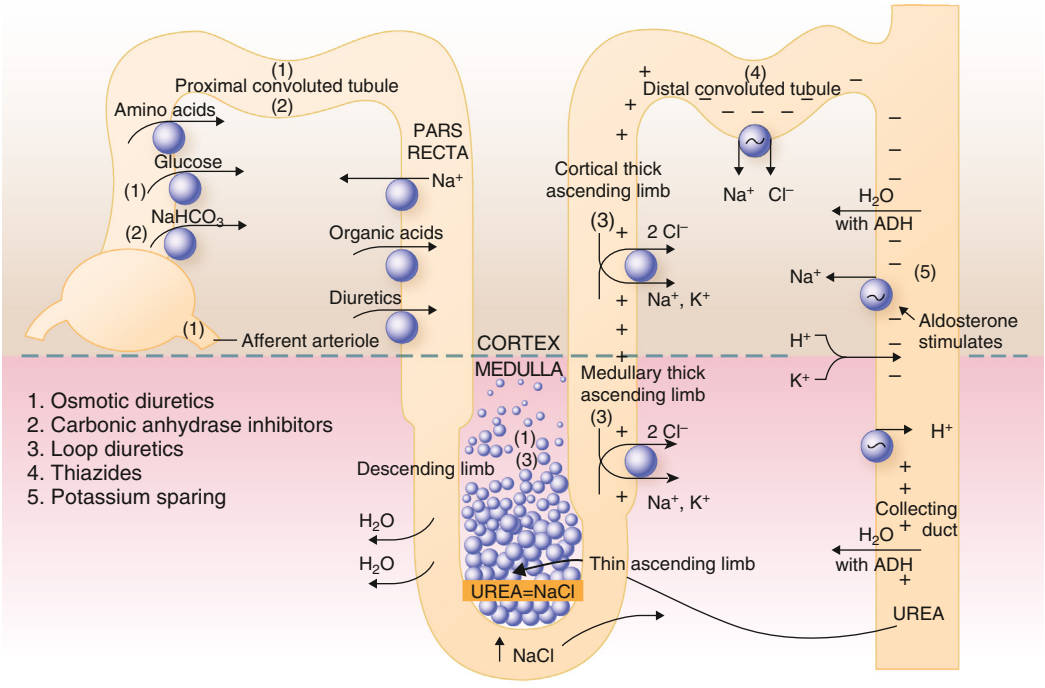
Distal tubule diuretics generally are used in the same conditions as loop diuretics, except for chronic kidney disease and disorders of calcium metabolism. Distal tubule diuretics block the sodium-chloride cotransport mechanism across apical plasma membranes in the distal tubule. Thiazide diuretics promote calcium retention and are useful in managing hypercalciuric states, including some forms of nephrolithiasis (Chapter 111). As with loop diuretics, thiazide diuretics may cause hypokalemia and metabolic alkalosis.

Collecting Duct Diuretics

Spironolactone and eplerenone compete with aldosterone and inhibit the absorption of sodium in the collecting duct, where they also suppress potassium secretion. Triamterene and amiloride, which directly block sodium uptake by collecting duct cells, also suppress potassium secretion. These collecting duct agents are used in combination with thiazide and loop diuretics to avoid hypokalemia, but hyperkalemia may complicate their injudicious use. Spironolactone and eplerenone are useful in managing disorders characterized by secondary hyperaldosteronism (e.g., cirrhosis with ascites), in promoting natriuresis in hypokalemic patients, and in competitively blocking nonepithelial mineralocorticoid receptors in patients with left ventricular dysfunction (Chapter 46).

Proximal Tubule Diuretics

Proximal tubule diuretics are rarely, if ever, used as primary therapy but are occasionally helpful as supplements to loop diuretics when loop diuretics alone are insufficiently effective. Acetazolamide, which is a carbonic anhydrase inhibitor, blocks the proximal reabsorption of sodium bicarbonate and can lead to hyperchloremic acidosis, in contrast to all other diuretics, which act at loci before the late distal nephron. Used alone, acetazolamide does not produce significant diureses since distal tubular absorption of sodium is maintained. It can, however, produce significant volume loss when used in combination with loop diuretics. Metolazone blocks sodium chloride absorption in the proximal tubule as well as in the early distal tubule, but it can cause phosphaturia.



E-FIGURE 102-2. **Major transport processes along the nephron segments and primary sites of action of diuretics.** The site of action of diuretics is shown by numbers in parentheses in each nephron segment; numbers correspond to those next to the diuretics listed in the lower-left section of the figure. ADH = antidiuretic hormone. (From Kokko JP. Diuretics. In: Alexander RW, Schlant RC, Fuster V, eds. *The Heart*. 9th ed. New York: McGraw-Hill; 1998.)

TABLE 102-4 DIURETICS AND OTHER NATRIURETIC MEDICATIONS

CLASSES OF DIURETICS IN COMMON USE	DAILY DOSE RANGE	ADVERSE REACTIONS (CLASS)	COMMENTS (CLASS)
Thiazides (oral)		Rash, neutropenia, thrombocytopenia, hyperglycemia, hyperuricemia.	Usually not effective below GFR of 30-40 mL/mm (metolazone, 20-30 mL/mm)
Hydrochlorothiazide	25-100 mg		
Metolazone	2.5-5 mg		
Chlorthalidone	20-50 mg		
Loop diuretics (oral or iv)		Ototoxicity at high doses. Electrolyte disturbances.	Rapid onset, short duration Split doses in normal renal function; give intravenously in acute situations or if reduced gastrointestinal absorption Can use up to 500 mg furosemide (or equivalent) in severe renal insufficiency
Furosemide	20-320 mg		
Bumetanide	1-8 mg		
Torsemide	20-200 mg		
Potassium-sparing diuretics (oral)		Hyperkalemia	Not very potent
Spironolactone	25-400 mg		
Triamterene	25-100 mg		
Amiloride	5-20 mg		
Eplerenone	25-50 mg		
Vaptans		Constipation, increased thirst, hyperglycemia, hepatotoxicity	Used for hypervolemic hyponatremia
Tolvaptan (oral)	15-60 mg		
Conivaptan (IV)	20-40 mg IV		

GFR = glomerular filtration rate; IV = intravenous.

Combination Diuretic Therapy

Patients with severe degrees of renal sodium avidity can be resistant to conventionally recommended doses of loop diuretics and may require combinations that act at different sites along the nephron. Using various combinations of a loop diuretic with a thiazide diuretic, mineralocorticoid antagonist (e.g., spironolactone), or a proximal tubule diuretic (e.g., acetazolamide) can augment sodium loss as compared with a loop diuretic alone. Plasma concentrations of sodium, potassium, magnesium, calcium, and phosphate must be monitored carefully in such patients.

Sodium restriction does not clearly augment negative fluid balance over what can be achieved by furosemide alone. If dietary sodium is not restricted, however, patients will require higher doses of diuretics and can reaccumulate fluid. Sodium restriction to 50 to 100 mmol/day, which requires abstention from added salt as well as from foods rich in sodium, may be helpful. Sodium substitutes also can be useful, but they must be used with caution to avoid hyperkalemia if the salt substitute contains potassium. Caloric intake and nutrition must be monitored to ensure that a low-salt diet does not cause protein-energy malnutrition. Water restriction is not an appropriate therapy for hypervolemia unless hyponatremia develops. Similarly vasopressin V2-receptor antagonists, which may augment water loss, do not improve symptoms of heart failure but can raise the serum sodium concentration in patients who have hyponatremia (see Hyponatremia).

Extracorporeal Ultrafiltration

A small subset of patients have superimposed renal impairment or extreme resistance to the natriuretic actions of diuretics. Such patients may require the direct removal of excess volume by ultrafiltration, hemodialysis, or peritoneal dialysis (Chapter 117).

DISORDERS OF TONICITY OF BODY FLUIDS: HYPONATREMIA AND HYPERNATREMIA

PATHOBIOLOGY

Regulation of the Tonicity of Body Fluids

Osmotic pressure is a function of the sum of all solutes (in moles or equivalents) in a given volume of body fluids (osmolality). Tonicity is equal to the osmolality minus the concentration of ineffective solutes. Osmolality is a property of a particular solution and is independent of any membrane. Tonicity is a property of a solution in reference to a particular membrane. Tonicity (osmolality) is a highly regulated physiologic human parameter, and reasonable variations in daily water intake do not change osmolality by more than 0.5%. Water is freely permeable via water channels (aquaporins) through most cellular membranes, so no osmotic gradients exist among the body's fluid compartments. In contrast to water, sodium cannot travel freely across cell membranes. Thus, drinking a large volume of water is followed by a reduction in extracellular osmolality, thereby causing water to diffuse into the cell. This exchange causes an acute increase in cell volume, which is usually well tolerated except in cells that are encased in rigid compartments such as in the brain. Over time, compensatory mechanisms will decrease or increase intracellular osmoles in parallel with changes in extracellular osmolality, thereby restoring cell volume towards normal. The opposite phenomenon is seen when extracellular osmolality increases acutely (e.g., after consuming a high-salt diet).

A good approximation of osmolality can be obtained by measuring the serum or plasma sodium concentration, because sodium and its counter-ions (chloride and bicarbonate) comprise 90% of osmolality. With only a few exceptions, a normal Na concentration reflects normal osmolality. Thus, clinical states of low or high osmolality are frequently referred to as hyponatremia and hypernatremia, respectively.

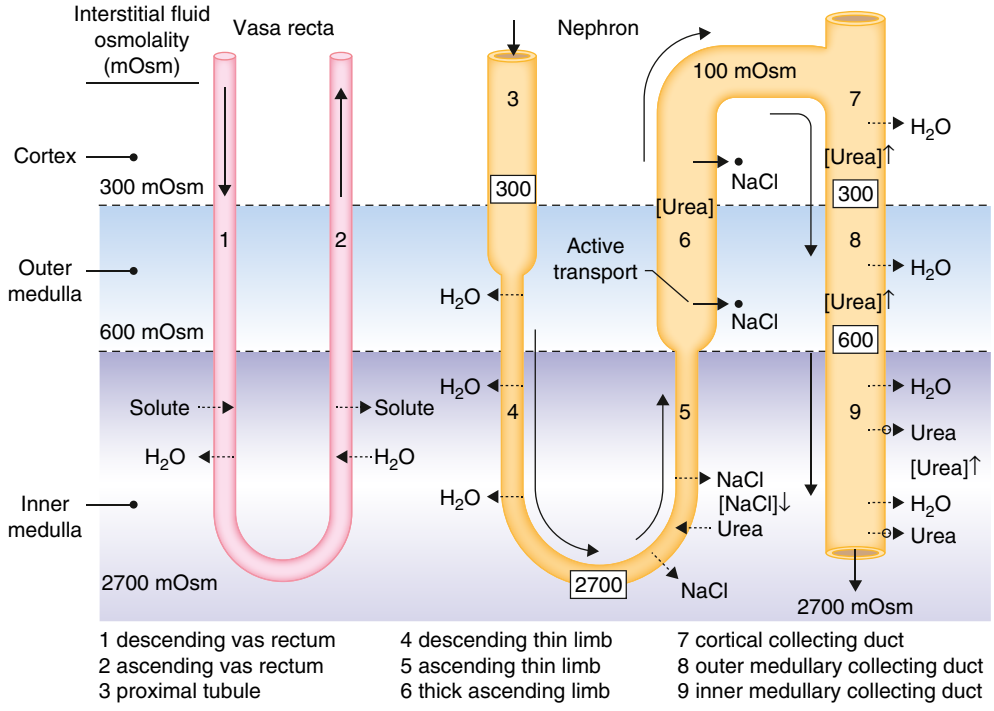
Importantly, the regulation of osmotic pressure is entirely a function of the regulation of water content rather than sodium content. The total sodium *content* of the body fluids is most closely related to the total extracellular volume, whereas the sodium *concentration* is related to osmolality or water content. In hyponatremia, the total body sodium content may be high, low, or normal, but from the perspective of osmolar regulation, the water content is always too high relative to the sodium content.

The balance of water intake and excretion relative to sodium intake and excretion determines serum osmolality. Free water is the volume of electrolyte-free water. For example, 1.0 L of half-normal sodium chloride equals 0.5 L of normal saline and 0.5 L of free water, so infusion of 1.0 L of half-normal saline increases free water content by 0.5 L. When electrolytes other than sodium (e.g., potassium) are added to fluids, they reduce free water by corresponding amounts.

Body fluid tonicity (as measured in the serum) reflects the balance of free water input compared with free water output. Only the renal free water output is regulated; in the steady state, this renal free water output must equal free water input minus nonrenal water losses. Free water input equals oral intake plus intravenous intake. Nonrenal free water losses include cutaneous and respiratory insensible losses, as well as any water lost in the stool.

Oral intake varies with thirst and with habits. Thirst is stimulated by an increase in the osmotic pressure of the body fluids as well as by nonosmotic stimuli, such as hypotension or plasma volume depletion. These latter stimuli can dominate, and thirst, which is quenched only with hypotonic fluids, may be stimulated despite the presence of hypo-osmolarity. Insensible losses increase with increased ambient temperature, fever, or extensive damage to the skin, such as burns (Chapter 97). These variations can be very large; for example, the maximum rate of sweating is about 1 liter per hour.

The renal output of free water is a function of the urine volume and the concentration of the urinary solutes (E-Fig. 102-3). In the proximal tubule,



E-FIGURE 102-3. Diagram of a single vas rectum and single long-looped nephron. In the outer medulla, active transport of NaCl out of the water-impermeable thick ascending limb (indicated by *solid arrows* and *black dots*) creates the small osmotic pressure difference between that limb and the descending limb sufficient for classic countercurrent multiplication to generate the osmotic gradient (approximate osmolalities for rat kidney given by numbers in the *black boxes*). For the proposed "passive" mechanism in the inner medulla, urea ([urea]) is concentrated ([urea]↑) in urea-impermeable cortical and outer medullary collecting ducts by reabsorption of NaCl and water (*broken arrows* indicate passive movement). Urea then moves passively out of the inner medullary collecting ducts via vasopressin-regulated urea transporters (UT-A1, UT-A3; *open circles* and *broken lines*) into the surrounding inner medulla interstitium. This increased concentration of urea in the inner medullary interstitium draws water from descending thin limbs (DTLs) and inner medullary collecting ducts (IMCDs), thereby reducing inner medullary interstitial concentration of NaCl ([NaCl]↓). These processes result in a urea concentration in the interstitium that is higher than the urea concentration in the ascending thin limbs (ATLs) and an NaCl concentration in the ATLs that is higher than the NaCl concentration in the interstitium. NaCl will then tend to diffuse out of the ATLs (*broken arrows*) and urea will tend to diffuse into the ATLs (*broken arrows*). If the permeability of the ATLs to NaCl is sufficiently high and to urea sufficiently low, the interstitial fluid will be concentrated (producing the osmotic gradient) as the ATL fluid is being diluted. Countercurrent exchange of solutes and water helping to preserve this gradient is indicated in the vas rectum. Segments are numbered according to the key. (Reproduced with permission from Dantzler WH, Layton AT, Layton HE, et al. Urine-concentrating mechanism in the inner medulla: function of the thin limbs of the loops of Henle. *Clin J Am Soc Nephrol*. 2014;9:1781-1789.)

where more than 60% of the glomerular filtrate is reabsorbed, water permeability is so high that the osmotic pressure at the end of the segment is similar to that of plasma. The volume of glomerular filtrate that reaches the loop of Henle varies with the glomerular filtration rate and the extent of proximal tubule reabsorption. As the fluid courses through the thick ascending limb, active salt reabsorption combined with low water permeability causes dilution of the tubular fluid. The salt that is reabsorbed (without much water) into the medulla establishes a hyperosmolar region. This gradient provides the driving force for water reabsorption from the collecting duct. As the thick ascending limb ends and the distal tubule, which is termed the cortical diluting segment, begins, salt reabsorption in the presence of low water permeability continues to reduce the tonicity of the urine to one third of that of plasma. The volume of hypotonic fluid reaching the collecting duct is about 25 L/day. If the collecting duct is relatively impermeable to water, then much of this volume can be excreted. At the other extreme, if the collecting duct is fully permeable to water and if the medullary concentration gradient is undisturbed, then water is maximally reabsorbed and only a small volume of concentrated urine is excreted (perhaps 0.5 L at 1200 mOsm/L). Arginine vasopressin, which is human antidiuretic hormone (ADH), regulates the collecting duct water permeability.

ADH is synthesized in the supraoptic and paraventricular nuclei and stored in the neurohypophysis. Thirst is mediated by adjacent cells intermingled with cells that synthesize ADH. Hypothalamic osmoreceptors modulate release of ADH in response to very small changes in the plasma osmolality. However, below a certain plasma osmolality, the ADH level does not decrease further. This set point, which is characteristic of each individual, represents the set point of the *osmostat*. ADH is released into the circulation, where it has a short half-life. ADH activates two types of G-protein coupled receptors, V1 that mediates vasoconstriction in vascular smooth muscle and V2 that is expressed in the principal cells of the collecting duct of the kidney. The luminal membrane of these cells is relatively impermeable to water. However, activation of the V2 receptors by ADH causes insertion of a specific water channel, aquaporin 2, into the luminal membrane of the cortical and medullary collecting duct, thereby leading to increased water absorption driven by the osmotic gradient.

Other factors can also stimulate ADH release. Low arterial filling in hypotension (Chapter 64), heart failure (Chapters 45 and 46), cirrhosis (Chapter 139), and intravascular volume depletion stimulate ADH release by activating the carotid sinus and left atrial receptors. Decreases in extracellular volume cause a decrease in the set point but an increase in the steepness of the relation between ADH secretion and osmolality. Compared with a normovolemic person, the same plasma osmolality in a volume-depleted person is associated with a higher ADH level.

HYPONATREMIA

DEFINITION

Hyponatremia is defined as a serum sodium below 135 mmol/L, which corresponds to a serum osmolality <280 mOsm/kg H_2O (Table 102-5). Hyponatremia generally indicates hypo-osmolarity, but with two exceptions. First, in marked hyperlipidemia (Chapter 190) or paraproteinemia (Chapter 173), the aqueous portion of a volume of plasma is reduced. Since Na^+ is present only in the aqueous phase, the Na^+ concentration appears to be low (pseudohyponatremia) even though the measured osmolality is normal. Second, the serum Na^+ concentration may be low in the presence of high concentrations of effective osmoles, such as seen with hyperglycemia (Chapter 210), alcohol ingestions, and mannitol. These molecules do not readily enter cells, but they withdraw water from cells, thereby leading to dilution of the serum Na^+ concentration and initially leading to a normal serum osmolality. However, severe dehydration in the presence of uncontrolled blood glucose elevations can lead to the hyperosmolar hyperglycemic syndrome (Chapter 210), in which the serum is hyperosmolar owing to the elevated concentration of these osmotically active substances.

TABLE 102-5 DEFINITIONS OF HYPONATREMIA

	SERUM SODIUM (mmol/L)	PLASMA OSMOLALITY (mOsm/kg H_2O)	ETIOLOGY
Hypo-osmolar	<135	Low (<280)	Volume depletion (true and effective)
Iso-osmolar	<135	Normal (280-295)	Hyperlipidemia, paraproteinemia, hyperglycemia, alcohols
Hyper-osmolar	<135	High (>295)	Hyperglycemia, alcohols (with severe dehydration)

EPIDEMIOLOGY

The incidence of hyponatremia (serum sodium concentration <135 mmol/L) is as high as 15 to 30% in hospitalized patients. Using a definition of serum sodium concentration <130 to 131 mmol/L, which may represent a more clinically significant threshold, the incidence is about 1 to 4%. In the nonhospitalized general population in the United States, the prevalence of hyponatremia (serum sodium concentration <133 to 136 mmol/L) is estimated to be 1.7%.

PATHOBIOLOGY

In every case of hypo-osmolar hyponatremia, either free water intake minus insensible losses is elevated, renal free water output is decreased, or both. Urine is diluted by the reabsorption of sodium in nephron segments with a low permeability to water. In the absence of antidiuretic hormone, such segments include the thick ascending limb of Henle, the distal tubule, and the collecting tubules. Urine is not diluted in the proximal tubule because reabsorption of sodium is isosmotic to plasma. For the kidney to generate a large volume of dilute urine, a sufficient volume must reach the distal nephron segments. Several mechanisms may impair the kidney's capacity to produce dilute urine, thereby leading to hyponatremia (Table 102-6).

Kidney Failure

In both acute (Chapter 106) and severe chronic renal failure (Chapter 116), a low glomerular filtration rate impairs the delivery of fluid to the distal cortical diluting segment of the nephron. Since the urine volume is relatively fixed, any increase in the intake of free water above the limited urine volume will lead to hyponatremia.

Primary Polydipsia

The capacity of the normal kidney to excrete free water under normal hemodynamic conditions is very large, about 20 L/day. Only rarely, such as in psychogenic polydipsia, can a patient become hyponatremic simply by increasing water intake. The hallmark of psychogenic polydipsia is hyponatremia with a maximally dilute urine (osmolality well below 100 mOsm/kg).[8]

Low Dietary Solute

A diet low in solutes will lead to decreased delivery of urine to the distal diluting segments. When this diet is combined with an increased intake of free water, hyponatremia ensues. For example, beer potomania syndrome occurs when patients consume large volumes of beer (rich in carbohydrates and water but poor in sodium and protein), thereby limiting urinary solutes and hence urinary water excretion. A similar phenomenon is noted with a diet of tea and toast.

Extracellular Volume Depletion

In true volume depletion, the genesis of hyponatremia involves two defects: antidiuretic hormone is secreted despite hypo-osmolarity and, to a lesser extent, inadequate delivery of tubular fluid to the diluting segment. The secretion of antidiuretic hormone is increased owing to the activation of volume receptors. If volume depletion is treated with hypotonic fluids, hyponatremia will ensue.

TABLE 102-6 MECHANISMS OF HYPONATREMIA

MECHANISM	EXAMPLES
Low GFR leading to decreased delivery to distal nephron	Acute or chronic kidney failure
Excessive free water intake exceeding kidney capacity to excrete free water	Primary polydipsia
Low dietary solute	"Beer potomania" and the "tea and toast diet"
True extracellular volume depletion	Diarrhea and vomiting, hypoadrenalism
Effective plasma volume depletion	Heart failure, cirrhosis
Syndrome of inappropriate ADH secretion (SIADH)	See Table 102-7
Multiple mechanisms	Thiazides, NSAIDs

ADH = antidiuretic hormone; GFR = glomerular filtration rate; NSAIDS = nonsteroidal anti-inflammatory drugs.

The urine sodium levels will be low and serum uric acid will be elevated in such conditions, with the exception of active use of diuretics, which will elevate urine sodium levels. Similar findings are seen in patients with a loss of effective intravascular volume (e.g., heart failure), but such patients will have edema.

Thiazide-induced hyponatremia, which is one of the most common causes of drug-induced hyponatremia, occurs in about 9% of treated patients,[9] especially in older female patients. The pathogenesis of hyponatremia is likely multifactorial, owing to an increased intake of water with an impaired capacity to excrete water. Thiazide diuretics reduce the generation of free water because they inhibit Na^+ reabsorption in the diluting segment. In addition, the mild volume depletion caused by thiazides induces a decrease in fluid delivery out of the proximal tubule, thereby further reducing the volume of dilute urine generated by the kidney. Finally, the collecting duct is more permeable to water, likely due in part to an increase in antidiuretic hormone induced by mild volume depletion. Hyponatremia is uncommon with the chronic use of loop diuretics because they abolish the medullary concentration gradient, which is maintained with thiazide diuretics.

Cerebral salt wasting occurs uncommonly after head injury, subarachnoid hemorrhage, and neurosurgical procedures. The pathogenesis is thought to result when proximal tubular salt wasting of unknown etiology leads to volume depletion and subsequent stimulation of antidiuretic hormone. Since uric acid is also lost from the proximal tubule defect, urinary concentrations of sodium and serum uric acid are unreliable markers of volume depletion.

Hypoadrenalism (Chapter 208) is typically associated with hyponatremia, in large part because of the extracellular volume depletion that is a feature of this disease. The volume depletion results from a decrease in salt reabsorption in the collecting duct owing to the absence of aldosterone. In contrast to other patients with extracellular volume depletion, urinary sodium excretion will be high in these patients. Glucocorticoid deficiency may also contribute to the development of hyponatremia (see later).

Effective Volume Depletion

In patients with heart failure (Chapters 45 and 46) and cirrhosis (Chapter 139), the intra-arterial volume is typically low despite total body hypervolemia. The urine sodium concentration is low and serum uric acid elevated, similar to what is seen in volume-depleted patients (in whom the urine sodium may not be low in the presence of diuretics).

Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH)

In the presence of high concentrations of antidiuretic hormone, water is avidly reabsorbed in the collecting duct. If water intake is not curtailed, hyponatremia will result. A subclinical increase in the extracellular volume will lead to a decrease in the reabsorption of salt. Urine sodium levels will be high, and, as a result of decreased proximal tubular reabsorption of uric acid, the serum uric acid will be low.

The syndrome of inappropriate antidiuretic hormone (SIADH; Table 102-7)[10] is seen with a number of conditions, including tumors that secrete antidiuretic hormone, various pulmonary abnormalities and CNS disorders, and a number of medications (Table 102-8). Patients with tumor-induced SIADH have high antidiuretic hormone levels regardless of the plasma osmolality. Other patients seem to have a resetting of the osmostat (i.e., they are able to suppress antidiuretic hormone but at a lower plasma sodium concentration than normal). Still others seem to have a continuous low level of antidiuretic hormone secretion regardless of the plasma osmolality, as if there was a continuous leak of antidiuretic hormone from the posterior pituitary. A few others have perfectly normal responses, thereby implying that they might express another antidiuretic hormone.

The nephrogenic syndrome of inappropriate antidiuresis is a very rare condition that is clinically similar to SIADH. In this disorder, gene variants in *V2R* cause constitutive activation of the V2 receptor and result in antidiuresis. Unlike SIADH, plasma vasopressin levels are suppressed.

Isolated glucocorticoid deficiency occurs in association with anterior pituitary disorders (Chapter 205) that impair normal secretion of ACTH, thereby leading to secondary adrenal insufficiency. The deficiency of cortisol leads to failure to suppress vasopressin levels, and the hyponatremia resembles SIADH rather than classic primary adrenal insufficiency in which hypovolemia occurs consequent to a lack of aldosterone.

Other Causes

Hypothyroidism (Chapter 207) is rarely associated with hyponatremia. Patients typically have high antidiuretic hormone levels, perhaps owing to a decrease in cardiac output. However, hypo-osmolality is frequently out of proportion to the clinical signs of decreased cardiac output. Thyroid hormone also appears necessary to maintain the number of sodium pumps in the kidney; because salt reabsorption in the ascending limb of the loop of Henle is dependent on sodium pumping, more Na^+ will be lost in the urine.

Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit prostaglandin synthesis, and prostaglandins inhibit the effect of antidiuretic hormone on the collecting duct. Thus, NSAIDs increase the sensitivity of the tubule to ADH. This effect will not in and of itself impair free water absorption unless the vasopressin level is increased, as it often is in the setting of volume-depletion or heart failure. In addition, prostaglandins also enhance the effects of angiotensin II. When NSAIDs are administered to volume-depleted patients with elevated angiotensin II, the effect of angiotensin II is potentiated, the filtration fraction is increased, the proximal tubular reabsorption of water is

TABLE 102-7 CRITERIA FOR THE DIAGNOSIS OF THE SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

Decreased effective osmolality of the extracellular fluid (plasma <275 mOsmol/kg H_2O). Inappropriate urinary concentration (Uosm >100 mOsmol/kg H_2O with normal renal function) at some level of plasma hypo-osmolality.
Clinical euvolemia, as defined by the absence of signs of hypovolemia (orthostasis, tachycardia, decreased skin turgor, dry mucous membranes) or hypervolemia (subcutaneous edema, ascites).
Elevated urinary sodium excretion (>20 to 30 mmol/L) while on normal salt and water intake.
Absence of other potential causes of euvolemic hypo-osmolality (e.g., severe hypothyroidism, hypocortisolism [glucocorticoid insufficiency]).
Normal renal function and absence of diuretic use, particularly thiazide diuretics.

TABLE 102-8 CAUSES OF THE SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

ECTOPIC ADH PRODUCTION FROM TUMORS
Bronchogenic carcinoma (Chapter 177)
Adenocarcinoma of pancreas (Chapter 180)
Adenocarcinoma of duodenum (Chapter 179)
Carcinoma of the ureter (Chapter 182)
Non-Hodgkin lymphoma (Chapter 171)
Hodgkin disease (Chapter 172)
Thymoma (Chapter 390)
PULMONARY DISEASE
Tuberculosis (Chapter 299)
Pneumonia (Chapter 85)
Aspergillosis with cavitation (Chapter 311)
Lung abscess (Chapter 78)
Chronic chest infections (e.g., bronchitis; Chapter 78)
Positive pressure mechanical ventilation (Chapter 91)
CENTRAL NERVOUS SYSTEM DISEASE
Brain tumor (Chapter 175)
Encephalitis (Chapter 383)
Meningitis (Chapter 381)
Brain abscess (Chapter 382)
Head injury (Chapter 368)
Subarachnoid hemorrhage (Chapter 377)
Guillain-Barré syndrome (Chapter 380)
Acute intermittent porphyria (Chapter 194)
In response to stress (Chapter 97)
DRUG-INDUCED
AVP analogs: desmopressin (Chapter 206), oxytocin (Chapter 206)
Alkylating agents/antimetabolites (Chapter 164)
Anticonvulsants (Chapter 372)
Antipsychotic agents (Chapter 362)
Antidepressants (Chapter 362)
Nicotine (Chapter 363)
Opiates (Chapter 365)
3-4-Methylenedioxymethamphetamine (Ecstasy; Chapter 365)

AVP = arginine vasopressin.

increased, and the distal delivery of water is diminished. As a result, free water excretion is decreased.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hyponatremia, which is a plasma sodium concentration of less than 136 mmol/L, is often an incidental finding on routine laboratory testing or is found as part of the investigation of other clinical syndromes. Hyponatremia may be hypertonic, isotonic, or hypotonic. Hypertonic hyponatremia is caused by an accumulation of non–sodium-containing effective solutes, such as very high concentrations of glucose in diabetic patients or exogenously administered mannitol or glycerol. Isotonic hyponatremia is not accompanied by any abnormalities in other electrolytes and nearly always reflects pseudohyponatremia from marked hyperlipidemia or hyperglobulinemia.

Hypotonic hyponatremia always reflects an important underlying disorder with abnormal retention of body water (see Table 102-6). Hypotonic hyponatremia can be further classified as hypervolemic (e.g., heart failure [Chapter 45], cirrhosis with ascites [Chapter 139], advanced renal failure [Chapter 116]) or hypovolemic hyponatremia (more sodium than water is lost through the gastrointestinal tract [diarrhea] or in the urine [e.g., thiazide diuretics], or ingested or administered replacement fluid is more hypotonic than the lost fluid).

The symptoms of hypotonic hyponatremia depend on its duration, severity, and rate of development.[11] When it develops over hours to days, acute brain swelling or cerebral edema may be manifested as headache, lethargy, seizures, and decreased levels of consciousness that can lead to coma and death, especially in women between menarche and menopause.[12] By comparison, if the rate of decline in the plasma sodium concentration is more gradual, osmotic adaptation may avoid serious clinical manifestations even with severe hyponatremia (plasma sodium concentration <120 mmol/L).

A careful evaluation, including a review of prior plasma sodium values, will help determine the rate of decline and provide important clues to the cause (Fig. 102-3). The physical examination should assess for hypervolemia (Chapters 7 and 39). Conversely, orthostatic hypotension and tachycardia suggest hypovolemia. The BUN, plasma electrolytes, glucose level, and osmolality should be checked to allow comparison of the measured with the calculated plasma osmolality according to the following equation:

$$\text{Plasma osmolality (mOsm/kg)} = 2\text{Na}^+\text{(mmol/L)} + (\text{blood urea nitrogen[mg/dL]}/2.8) + (\text{glucose[mg/dL]}/18)$$

Other laboratory tests in selected patients should include liver function tests and measurement of plasma creatinine, uric acid, thyroid-stimulating hormone, and cortisol concentrations; if indicated, an adrenocorticotropic hormone stimulation test should be performed (Chapter 209). Symmetrically elevated levels of both BUN and creatinine point to intrinsic renal disease, whereas a disproportionate elevation of BUN over creatinine suggests hypovolemia with a tendency to prerenal azotemia (Chapter 106). In contrast, very low levels of BUN and uric acid are typical of both SIADH and cerebral salt-wasting syndrome (see Normovolemic and Hypovolemic Hyponatremia).

About 85% of inpatients with hyponatremia have true hyponatremia, about 25% of whom are hypovolemic, about 25% of whom have an edematous state, about one third of whom are normovolemic, and the remainder of whom usually have renal failure. Since the plasma sodium concentration declines by approximately 1.6 mmol/L for each increase of 100 mg/dL (5.5 mmol/L) in plasma glucose concentration, marked elevation in the plasma glucose concentration can cause *hypertonic* hyponatremia. In contrast to hyperglycemia, an elevated BUN does not alter the plasma sodium concentration, even though urea contributes to the laboratory measurement of plasma osmolality; thus, a hyponatremic patient with a normal or elevated laboratory measurement of plasma osmolality that can be fully attributed to an increased BUN should be considered as having hypotonic hyponatremia.

A discrepancy in which measured plasma osmolality exceeds calculated plasma osmolality, even after accounting for glucose and urea, indicates the presence of an unidentified small solute (osmolar gap), including alcohols (e.g., ethanol, methanol, ethylene glycol, and isopropyl alcohol) and the organic anions of weak acids, which raise the plasma anion gap. Because these small

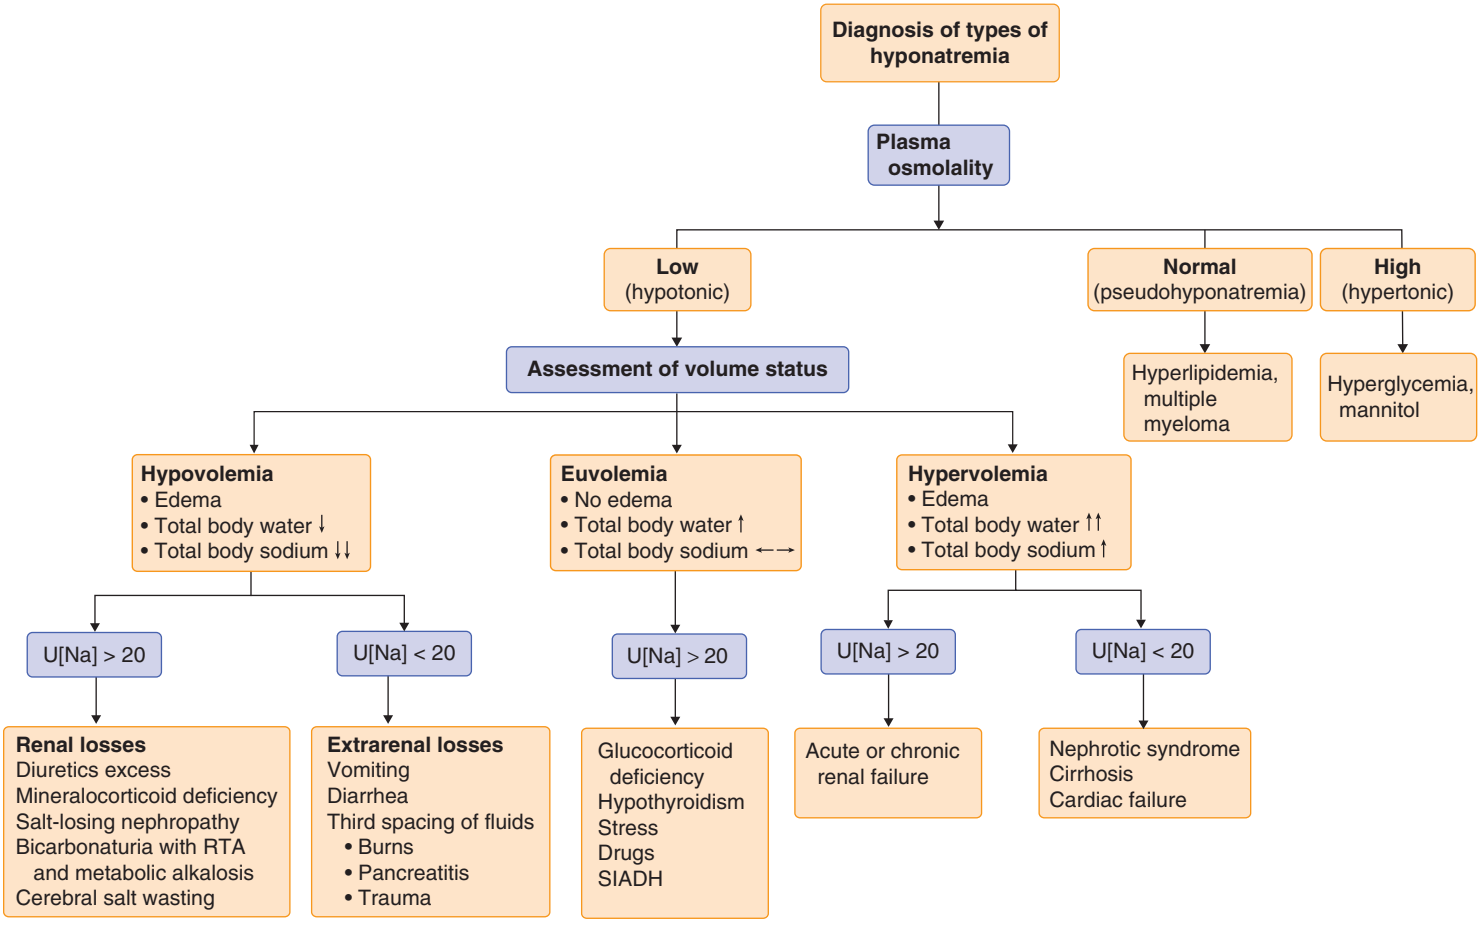


FIGURE 102-3. Diagnostic approach to hyponatremia. RTA = renal tubular acidosis; SIADH = syndrome of inappropriate antidiuretic hormone secretion; U[Na] = urinary sodium concentration. (Modified from Halterman R, Berl T. Therapy of dysnatremic disorders. In: Brady H, Wilcox C, eds. *Therapy in Nephrology and Hypertension*. Philadelphia: Saunders; 1999:256; and data from Cohen DM, Ellison DH. Evaluating hyponatremia. *JAMA*. 2015;313:1260-1261.)

molecules do not affect the movement of water, the patient's water balance is determined by the plasma sodium concentration. However, an osmolar gap should prompt a thorough investigation for poisoning, intoxication, or an organic acidosis (Chapter 104).

As soon as true hypotonic hyponatremia is established, the evaluation aims at classifying the cause into one of three categories based on the patient's volume status (see Fig. 102-3). Abnormal liver function test results can provide adjunctive support for hepatic disease and a hypervolemic hyponatremic state. The diagnosis of heart failure should be made clinically, but it can be assisted by a BNP level, chest radiograph, or echocardiography (Chapter 45).

In the absence of a clinically obvious edema, a low urine sodium concentration (<20 mmol/L) or a low fractional excretion of sodium (<1%) supports the diagnosis of hypovolemic hyponatremia secondary to extrarenal losses or past renal losses that have since abated. In hypovolemia caused by ongoing renal losses, the urine sodium concentration may remain high despite hypovolemia, but the fractional excretion of urea may also be low (<35%). A high urinary concentration of potassium is suggestive of potassium-depleting diuretic use, whereas the urinary potassium concentration of potassium is low (<20 mmol/L) if potassium is being lost because of diarrhea or vomiting.

The combination of hypotonic hyponatremia without hypovolemia, hypervolemia, hypothyroidism, or adrenal insufficiency combined with low plasma urea and uric acid concentrations strongly suggests SIADH. The urine sodium concentration typically is higher than 40 mmol/L, often higher than 100 mmol/L. Lack of sustained improvement after a salt-containing volume challenge further supports the diagnosis of SIADH and should prompt a search for its cause (see Table 102-8). A radiograph or chest computed tomography scan may help identify intrathoracic lesions that are associated with SIADH.

Hypervolemic Hyponatremia

In hypervolemic hyponatremia, both water and sodium are in excess, but the excess of water is greater than the excess of sodium. The most frequent causes are heart failure (Chapter 45), decompensated cirrhosis (Chapter 139) with ascites (Chapter 132), and advanced renal failure (Chapter 117), just as in hypervolemia without hyponatremia. The urine sodium concentration is less than 20 mmol/L and the fractional sodium excretion is less than 1% (despite obvious volume expansion, commonly with edema) unless it is altered by a diuretic-induced natriuresis.

Normovolemic and Hypovolemic Hyponatremia

Normovolemic and hypovolemic hyponatremia may be difficult to distinguish from each other because mild hypovolemia can be difficult to detect on the history and physical examination. A low urine sodium concentration and low fractional excretion of sodium are characteristic of extrarenal hypovolemia, but the urine sodium concentration is usually elevated when hypovolemia is due to urinary loss.

Hypovolemic hyponatremia always signifies past or ongoing sodium loss (often with potassium) accompanied by a lesser degree of water loss, with appropriately elevated ADH levels in response to the hypovolemia. In most cases, loss of sodium results in volume depletion, which activates thirst, thereby inducing the patient to drink water; because volume-mediated release of antidiuretic hormone is retained, hyponatremia develops. Hyponatremia is a common complication of diarrhea (Chapter 126) when the diarrheal fluid is secretory and rich in electrolytes. Sweating-induced hyponatremia occurs when individuals ingest high volumes of hypotonic fluid, often pure water, while losing sodium in sweat.

The renal causes of hypovolemic hyponatremia (see Fig. 102-3) include thiazide-induced hyponatremia and the cerebral salt-wasting syndrome. Thiazide-induced hyponatremia occurs when patients with impaired urinary diluting capacity excrete concentrated urine because thiazides do not affect the ability of the renal medulla to concentrate urine. Thiazide-treated patients are particularly susceptible to hyponatremia when they ingest or receive hypotonic solutions that exceed their maximal capacity to excrete electrolyte-free water in their urine. In cerebral salt wasting, patients who have suffered a head injury or intracranial hemorrhage have inappropriate renal sodium wasting; antidiuretic hormone levels rise and patients develop hyponatremia if hypotonic fluid is then ingested or administered. SIADH also is characterized by a high urine sodium concentration and hyponatremia, but a high fractional excretion of uric acid is found only in cerebral salt wasting.

In normovolemic hypotonic hyponatremia, urine containing sodium concentrations greater than 40 mmol/L usually indicate SIADH (Table 102-8),[13] but hypothyroidism (Chapter 207) and adrenal glucocorticoid insufficiency (Chapter 208) can be associated with hypotonic hyponatremia that mimics SIADH without clinically evident hypovolemia. Pregnancy, which also is associated with thirst as well as a reduction in the osmotic threshold for ADH release, results in mild hyponatremia (Chapter 221).

TREATMENT

Treatment of hyponatremia varies depending on the urgency of the clinical situation, its cause, and the underlying diagnosis (see Fig. 102-3). Some data suggest that a bolus of 3% saline (100 mL repeated up to two more times) may safely correct hyponatremia more rapidly than a continuous infusion. Hyponatremia should be approached from the perspective of free water intake compared with renal free water output.

The first principle is that the rate of correction should be guided by the patient's age, gender, and neurologic status and any information about recent and past plasma sodium concentrations or osmolality values. Delayed correction of hyponatremia can perpetuate cerebral edema and result in irreversible neurologic damage and death, especially in women of reproductive age and in patients whose hyponatremia developed at a pace that outstripped the rate of osmotic adaptation in the brain. In contrast, overly rapid correction or correction to a sodium concentration that is above the level needed to safeguard the patient from the neurologic sequelae of cerebral edema can result in the devastating and often irreversible *osmotic demyelination syndrome* (Chapter 384), which is characterized by fluctuating levels of consciousness, pseudobulbar palsy, ataxia, dysarthria, difficulty in swallowing, and characteristic abnormalities in the region of the brain stem on magnetic resonance imaging (MRI; see Fig. 384-3). Risk factors for the development of osmotic demyelination syndrome include severe hyponatremia (serum sodium concentration <105 mmol/L), hypokalemia, alcohol use disorder, malnutrition, and advanced liver disease.

The second principle is the importance of identifying and treating any underlying disorder, such as the hypervolemia of heart failure (Chapters 45 and 46). In hypovolemic patients, appropriate fluid administration can correct the hyponatremia.

Acute Symptomatic Hyponatremia

Acute symptomatic hyponatremia that requires urgent treatment includes self-induced acute water intoxication (e.g., psychiatric diseases such as acute psychosis or schizophrenia; endurance exercise), known hyponatremia with a duration <24 to 48 hours; hyponatremia from an intracranial cause (includes increased intracranial pressure); or hyponatremia accompanied by seizures or coma, regardless of chronicity. The goal is urgent correction by 4 to 6 mmol/L to prevent brain herniation and neurologic damage from cerebral ischemia.

For severe symptoms, 100 mL of 3% NaCl should be infused intravenously over 10 minutes, repeated twice as needed.[14] This rapid bolus approach is as good as a continuous infusion for correcting hyponatremia with a lower risk of overcorrection.[A6] For mild to moderate symptoms with a low risk of herniation, 3% NaCl should be infused at 0.5 to 2 mL/kg/hour. The rate of correction need not be restricted in patients who have true acute hyponatremia, nor should inadvertent overcorrection be reversed. If, however, the hyponatremia might be chronic rather than acute, the limits for correction of chronic hyponatremia should be followed.

Chronic Hyponatremia

Symptomatic hyponatremia or sodium concentrations below 125 to 130 mmol/L require specific treatment, but mild degrees of asymptomatic hyponatremia can be tolerated for long periods. When deciding treatment strategies in such patients who are known to have developed hyponatremia, the severity of symptoms, risk factors for osmotic demyelination syndrome, and the underlying cause of hyponatremia should be taken into consideration. Frequent monitoring of the plasma sodium concentration and osmolality is crucial. If the safe target rate of correction is exceeded, osmotic demyelination can be prevented by slowing the correction rate, by returning to a lower plasma sodium concentration with the judicious readministration of hypotonic solutions, or by administering vasopressin analogues (see later).

Patients who are at risk for osmotic demyelination syndrome have hyponatremia with serum [Na^+] <120 mmol/L of >48 hours' duration. Examples include outpatients who have been drinking conventional volumes of water, are treated with thiazide diuretics, or have hospital-acquired hyponatremia with a known duration of >48 hours.

To avoid osmotic demyelination syndrome in such patients, the goal of therapy is minimum correction of serum sodium concentration by 4 to 8 mmol/L per day, with a lower goal of 4 to 6 mmol/L per day if the risk of osmotic demyelination syndrome is high. The rate of correction should not exceed 8 mmol/L in any 24-hour period in patients who are at a high risk of osmotic demyelination syndrome, and it should not exceed 10 to 12 mmol/L in any 24-hour period (or 18 mmol/L in any 48-hour period) for patients at normal risk of osmotic demyelination syndrome.

If the correction of chronic hyponatremia has been inadvertently excessive, intervention is probably unnecessary if the starting serum sodium concentration was ≥120 mmol/L. However, if the starting serum sodium concentration was <120 mmol/L, the serum sodium should be lowered to the recommended level

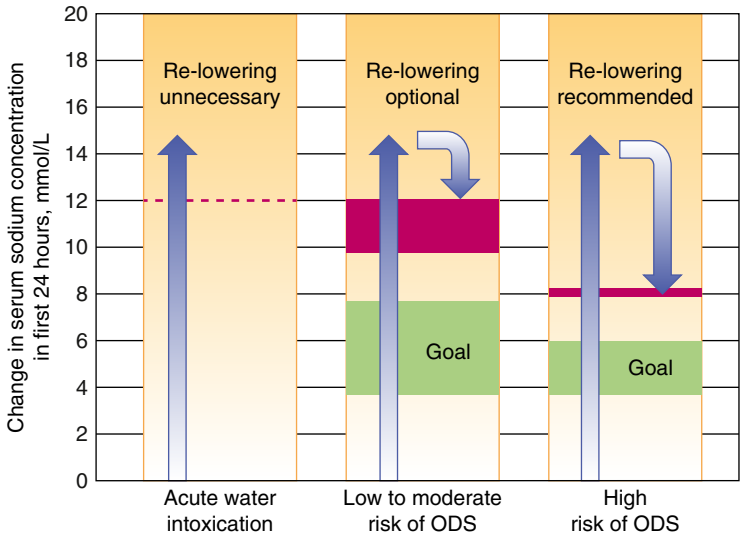

FIGURE 102-4. Recommendations for relowering of serum sodium concentration ([Na]) to goals *(green)* for patients presenting with serum [Na] <120 mmol/L who exceed the recommended limits of correction *(red)* in the first 24 hours. ODS = osmotic demyelination syndrome. (Reproduced with permission from Verbalis JG, Goldsmith SR, Greenberg A, et al. Diagnosis, evaluation, and treatment of hyponatremia: expert panel recommendations. *Am J Med*. 2013;126:S1-S42.)

if overcorrection occurs. To relower the serum sodium concentration (Fig. 102-4), desmopressin (2 to 4 mcg every 8 hours parenterally) should be administered to prevent further water losses, and water losses should be replaced with 5% dextrose in water intravenously at a rate of 3 mL/kg/hour. The next dose of a vasopressin antagonist should be withheld if the correction is >8 mmol/L. The serum sodium concentration should be checked hourly, and water replacement should be continued until the serum sodium concentration is reduced to goal. High-dose glucocorticoids (e.g., dexamethasone, 4 mg every 6 hours) for 24 to 48 hours is recommended if correction has occurred.

Hypervolemic Hyponatremia

In hypervolemic hyponatremia (e.g., heart failure), the goal is to remove salt and water, but relatively more of the latter. Water restriction is helpful but is often inadequate. Treatment with the AVP V_2-receptor antagonist tolvaptan (starting at 15 mg once daily, with a maximal dose of 60 mg once daily) increases the plasma sodium concentration significantly at 30 days in patients with euvolemic or hypervolemic hyponatremia,[A7] but it also increases the risk of overcorrection.[A8] Tolvaptan is not recommended in patients who have cirrhosis because of its potential liver toxicity.

Hypovolemic Hyponatremia

When hypovolemia is clearly evident (appropriate clinical history, orthostatic hypotension, low urine sodium concentration in the setting of extrarenal fluid losses, elevated plasma urea disproportionate to the rise in the serum creatinine level, and elevated uric acid concentrations), isotonic saline is the treatment of choice. However, caution should be exercised in the administration of isotonic saline to these patients because the administration of small volumes of isotonic saline can sometimes induce a brisk and rapid decrease in urine osmolality, an accompanying water diuresis, and an overly rapid correction of hyponatremia. Accordingly, hourly monitoring of urine output, urine osmolality, plasma sodium concentration, and plasma osmolality is required. A rapid drop in urine osmolality accompanied by water diuresis should prompt cessation of volume repletion and, in some cases, administration of hypotonic solutions or even analogues of vasopressin itself (see later) to bring the rise in sodium concentration to within the recommended guidelines. When hypovolemia is not clearly evident but cannot be excluded, a brisk drop in urine osmolality in response to a saline challenge confirms the suspicion of hypovolemia and simultaneously initiates therapy. In contrast, failure to induce such a response lends support to the diagnosis of normovolemic hyponatremia.

Normovolemic Hyponatremia

In patients with normovolemic hyponatremia, the appropriate therapeutic approach is to address the underlying hypothyroidism (Chapter 207), adrenal insufficiency (Chapter 208), or SIADH. If an underlying cause cannot be identified or reversed, treatment aims to generate a gradual net negative water balance. Fluid restriction is usually the first-line strategy.

Fluid restriction should address all intake that is consumed by drinking, not just water, aiming for an intake that is 500 mL/day below the 24-hour urine volume. Neither sodium nor protein intake should be restricted unless the patient has another indication for doing so. Unfortunately, fluid restriction may be insufficient in the setting of a high urine osmolality (e.g., >500 mOsm/kg H_2O), when the sum of the urine sodium and potassium concentrations exceeds the serum sodium concentration, when 24-hour urine volume is <1500 mL/day, or when the increase in serum sodium concentration is <2 mmol/L/day despite fluid restriction below 1 L/day for 24 to 48 hours. In such patients, titrated oral tolvaptan (beginning at 15 mg once daily and increasing to a maximum of 60 mg once daily) is indicated, especially in hospitalized patients, provided that the patient has an intact thirst mechanism to avoid polyuria or hypernatremia. When volume status is in doubt, however, these agents are better avoided.

Vaptans should not be used in patients who have hypovolemic hyponatremia, in conjunction with other treatments for hyponatremia, or immediately after the cessation of other treatments for hyponatremia, particularly 3% NaCl. For the first 24 to 48 hours after initiating treatment, the serum sodium concentration must be monitored every 6 to 8 hours, and ad libitum fluid intake should be maintained. Hyponatremia can correct too quickly if vaptans are given with coincidental fluid restriction in patients who have a defective or impaired thirst mechanism (e.g., intubated or unconscious patients), so sufficient fluid must be provided to prevent overly rapid correction owing to unopposed aquaresis. Vaptans should be discontinued if the patient develops complications that limit their ability to request, access, or ingest fluid. For severe, symptomatic hyponatremia or a serum sodium concentration below <120 mmol/L, treatment should be with 3% NaCl, which provides a quicker and more certain correction of the serum sodium concentration than do vasopressin antagonists. If overcorrection occurs, the serum sodium concentration can be relowered to safe limits as for acute hyponatremia.

Urea (typically starting at 15 g/day diluted in water and divided into two or three daily doses and with the dose increased to 90 g/day based on the patient's response) can increase the excretion of urinary solutes and thereby water excretion in patients with SIADH. Urea is well tolerated and can be used chronically in patients who have SIADH.

PROGNOSIS

Hyponatremia is a marker for worse outcomes among hospitalized patients. A serum sodium level <135 mmol/L is associated with about a 45% relative increased rate of intensive care unit admission.[15]

HYPERNATREMIA

Hypernatremia (a plasma sodium concentration higher than 144 mmol/L) always reflects a state of hypertonicity, with an increased concentration of osmotically active solutes throughout all body fluid compartments. Under normal conditions, the obligate daily loss of water is approximately 500 mL, consisting mostly of the water vapor in expired air and the loss due to insensible sweating. The minimal amount of water needed to keep the urinary solutes in solution is about 500 mL per day. However, sweating in hot, dry environments can lead to massive water losses as high as 1 L/hr. If the daily water intake is less than the obligate water loss, the osmotic pressure of the body fluids will increase.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Although hypernatremia can be diagnosed as an incidental laboratory abnormality, it most commonly occurs in the setting of a severe underlying disease with other accompanying disturbances to body fluid homeostasis (Table 102-9). Patients with hypovolemic hypernatremia have lost both sodium and water, but the net loss of water is disproportionately greater than the net loss of sodium.

The main clinical consequences of increased body fluid tonicity are confusion, seizures, focal neurologic deficits, and a progressively decreasing level of consciousness that can progress to coma. In the absence of an underlying neurologic problem or disturbance in the thirst mechanism, the patient would be expected to complain of thirst unless the neurologic injury has disturbed consciousness. Failure to replace hypotonic fluid losses generally reflects impairment in thirst, disability or infirmity that prevents the patient from responding to thirst, or failure of the clinician to recognize the need for hypotonic fluid replacement. Rarely, impaired thirst in patients who are awake and alert can be caused by damage to the hypothalamic osmoreceptors that control thirst perception and response, a condition known as *primary hypodipsia*. In patients with hypernatremia of sufficient duration to enable brain cells to undergo osmotic adaptation, few, if any, clinical manifestations are observed.

The causes of hypernatremia include loss of thirst or increased insensible loss of water, diabetes insipidus, or osmotic diuresis. Renal failure (Chapter 116)

TABLE 102-9 CAUSES OF HYPERNATREMIA CLASSIFIED BY EXTRACELLULAR FLUID VOLUME (TOTAL BODY SODIUM CONTENT)

Hypervolemia	Hypertonic saline excess Hypertonic sodium bicarbonate solutions
Hypertonicity with near normovolemia	Diabetes insipidus Febrile fluid loss
Hypovolemia	Gastrointestinal loss (diarrhea, vomiting) Skin fluid loss (burn, sweat) Loop diuretics Osmotic diuresis Impaired thirst perception

and tubulointerstitial disease (Chapter 108) cause relatively mild concentrating defects and tend not to be associated with significant hypernatremia, provided that a normal mechanism can readily compensate for it.

The laboratory diagnosis of hypernatremia should be repeated to confirm its accuracy and should be corroborated by an elevated plasma osmolality. The underlying cause is usually evident from the history and physical examination.

In hypovolemic hypernatremia with extrarenal fluid loss, urine output is usually less than 500 mL/day and urine osmolality is the maximum for age (>1000 mOsm/kg in young adulthood decreasing to >600 mOsm/kg by age 60 years). Polyuria with a submaximal urine osmolality suggests impaired urine-concentrating ability, owing to underlying intrinsic renal disease or diuretic agents. A spot urine osmolality less than 100 to 200 mOsm/kg or polyuria (>3 L/day) combined with 24-hour urine solute excretion less than 600 mOsm/day suggests diabetes insipidus (see later). In contrast, daily solute excretion greater than 800 to 1000 mOsm/day suggests an osmotic diuresis.

Hypervolemic hypernatremia is usually associated with prior administration of sodium-containing solutions, and the findings on physical examination are consistent with volume expansion. In the absence of underlying intrinsic renal disease or diuretic use, urine osmolality is high because the hypertonic stimulus to release vasopressin overrides the effects of hypervolemia.

TABLE 102-10 REASONS FOR POLYURIA

WATER DIURESIS
Diabetes insipidus
Central (neurogenic)
Inherited
Acquired (e.g., tumors, trauma, hypoxia)
Nephrogenic

Urea
Exogenous loading (e.g., urea, protein, amino acids)
Diuretic phase of acute kidney injury
Postobstructive diuresis
Hypercatabolic states
Hemoglobin/myoglobin driven (post-rhabdomyolysis or reabsorption of a hematoma)
Other
Radiocontrast agents

TREATMENT

The management of serious symptomatic hypovolemic hypernatremia is challenging and includes rapid correction of the depleted volume followed by gradual replacement of the water deficit.[16] If volume contraction is severe, isotonic saline is generally the fluid of choice, and the volume and rate of administration should be guided by clinical parameters related to reversal of hypovolemia. After tissue perfusion has been restored, further fluid replacement aims to correct the estimated water deficit:

$$\text{Total body water deficit} = 0.4 \times \text{premorbid weight} \times ([\text{Na}/140] - 1)$$

Unlike the initial isotonic fluid replacement, water replacement should be gradual over hours to days, so the rate of water replacement can match the rate at which brain intracellular solutes can be adaptively extruded or removed, unless the hypernatremia has itself clearly developed over minutes to hours. The estimated water deficit should be replaced at a rate that will lead to a reduction of approximately 0.5 to 1.0 mmol/L in measured plasma sodium concentration per hour and more than 6 mmol/L but no more than 10 to 12 mmol/L in 24 hours. In addition to the estimated water deficit, water replacement should consider estimated ongoing insensible water loss of at least 1 L per 24 hours, supplemented to account for ongoing water losses (renal or gastrointestinal) owing to the underlying disease process. Patients often require large volumes of water, sometimes reaching 5 to 10 L, for the duration of the correction period. This water requirement can be met by the dietary ingestion of tap water or administration of a hypotonic intravenous solution, such as D_5W or half-isotonic saline. The sodium concentration should be monitored at least every 4 hours, and the patient's volume status should be monitored to avoid hypervolemia.

The hypertonic state of uncontrolled diabetes with hyperglycemia (Chapter 210) requires insulin as well as fluid therapy.[17] Some hospitalized patients with hypervolemic hypernatremia require hypotonic solutions combined with a continuous infusion of loop diuretics or even extracorporeal removal of both the sodium and water excess. Once the sodium concentration has normalized, a patient with an intact thirst mechanism will generally correct the hypertonic state by spontaneous oral fluid intake.

PROGNOSIS

Hypernatremia is associated with increased morbidity and mortality, both in the hospital and after discharge. Since hypernatremia in adults is typically associated with serious comorbid conditions, the mortality rates may reflect the severity of the underlying diseases rather than that of hypernatremia itself.

POLYURIA

Polyuria (Table 102-10),[18] which is defined as a urine output of more than 3 L/day, should be distinguished from urinary frequency, which can occur with frequent voiding of small volumes totaling less than this amount per day. Polyuria can be a water diuresis or a solute diuresis.

The evaluation for polyuria centers around the analysis of urine osmolality (Fig. 102-5). Urine osmolality <100 mOsm/kg suggests water diuresis, whereas a urine osmolality >300 mOsm/kg is typically related to solute diuresis.

DIABETES INSIPIDUS

The failure to release antidiuretic hormone is termed central diabetes insipidus (Chapter 206), whereas a lack of responsiveness to antidiuretic hormone is termed nephrogenic diabetes insipidus.[19] In diabetes insipidus, the urine becomes progressively dilute as it ascends in the loop of Henle, reaching osmolalities as low as 100 to 150 mOsm/kg in the distal tubule. In the absence of antidiuretic hormone, urine will be diluted further in the collecting tubules. The daily volume of this dilute urine can be as high as 20 liters.

Central diabetes insipidus (Chapter 206) results from destruction of the hypothalamus by tumor (Chapter 204), head injury (Chapter 368), hemorrhage (Chapter 375), surgical trauma, or congenital causes. If the involved area is extensive, the thirst mechanism will also be impaired. A few patients who manifest partial diabetes insipidus can concentrate their urine, though not to maximal levels.

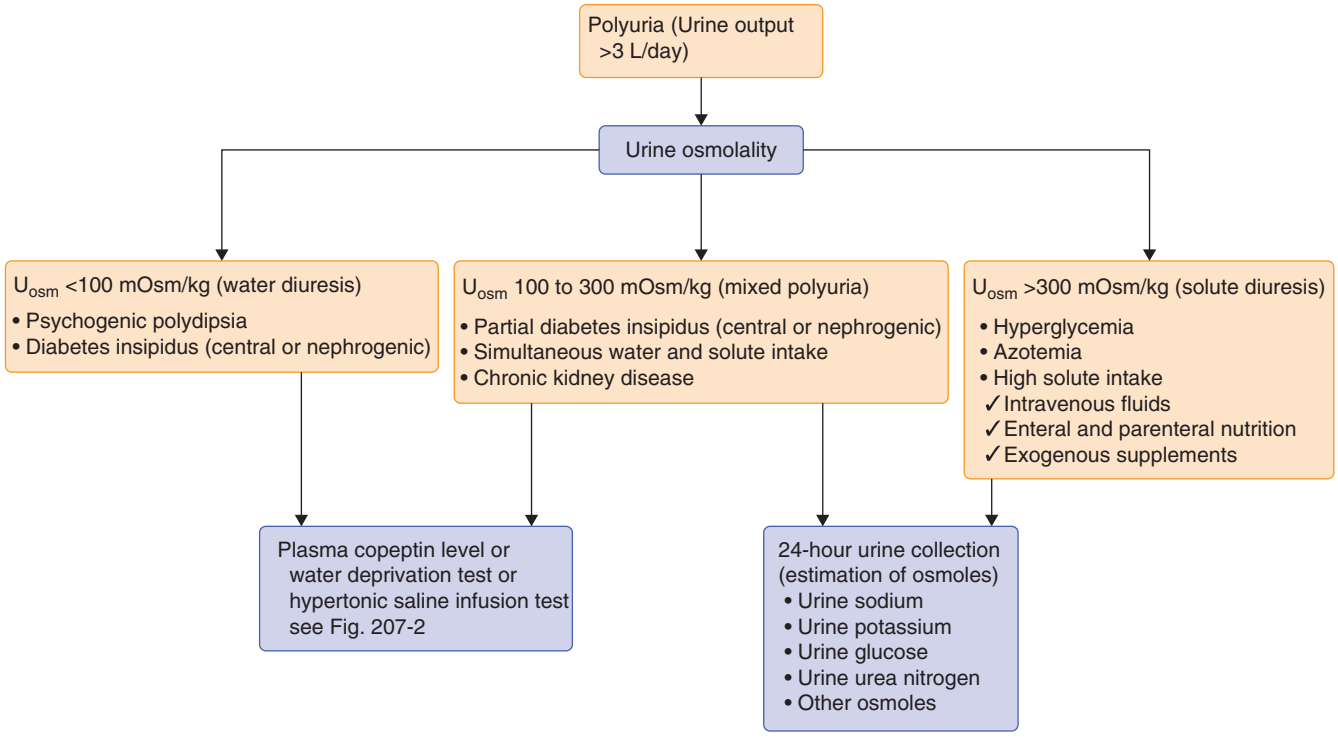

FIGURE 102-5. Diagnostic approach to polyuria. U_{osm} = urinary osmolality. (Adapted with permission from Bhasin B, Velez JCQ. Evaluation of polyuria: the roles of solute loading and water diuresis. *Am J Kidney Dis*. 2016;67:507-511.)

Nephrogenic diabetes insipidus can be caused by a mutation in the vasopressin V2 receptor or the aquaporin 2 water channel.[20] Drugs also can cause nephrogenic diabetes insipidus by interfering with the action of antidiuretic hormone, thereby preventing the insertion of aquaporin water channels into the luminal membrane of the principal cells of the collecting ducts. For example, lithium, used in the treatment of manic-depressive psychosis (Chapter 362), commonly causes polyuria, which can be quite severe. Demeclocycline, a tetracycline now rarely used in dermatologic conditions, also causes nephrogenic diabetes insipidus and is used to treat SIADH that cannot be controlled by water restriction.

Clinically, polyuria, which may be massive, is the hallmark of the disease. Although polyuria itself is not deleterious to health, it is a nuisance if the patient passes more than 6 or 7 liters of urine daily. It can be dangerous, however, if the thirst mechanism is depressed and hyperosmolarity supervenes. Repeated hyperosmolar episodes in such patients frequently lead to irreversible brain damage. If present from childhood, diabetes insipidus frequently leads to massive dilatation of the renal pelvis, ureters, and bladder.

OSMOTIC DIURESIS

Large volumes of urine can be excreted in the presence of large amounts of a poorly reabsorbed solute, most commonly glucose. For example, when the blood sugar concentration rises above the capacity of the kidney to reabsorb all of the filtered glucose, a large volume of glycosuria results. In fact, polyuria and polydipsia are the most common presenting features of diabetes mellitus (Chapter 210).

The more blood that flows through the medulla, the less concentrated it becomes. In some clinical situations, such as intravascular volume expansion and osmotic diuresis, medullary blood flow increases, thereby leading to a washout of the medullary gradient. Osmotic diuretics also impair water reabsorption at the collecting duct.

Osmotic diuresis also occurs after the relief of obstruction to the urinary tract. In this situation, the principal osmotic agent is urea, although other retained solutes also play a role in diuresis.

As the number of functioning nephrons is gradually reduced in renal failure, the amount of solutes added is also reduced; hence the inability to concentrate the urine, manifesting as nocturia and polyuria, is an early sign of renal failure. Direct damage to medullary tubules can also decrease the reabsorption of salt, particularly with tubulointerstitial kidney diseases (Chapter 108), such as analgesic nephropathy and sickle cell disease.

TREATMENT

The clinical manifestations and treatment of polyuria should address its underlying causes (Fig. 206-2). Depending on the nature of fluid intake and medication used at the onset of polyuria, a significant percentage of polyuric patients will have alterations in plasma sodium and volume, so treatment must also address these accompanying fluid and electrolyte abnormalities.

103 POTASSIUM DISORDERS

JULIAN LAWRENCE SEIFTER

DEFINITION

Maintenance of a normal and narrow range of blood plasma potassium concentration, $[K^+]$, usually on the order of 3.5 to 5.0 mmol/L, is vital for health. *Hyperkalemia* refers to an increased plasma $[K^+]$, and *hypokalemia* to a decreased plasma $[K^+]$. Within the human body, K^+ is not equally distributed in the total body water. Approximately two thirds of body water is intracellular, and K^+ is the major cation within that compartment, reaching concentrations as high as 140 mEq/L. Consequently, more than 98% of K^+ resides within cells. An *excess* of total body K^+ stores is less common than K^+ *depletion* unless renal function is compromised. K^+ *adaptation* defines changes in regulatory mechanisms resulting from K^+ excesses or deficits.

EPIDEMIOLOGY

Because K^+ is widely distributed in both plant and animal dietary sources, avoiding K^+ is difficult in the well-fed state. As a result, a healthy person on a regular diet is likely to require high rates of urinary K^+ losses, primarily by secretion in the cortical distal nephron, to prevent hyperkalemia. The ready availability of potassium in the diet also makes hypokalemia uncommon, unless excessive potassium is lost in gastrointestinal or renal body fluids. The kidney must be able both to eliminate and at other times conserve large amounts of potassium.

Disorders of K^+ balance are common in both inpatient and outpatient settings. Diets high in K^+ and low in Na^+ are associated with lower blood pressure and decrease the risk of cardiovascular disease, including stroke and chronic kidney disease. Mild decreases in plasma $[K^+]$ are seen in healthy well-trained athletes and during normal pregnancy. Patients with chronic kidney disease (Chapter 116) and insulin-deficient diabetes (Chapters 109 and 210) have a tendency to develop hyperkalemia with high-K^+ diets or treatment with medications that interfere with the renin-angiotensin-aldosterone system.[1] Starvation, gastrointestinal disease, commonly used diuretics, and other medications may cause hypokalemia. Some renal disorders, such as tubular interstitial diseases and urinary tract obstruction, may be associated with hyperkalemia, whereas others, particularly if associated with Fanconi syndrome, result in hypokalemia. Some endocrine diseases, including adrenal insufficiency (Chapter 208), characteristically cause hyperkalemia, whereas hypokalemia is a common finding in patients who have hyperaldosteronism or tumors with ectopic secretion of adrenocorticotropic hormone (ACTH; Chapter 208).

Polyuric states may lead to K^+ depletion due to increased urinary flow rates over a period of time. However, chronic hypokalemia is itself a cause of polyuric nephrogenic diabetes insipidus (Chapter 102).

PATHOBIOLOGY

Potassium Balance

Most cells express sodium-potassium adenosine triphosphatase (Na^+, K^+-ATPase) on the cell plasma membranes and thereby use metabolic energy in the form of ATP to develop gradients of Na^+ and K^+. As a result, cellular $[K^+]$ may exceed extracellular concentrations 35-fold. These established electrochemical gradients enable normal muscle and neural function, as well as transcellular solute transport in intestinal and renal epithelia. K^+ entry into cells is balanced by extrusion by K^+ channels and transporters in a regulated and coordinated fashion.

The total body amount of K^+ is usually on the order of 50 mmol/kg of body weight, so a 70-kg individual has a store of about 3500 mmol of K^+, mostly in skeletal muscle. The potassium content of the total extracellular fluid is about 56 mmol, which may approximate the potassium content of a single meal. After a meal containing an 8-ounce steak, baked potato, 1 serving of spinach, and an 8-ounce glass of tomato juice, the plasma $[K^+]$ might rise to 9.25 mmol/L, a likely fatal value, if it were not for the ability of potassium to distribute within minutes from the extracellular space to the intracellular space. The intracellular space, given its large volume and potassium content, can accommodate, or buffer, an extra load of potassium without significant changes in the plasma or cellular $[K^+]$. In contrast without the shift, K^+ would rise greatly in the extracellular fluid, and the large change in ratio would electrically cause serious arrhythmias. Fortunately, carbohydrate and amino acids in a meal increase the secretion of insulin, which increases the shifting of K^+ into cells. Within hours, renal elimination of potassium matches the dietary intake.

Discordance between total body stores and the plasma $[K^+]$, owing to shifts between the intracellular and extracellular compartments, is the reason why total body potassium is poorly reflected by the plasma potassium concentration. Hyperkalemia may occur despite total body K^+ depletion (e.g., diabetic ketoacidosis with an osmotic diuresis causing urinary losses of Na^+ and K^+, a depletion in extracellular volume, and acute kidney injury), and hypokalemia may occur despite total body K^+ excess (e.g., acute diarrhea in a patient who has chronic kidney disease).

The Importance of Potassium

Potassium is essential for a number of critical body functions, including enzymatic reactions that regulate protein and glycogen synthesis, as well as cell growth and division. Within the normal dietary range, a higher intake of potassium and a lower intake of sodium are associated with a lower cardiovascular risk.[2]

The ability of cells to take up or to extrude potassium contributes to the regulation of cell volume during periods of osmotic stress. Because of the relative magnitudes of cellular and extracellular concentrations, larger percentage changes tend to occur in the extracellular potassium concentration, which consequently has the greatest impact on the electrical properties across cell membranes. In excitable cells, such as cardiac myocytes and skeletal muscle, the relationship of intracellular to extracellular potassium concentration contributes to the resting membrane potential. Hypokalemia hyperpolarizes these cells and decreases potassium conductance in some potassium channels required for repolarization (Chapter 48).

The increased potassium conductance in hyperkalemia antagonizes the normal slow depolarization and decrease in potassium conductance of pacemaker tissue, thereby making sinus bradycardia a common first sign of hyperkalemia. Certain muscle-depolarizing anesthetic agents, such as succinylcholine, may potentiate the effects of hyperkalemia.

Potassium is as important a body fluid osmole as sodium. Potassium losses, extracellular volume depletion, increased intake of water, and retained medullary urinary concentrating ability each contribute to thiazide diuretic–induced hyponatremia (Chapter 102). Summative iso-osmotic losses of potassium and sodium salts in watery diarrhea (Chapter 126) may result in isotonic extracellular volume depletion. Similarly, if potassium chloride is added to isotonic saline, the resultant hypertonic solution causes potassium to enter cells as sodium exits, thereby contributing to hypernatremia.

Potassium is also an important local mediator of vascular tone in muscle beds. During exercise, local interstitial fluid potassium concentrations may rise several-fold, thereby causing local vasodilation to allow more blood supply to the exercising muscle, but also resulting in sarcolemmal depolarization that creates muscle fatigue. Very little of that local tissue potassium enters the total extracellular fluid, so severe hyperkalemia does not usually occur with exercise. The trained athlete develops an adaptive increase in Na^+, K^+-ATPase to allow efficient reuptake of potassium into muscle cells but still may have chronically low plasma $[K^+]$ or postexertional hypokalemia. Experienced marathoners know that their diet must provide adequate potassium stores needed for muscle endurance because overexertion during a state of potassium depletion can lead to rhabdomyolysis (Chapter 99).

Potassium excretion follows a circadian rhythm. This rhythm appears to include an intestinal feed-forward sensing mechanism that results in the highest level of urinary potassium excretion coinciding with the anticipated dietary intake of potassium. The relationship likely involves potassium sensing within the gastrointestinal tract or splanchnic or hepatic circulation. In healthy humans, potassium excretion is greatest during the daytime hours but can increase several-fold after a meal without requiring a noticeable change in the blood potassium level. Independent of aldosterone, a direct relationship between increased potassium and sodium excretion may account for the beneficial association of high-potassium diets with lower blood pressures. Additionally, increased dietary potassium may restore a nocturnal dip in blood pressure, thereby potentially reducing cardiac risk in hypertensive patients. The distribution of potassium between the extracellular and intracellular spaces shows a circadian variation that may contribute to the diurnal variance in cardiac arrhythmias and sudden death in patients at risk.

ABSTRACT

Potassium is ubiquitous in animal and plant cells, where it subserves critical electrophysiologic roles in excitable cells and transport functions in epithelial cells. Functions such as growth, protein synthesis, and osmotic survival require adequate potassium. There must be intact food sources of K^+ and a high capacity to eliminate K^+ from the body (external balance). Since more than 98% of K^+ lies within the intracellular space, there must be effective mechanisms to buffer dietary loads of K^+ within cells (internal balance) while the slower excretory processes achieve balance. This chapter discusses the normal pathways of K^+ handling by the renal epithelial cells in states of both depletion and excess of K^+. Mechanisms of reabsorption and secretion are considered, with emphasis given to the distal nephron's regulation of K^+ handling, including the roles of urinary flow rates and of secretory and reabsorptive channels and pumps depending on metabolic energy. Interconnections with acid-base disorders, salt, and osmotic balance are also discussed. Syndromes associated with hypertension or hypotension, acidosis or alkalosis are reviewed, as are hormonal, acquired, toxic, environmental, and genetic disorders. The consequences and physiologic management of hyperkalemia and hypokalemia are also reviewed.

Renal Potassium Handling

In the kidney, potassium excretion begins with filtration. Because the extracellular concentration of potassium is approximately 4 mmol/L and that of sodium is 140 mmol/L, far less potassium is filtered than sodium. The renal proximal tubule reabsorbs potassium, primarily by the paracellular pathway, in the process of reabsorbing sodium and water. In the thick ascending limb of the loop of Henle, potassium is reabsorbed both by the apical sodium–potassium–2 chloride cotransporter (NKCC2) and, like calcium and magnesium, by paracellular reabsorption of the cation. The latter mechanism is a consequence of the development of an electropositive lumen that is created by the recycling of K^+ to the lumen through renal outer medullary potassium channels (ROMK) in the thick ascending limb of the loop of Henle. Barrter syndrome (Chapter 113) stems from loss-of-function mutations either in the NKCC2, ROMK, or in the chloride channel.

Potassium is neither appreciably reabsorbed nor secreted by the early distal convoluted tubular cells. Potassium that is reabsorbed downstream into the medullary collecting duct interstitium re-enters the tubular fluid by secretion into the thin descending limb in a process known as medullary potassium recycling. This decreased lumen-to-interstitial-fluid gradient facilitates high potassium excretion from the medullary collecting duct when required.

Luminal ammonium (NH_4^+) can substitute for potassium on the thick limb NKCC2; the resulting increase in medullary interstitial fluid NH_4^+ concentrations enhances medullary collecting duct net acid excretion. In hyperkalemic states, less NH_4^+ appears in the urine because the high concentration of luminal potassium competes with NH_4^+ for reabsorption in the thick limb. As a consequence, metabolic acidosis may develop in hyperkalemic states, and lowering of elevated plasma potassium levels helps treat acidosis.

In hypokalemia, whether through proximal tubule intracellular acidosis or other mechanisms, glutaminase enzymes are increased and more ammonia is produced. This ammonia leads to greater medullary interstitial fluid concentrations and therefore to enhanced net acid elimination. Ammonium production in hypokalemia allows potassium reabsorption to continue as cationic NH_4^+ accompanies excreted anions into the urine. The increase in ammonia production may have a deleterious effect in that it may contribute to the chronic tubulointerstitial nephritis of chronic hypokalemia.

By the time the tubular fluid reaches the distal tubule and collecting duct, more than 90% of filtered potassium and sodium has been reabsorbed. The absolute amount of sodium that needs to be reabsorbed far exceeds the amount of potassium that needs to be excreted. Therefore, the basolateral mechanism for potassium reabsorption is required to avoid potassium depletion. In potassium depletion, an increase in the apical membrane hydrogen-potassium ATPase (H^+, K^+-ATPase) of the collecting duct intercalated cell allows additional reabsorption of potassium from the urine. This process may sustain a metabolic alkalosis. It is unusual to see potassium concentrations in the urine lower than 5 to 10 mmol/L. In contrast, when dietary potassium is abundant, the reabsorption of 90% of filtered potassium by the proximal and distal nephron is followed by net potassium secretion in the collecting duct.

The secretion of potassium in the cortical collecting duct (E-Fig. 103-1), which may vary according to need by as much as 400%, is controlled by three major mechanisms: (1) apical membrane depolarization due to Na^+ current through epithelial Na^+ channels (ENaC) supporting K^+ secretion across the apical membrane; (2) regulated apical membrane secretory potassium channels; and (3) tubular fluid flow dependency. The urinary potassium most closely reflects potassium secreted by the distal nephron.

Early Sodium Reabsorption

The traditional view of regulating potassium secretion and therefore excretion has focused on the central role of aldosterone, the steroid hormone synthesized and secreted by the zona glomerulosa of the adrenal cortex. The renal effects of aldosterone show overlap of functions to conserve sodium and to eliminate potassium. Aldosterone is stimulated by angiotensin II in hyperreninemic states and independently by dietary potassium loading. In what has been called the *aldosterone paradox*, undesired losses of potassium are prevented when sodium retention (e.g., via the angiotensin II stimulus) is required to maintain extracellular volume. Conversely, undesired retention of sodium is prevented when potassium loading alone provides the stimulus to aldosterone secretion. The negative feedback that couples aldosterone with serum potassium is fundamental in potassium regulation. Hyperaldosteronism results in potassium loss, whereas hypokalemia reduces aldosterone production. Hyperkalemia stimulates aldosterone release, thereby facilitating urinary potassium.

The major site for potassium secretion resides in the aldosterone-sensitive distal nephron, which is composed primarily of the principal cells of the connecting tubule and the cortical collecting duct. Aldosterone regulates sodium reabsorption by the apical epithelial sodium channel. The reabsorption of sodium is dependent on the low intracellular sodium concentrations that result from the energy-requiring Na^+, K^+-ATPase on the basolateral membrane. Both increased intracellular Na^+ and extracellular K^+ stimulate the Na^+, K^+-ATPase.

To optimize potassium secretion, sodium must be delivered in ample amounts (depending on the flow rate and sodium concentration of the tubular fluid) to result in sodium reabsorption through the apical epithelial sodium channel in the cortical collecting duct cells. If sodium delivery is not limiting, reabsorption of the sodium cation creates a lumen-negative transepithelial potential difference. Aldosterone affects this transepithelial potential difference in several ways. The intracellular mineralocorticoid receptor functions to increase the activity and density of the epithelial sodium channel and of basolateral Na^+, K^+-ATPase enzymes. Cortisol, which is normally present in higher concentrations than aldosterone, has equal affinity for the aldosterone receptor and therefore could lead to increased epithelial sodium channel activity. However, the enzyme 11β-hydroxysteroid dehydrogenase type 2 is present in the principal cells and converts cortisol to inactive cortisone.

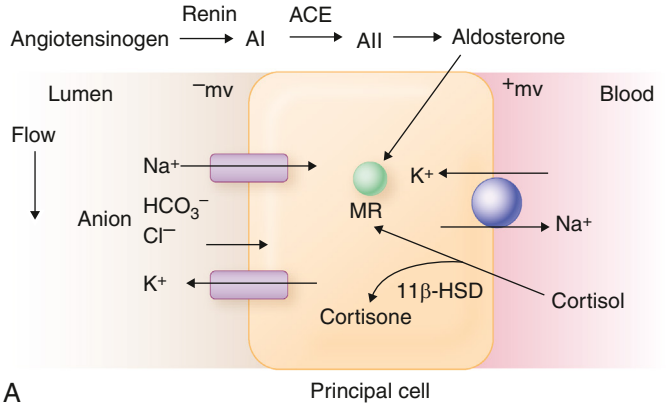
Role of Potassium Secretory Channels and Tubular Flow Rate

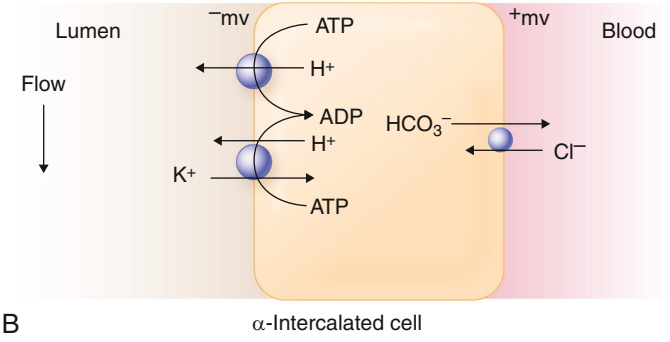
Potassium secretion requires adequate function of several types of potassium secretory channels on the luminal membranes of distal nephron cells. Two predominant potassium channels are present in the apical membranes of the collecting duct cells. The renal outer medullary potassium channel (ROMK), which is located on the apical membrane of the principal cell in the connecting tubule and cortical collecting duct, is aldosterone sensitive, is increased by dietary potassium loads, and likely subserves constitutive K^+ secretion under basal conditions. ROMK undergoes new synthesis and increased cycling to the apical membrane under the control of aldosterone. The principal cell also mediates vasopressin-responsive water reabsorption. Factors regulating ROMK channels include antidiuretic hormone (ADH) and intracellular pH. The increase in ROMK channel activity in response to ADH, combined with an ADH effect to increase epithelial sodium channel and osmotic water flow, allows the highest possible potassium concentration in the urine with the low tubular flow that accompanies antidiuresis. When ADH is suppressed, luminal potassium concentrations are lower, thereby favoring gradients for potassium secretion, but low ADH levels also suppress ROMK activity, thereby allowing independence of the regulation and the excretion of water and K^+. Cellular acidification inhibits potassium secretion through an effect on ROMK, thereby providing a renal mechanism for decreased electrogenic potassium secretion when proton secretion is necessary during metabolic and respiratory acidoses. In alkalosis, ROMK activity is increased, thereby favoring increased potassium secretion, but the result may be significant potassium loss.

Additional potassium channels, known as maxi-K or big-K channels, are prominent in the principal cells and intercalated cells of the cortical collecting duct, as the intercalated cell also has a role in potassium secretion. The big-K channels are highly regulated by tubular fluid flow rate. One mechanism by which flow rate influences this potassium secretory channel is by the deformation of the primary cilium of the principal cell, which leads to a secondary increase in cellular calcium that has both direct and indirect effects to enhance BK potassium secretion.

Excretion Mechanisms and Normal Function

Thiazide-sensitive NaCl cotransport is independent of aldosterone in the early distal convoluted tubule but is inhibited by sensors in those cells related to high potassium intake, gastrointestinal feed-forward sensing mechanisms, and clock genes associated with the circadian rhythm for potassium excretion. Decreased sodium reabsorption in the early distal convoluted tubule will increase delivery of sodium and water to the downstream aldosterone-sensitive distal nephron. Then, in response to increased plasma potassium-stimulated aldosterone release, the epithelial sodium channel is increased, thereby leading to greater potassium secretion. A network of protein kinases, including the "with no lysine" or WNK kinases, is central to regulated early distal convoluted tubule NaCl cotransporter function and the epithelial sodium channel. When the early aldosterone-insensitive distal convoluted tubule basolateral sensors detect a small drop in blood $[K^+]$ during saline expansion, a regulatory "switch" provides crosstalk to the apical side in the form of phosphorylations, which activate NaCl cotransport and thereby increase the reabsorption of Na^+ in the distal convoluted tubule. The decreased delivery of Na^+ to the common





E-FIGURE 103-1. **Two cell types in the cortical collecting duct. A,** The principal cells mediate sodium (Na^+) reabsorption energized by the basolateral Na^+, K^+ pump. Entry from the lumen is through the epithelial Na^+ channel (ENaC), which renders the lumen negatively charged ($^-$mv). This transepithelial voltage stimulates secretion of potassium (K^+) through renal outer medullary potassium (ROMK) channels. Reabsorbable anions such as chloride (Cl^-) lessen the luminal negativity and decrease K^+ secretion. Bicarbonate (HCO_3^-) has an effect to increase K^+ secretion. High flow rates increase net K^+ secretion by activating maxi-K or big-K channels and by preventing development of high K^+ concentrations in the lumen. The effects of the renin-angiotensin-aldosterone axis are shown: increased mineralocorticoid receptor (MR) activation increases ENaC, the Na^+, K^+ pump, and K^+ channels, thereby increasing Na^+ reabsorption and K^+ secretion. Cortisol would also increase MR activity, but it is inactivated by the enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD). AI = angiotensin I; AII = angiotensin II; ACE = angiotensin-converting enzyme; mv = millivolts. **B,** Intercalated cells are carbonic anhydrase–rich cells that secrete acid and reabsorb HCO_3^-. The H^+-ATPase secretes H^+ in a way favored by the negatively charged lumen in conjunction with the aldosterone-stimulated effect on Na^+ reabsorption in neighboring principal cells. The K^+, H^+-ATPase is an electroneutral pump. The K^+/H^+ exchanger, reabsorbing K^+, is important in states of K^+ depletion when urinary K^+ is decreased. Intercalated cells also have apical big-K channels, indicating a role in K^+ secretion. ADP = adenosine diphosphate; ATP = adenosine triphosphate.

collecting duct leads to less K^+ secretion. If the regulation of NaCl cotransport is incremental, the mechanism controlling NaCl reabsorption through the NaCl cotransporter and downstream K^+ secretion performs as a rheostat.

In states of avid sodium reabsorption, including hypovolemic states, hepatorenal syndrome (Chapter 139), and severe heart failure (Chapter 45), sodium delivery from more proximal sites may become the rate-limiting step for potassium secretion. In hypovolemia, sodium reabsorption is increased by angiotensin II in the proximal tubule, the early and late distal convoluted tubule, and the connecting tubule so that very little sodium is delivered to the principal cells of the cortical collecting duct. Potassium losses are diminished because of this decreased delivery of sodium, and an angiotensin II–induced switch involving WNK kinases decreases ROMK activity. Although aldosterone will still activate principal cell epithelial sodium channels, the decrease in sodium delivery and decreased potassium secretion (favoring chloride reabsorption instead) will allow greater NaCl reabsorption while limiting potassium loss. Sodium delivery may be increased by decreased angiotensin II during extracellular volume expansion, but the low aldosterone limits potassium losses.

Internal Potassium Balance and Associated Disorders

Because of the delay in hours before renal excretion matches dietary intake and because potassium first enters the extracellular fluid from the gastrointestinal tract, it is critical that the process of cellular buffering be effective (Table 103-1).[3] Essentially, increases in postprandial blood potassium are minimized before potassium is eliminated from the body. A major factor in this regulation after meals is the feedback loop involving insulin and potassium. An increase in serum potassium stimulates insulin release from the β-cells of the pancreatic islets. Insulin increases potassium uptake into cells, primarily muscle, independent of its effect on glucose uptake. Acutely, potassium uptake is chiefly the result of increased Na^+, K^+-ATPase activity, whereas chronically there is increased abundance in the plasma membranes in these cells.

Another important mechanism of regulating the distribution of potassium between extracellular and cellular spaces involves the sympathoadrenal system. β-Adrenergic activation, particularly through the β_2-receptor, increases potassium uptake into muscle and fat cells. As with insulin, potassium uptake is the consequence of increased Na^+, K^+-ATPase activity associated with increased intracellular cyclic adenosine monophosphate. The adrenergic effect is important in regulating the serum potassium concentration during exercise and is independent of the additional effect that catecholamines may have on blood glucose with the expected increases in insulin. In the trained athlete, a chronic increase in Na^+, K^+-ATPase on cell membranes may cause a transient lowering of the serum potassium concentration after exertion. By the same mechanism, a severe stress may contribute to hypokalemia, through both direct β_2 effects and insulin action secondary to the blood glucose rise.

Phenylephrine, an α-adrenergic agonist, increases serum potassium. Importantly, epinephrine, which also has α-adrenergic effects, is associated with a transient increase in potassium release from the liver before a more prolonged period of decreased serum potassium mediated by the β_2-receptor.

Metabolic acidosis raises the potassium level more than does respiratory acidosis; both metabolic alkalosis and respiratory alkalosis lower the potassium level. Anion gap acidosis does not raise the potassium level, probably because of the movement of the organic anion (e.g., lactate) from cells into the extracellular space with an accompanying proton. In contrast, the ingestion of chloride salts has the most profound effect on the potassium level because chloride concentration increases in the extracellular space. In hyperchloremic acidosis, chloride enters into cells through chloride-bicarbonate exchange and recycles back into the extracellular space in cotransport with potassium. The ingestion of excessive chloride salts of arginine and lysine is associated with hyperkalemic acidosis. ε-Aminocaproic acid has also been associated with hyperkalemia and is hypothesized to exchange for cellular potassium, much like the other cationic amino acids.

Just as a single blood pH measurement can reflect mixed acid-base disturbances, many processes that affect the net potassium concentration can coexist. Metabolic acidosis may be associated with diarrheal or urinary losses of potassium that are sufficient to result in hypokalemia. Metabolic acidosis in diabetes can also be associated with insulin deficiency and renal failure, and it can cause hyperkalemia despite osmotically driven urinary losses of potassium and total body potassium depletion.

Other hormonal effects on potassium include thyroid and growth hormone, but patients with disorders of these hormones do not usually have significant changes in their blood potassium levels. Some patients with hyperthyroidism may have mild hypokalemia, perhaps related to increased sympathetic activity. Growth states are associated with a greater need for potassium; for example, in normal pregnancy, the maternal potassium concentration may fall as the developing fetus grows.

Hypomagnesemia frequently accompanies hypokalemia. Both magnesium and potassium are found predominantly in cells, but the Na^+, K^+-ATPase requires magnesium to function. If magnesium is deficient, potassium distributes more to the extracellular fluid, thereby masking the degree of potassium deficiency. Moreover, magnesium deficiency leads to increased activity of renal potassium secretory channels, so potassium depletion is difficult to correct until magnesium is repleted.

External Potassium Balance and Associated Disorders

Normally, no more than 10 to 20% of total potassium excretion is accomplished by the gastrointestinal tract, but colonic excretion is increased in renal failure, primarily through potassium-induced increases in epithelial Na^+, K^+-ATPase activity and aldosterone. In renal failure, the normal mechanisms to distribute potassium acquire increased importance.

Some conditions that cause the greatest losses of gastrointestinal potassium include secretory diarrheas of the colon, the result of infection or laxative abuse. Disorders of the small intestine, which may lead to large quantities of liquid stool with a low potassium concentration, engender favorable gradients for marked potassium secretion by the colon. A syndrome of watery diarrhea and hypokalemia is associated with neuroendocrine tumors (Chapter 213) that secrete vasoactive intestinal peptide. Rectosigmoid secretion of potassium may result in particularly high potassium losses, and potassium deficiency is seen in patients who have ureterosigmoidostomies. Potassium can be lost from a variety of other sources, including excess sweat or salivation.

Potassium can also be depleted by vomiting or diarrhea. In gastric alkalosis, the loss of potassium is in the urine. In renal tubular disorders, urinary losses may exceed intake when excessive quantities of osmotic or anionic products are excreted in the urine, or in patients who take diuretics.

Patients with pernicious anemia who receive vitamin B_{12} to stimulate erythropoiesis may deplete extracellular potassium and suffer from hypokalemia as a cost of producing new red blood cells. Leukemias with rapid growth rates (Chapter 168) also may cause a drop in the serum potassium level, and some forms of myelogenous leukemia are associated with a high level of lysozyme, which leads to urinary potassium loss.

It is unusual for hyperkalemia to be caused by excessive potassium intake unless the patient has renal dysfunction. However, in patients who have brisk hemolysis, internal hemorrhage, or rhabdomyolysis, particularly if the hemoglobinuria or myoglobinuria also results in acute kidney injury, life-threatening hyperkalemia can quickly develop by the rapid release of cellular potassium stores.

CLINICAL MANIFESTATIONS

Hypokalemia

Clinical manifestations of potassium depletion include hypertension, decreased growth, and muscle symptoms such as weakness, cramps, fasciculations, and even paralysis. In severe cases, the diaphragm may be paralyzed, leading to respiratory failure. Cardiac arrhythmias are a critical component of low potassium states and are usually seen when the serum potassium falls below 3 mmol/L or when ischemia, hypercalcemia, or drugs such as digoxin are simultaneously present. A patient who has a chronically low potassium level (e.g., from diuretic use) may be particularly vulnerable to supraventricular and ventricular tachyarrhythmias during periods of stress, such as head trauma, or during acute coronary syndrome,[4] to which cardiac ischemia also contributes. The prolonged cardiac repolarization phase of hypokalemia accounts for the characteristic electrocardiographic findings of broad, flattened T waves.

U waves are also indicative of this delay in repolarization (Fig. 103-1). In the intestine, hypokalemia may result in paralytic ileus, which may interfere with oral replacement.

In addition to these systemic effects of potassium imbalance, the kidney is particularly sensitive to depletion of potassium. Structural changes in the glomeruli and tubules lead to a decreased glomerular filtration rate, increased proximal tubule ammoniagenesis, increased sodium bicarbonate reabsorption, and net acid excretion, thereby causing and maintaining metabolic alkalosis. A condition of nephrogenic diabetes insipidus results when potassium depletion decreases expression of vasopressin-dependent water channels (aquaporin 2) in the collecting duct luminal plasma membranes. Hypokalemia diminishes insulin secretion and may be associated with glucose intolerance.

Hyperkalemia

Hyperkalemia can be a life-threatening emergency, especially if it develops rapidly. The depolarizing effect on the resting membrane potential and increased potassium channel conductance lead to the classic electrocardiographic changes of hyperacute peaked T waves associated with rapid repolarization (Fig. 103-2). Hyperkalemia commonly results in sinus bradycardia. Heart block, loss of P waves on the electrocardiogram, and prolonged QRS intervals are all seen in cases of severe hyperkalemia, usually in excess of 6 mmol/L. Although deep learning algorithms suggest that the electrocardiogram can be used to screen for hyperkalemia,[5] a standard reading of the electrocardiogram is not a sensitive indicator of severe hyperkalemia, and cardiac arrest may occur without clinical warning. Like hypokalemia, severe hyperkalemia can cause skeletal muscle paralysis; unlike hypokalemic paralysis, it is often ascending in nature.

DIAGNOSIS

The first clue to a disorder in potassium balance usually is an abnormal serum potassium concentration obtained as part of a laboratory evaluation, not because an abnormal potassium level itself is suspected. When the potassium concentration is elevated above normal, it is imperative to exclude common artifacts, known as pseudohyperkalemia. Hemolysis in the test tube is a common artifact; in cases of cold-induced hemolysis (Chapter 147), it is important to collect the blood and to allow it to clot in a warm environment. Some patients have pseudohyperkalemia resulting from high platelet counts, usually in excess of 1 million/μL, or myelogenous leukemia (Chapter 170); in such cases, potassium is released during clot formation in the test tube. Measurement of the plasma potassium level will avoid these artifacts. The serum potassium level may sometimes be elevated because of local ischemia related to application of the tourniquet and clenching of the fist.

A detailed medical history should focus on medications, family history, and sources of potassium excess or loss. The physical examination should pay particular attention to blood pressure, extracellular volume status, heart rate and rhythm, and muscle strength and reflexes.

Laboratory testing should include a complete blood count as well as serum levels of sodium, chloride, bicarbonate, creatinine, and blood urea nitrogen. In more serious cases, arterial blood gases and levels of creatine kinase and magnesium should be obtained. A 12-lead electrocardiogram also should be performed. A urinary potassium excretion rate in a timed urine test is the best measure of K+ excretion. In a hypokalemic patient, a urinary potassium concentration higher than 30 mEq/L suggests renal potassium wasting, whereas extrarenal losses are usually reflected by concentrations lower than 20 mEq/L. In a state of potassium excess, urinary potassium excretion should exceed about 35 mEq/L, unless urinary underexcretion was the cause of the hyperkalemia. A high aldosterone level causes a high urinary potassium-to-sodium ratio, whereas hypoaldosteronism may cause the opposite. Because water reabsorption complicates interpretation of the urinary K^+ concentration, distinguishing urinary loss or retention of K^+ in a hypokalemic or hyperkalemic state can

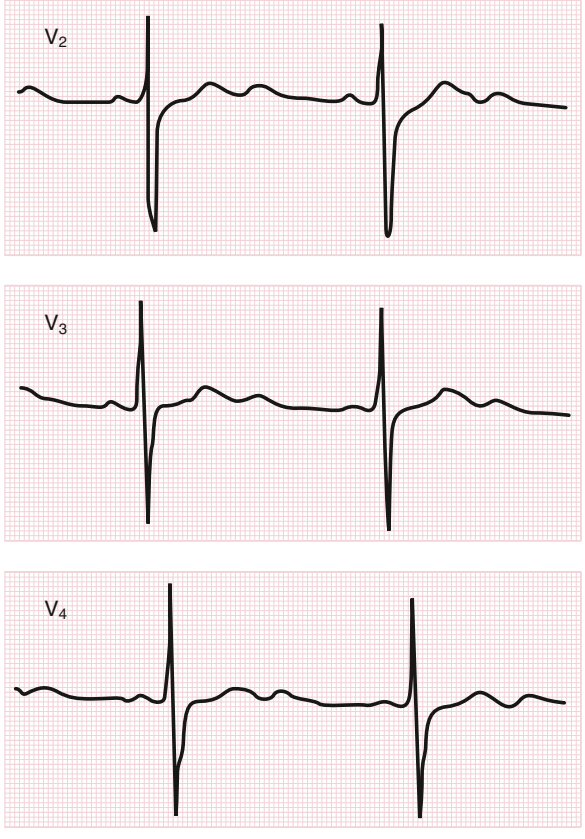

FIGURE 103-1. The electrocardiographic manifestations of hypokalemia. The serum potassium concentration was 2.2 mEq/L. The ST segment is prolonged, primarily because of a U wave following the T wave, and the T wave is flattened.

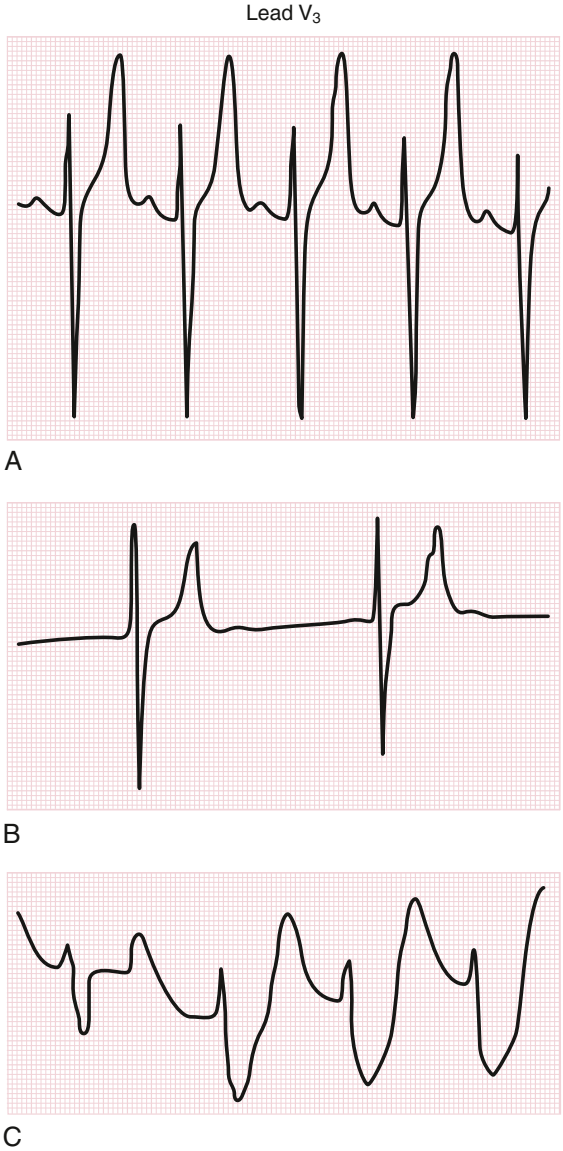

FIGURE 103-2. The effects of progressive hyperkalemia on the electrocardiogram. All of the illustrations are from lead V_3. **A**, Serum potassium concentration ($[K^+]$) = 6.8 mEq/L; note the peaked T waves together with normal sinus rhythm. **B**, Serum $[K^+]$ = 8.9 mEq/L; note the peaked T waves and absent P waves. **C**, Serum $[K^+]$ > 8.9 mEq/L; note the classic sine wave with absent P waves, marked prolongation of the QRS complex, and peaked T waves.

be made by measuring a urine [K^+]:[Cr] ratio using 15 to 20 mEq per gram of creatinine as a cutoff.

Hypokalemic Disorders

The most common cause of hypokalemia (Table 103-2) in medical practice is the use of thiazide or loop diuretics.[6] Patients may have low, normal, or high blood pressures, depending on their volume status and whether the diuretics were prescribed for hypertension or heart failure. The most common acute causes of hypokalemia are diarrhea and vomiting (Fig. 103-3).

Hypokalemic Hypertensive Syndromes

Evaluation of plasma renin and aldosterone levels can help distinguish among specific diagnoses (see Table 103-2). Primary hyperaldosteronism is associated with low renin levels due to volume expansion.[7] If it is corrected for plasma potassium, an aldosterone-to-renin ratio of 30:1 suggests a primary adrenal cortical tumor (aldosteronoma) or hyperplasia (Chapter 208). However, such ratios must be used with caution, and the absolute value of aldosterone is important, especially when the renin and aldosterone levels are both low.

More sensitive measurements of renin have led to the increased recognition of primary hyperaldosteronism (Chapter 208), especially due to microadenomas or increased clusters of adrenal zona glomerulosa cells. At early stages, signs may be absent or manifest only by salt sensitivity and systemic hypertension, whereas more advanced stages typically are associated with a full blown syndrome of hypertension, metabolic alkalosis, hypomagnesemia, and hypokalemia.

The tubular delivery of large amounts of sodium chloride in a setting of volume expansion and nonsuppressible aldosterone results in hypokalemia, which improves after sodium restriction and worsens with the administration of intravenous saline. In congenital adrenal hyperplasia (Chapter 208), such as 11β-hydroxylase deficiency, hypokalemic alkalosis is associated with excessive androgen production. In patients with renin-secreting tumors or unilateral renal artery stenosis, high renin levels stimulate angiotensin II and then aldosterone secretion, with a resulting increase in sodium reabsorption, hypertension, and hypokalemic metabolic alkalosis.

In some patients with overproduction of ACTH, as in ectopic production from lung and other malignant neoplasms (Chapter 164), cortisol may overwhelm the aldosterone receptor and result in hypertensive, hypokalemic alkalosis. The patient may not show signs of Cushing syndrome in the short term. In glucocorticoid-remediable aldosteronism, which is a familial disorder in which episodes of hypokalemia and hypertension develop, a chimeric gene duplication couples the ACTH-responsive 11β-hydroxylase promoter to the coding region of aldosterone synthase.

Glycyrrhizic acid, which is found in licorice and anisette, inhibits the renal enzyme 11β-hydroxysteroid dehydrogenase and thereby causes hypokalemia, metabolic alkalosis, and hypertension. A rare genetic disorder known as apparent mineralocorticoid excess syndrome produces the same effect due to deficiency of 11β-hydroxysteroid dehydrogenase. The syndrome produces a high ratio of cortisol to cortisone; as a result, renin and aldosterone are suppressed by the volume expansion. Hypokalemia may be precipitated by ACTH stimulation of cortisol.

Activating mutations of ENaC cause increased sodium reabsorption (Liddle syndrome; Chapter 113). The syndrome can be distinguished from primary or secondary hyperaldosteronism by suppressed renin and aldosterone levels (see also Fig. 103-3 for an approach to the patient with hypokalemia and metabolic alkalosis).

Hypokalemic Hypotensive Syndromes

In contrast to the hypokalemic hypertensive syndromes, in which increased sodium reabsorption is a primary event, many hypokalemic alkaloses are associated with extracellular volume depletion. With a physiologic response to volume depletion, the potassium losses may be a result of appropriate sodium reabsorption; signs of hypotension or extracellular volume depletion will be observed. Secretory diarrheas, whether associated with hypochloremic alkalosis or hyperchloremic acidosis, lead to extracellular volume depletion and secondary increases in renin and aldosterone; the result is both gastrointestinal and urinary potassium losses. The urinary losses in alkalosis (e.g., vomiting or other chloride-wasting syndromes) result in greater degrees of potassium depletion because of the early bicarbonaturia and volume contraction.

Diuretic use, Bartter syndrome (Chapter 113), and Gitelman syndrome (Chapter 113) are renal tubular causes of extracellular volume depletion, hypotension, and hypokalemic, hypochloremic alkalosis; sodium and chloride are lost in the urine, and secondary rises in renin and aldosterone occur. Increased urinary flow rates are important contributors to the increased potassium losses in each of these examples. Bartter syndrome affects the function of the thick ascending limb through mutations in NKCC2 or in potassium or chloride channels, whereas Gitelman syndrome is characterized by inactivating mutations or dysregulation of the NaCl cotransporter in the distal tubule. The hypokalemia in Gitelman syndrome may be caused by secondary hyperaldosteronism, bicarbonaturia, and hypomagnesemia.

Classic type 1 distal renal tubular acidosis (Chapters 104 and 113) is often associated with hypokalemia, which may improve with correction of the acidemia. In contrast, proximal renal tubular acidosis, when it is corrected with bicarbonate, often results in worsening of the hypokalemia because of greater bicarbonate wasting associated with increases in the filtered bicarbonate load.

Acetazolamide, when it is given to an alkalotic patient, is a particularly potent kaliuretic agent. Volume depletion and hyperaldosteronism contribute to the potassium losses, as does the bicarbonate wasting, which appears to have a direct effect on potassium secretion.

Tubular toxins that may be associated with severe potassium losses include aminoglycosides, cisplatin, and ifosfamide. Amphotericin B results in significant potassium wasting accompanied by renal tubular acidosis. In many of these

TABLE 103-2 CAUSES OF HYPOKALEMIA AND INCREASED POTASSIUM EXCRETION

CAUSES OF INCREASED K^+ EXCRETION AND HYPOKALEMIA	RENIN	ALDOSTERONE	EXTRACELLULAR VOLUME OR BLOOD PRESSURE	ACID-BASE STATUS
Increased ENaC: Liddle syndrome	Low	Low	High	Alkalosis
Decreased β-hydroxysteroid dehydrogenase: apparent mineralocorticoid excess, licorice	Low	Low	High	Alkalosis
Adrenal tumor or hyperplasia	Low	High	High	Alkalosis
Ectopic ACTH: Cushing syndrome	Low	Low	High	Alkalosis
Congenital adrenal hyperplasia	Low	High	High	Alkalosis
Unilateral renal artery stenosis	High	High	High	Alkalosis

TABLE 103-3 CAUSES OF HYPERKALEMIA AND DECREASED POTASSIUM EXCRETION

CAUSE OF DECREASED K^+ EXCRETION AND HYPERKALEMIA	RENIN	ALDOSTERONE	EXTRACELLULAR VOLUME OR BLOOD PRESSURE	ACID-BASE STATUS
Decreased ENaC Drugs: amiloride, triamterene, trimethoprim, lithium Pseudohypoaldosteronism type 1 autosomal recessive ENaC mutation	High	High	Low or normal	Normal or acidosis
Pseudohypoaldosteronism type 1 autosomal dominant MR mutation	High	High	Low	Acidosis
MR blockade: spironolactone, eplerenone, progesterone	High	High	Low	Acidosis
Hypoaldosteronism: adrenal insufficiency	High	Low	Low	Acidosis
Hyporenin-hypoaldosteronism: NSAIDs, β-blockers, autonomic neuropathy	Low	Low	Low	Acidosis
Pseudohypoaldosteronism type 2	Low	Low	High	Acidosis

ENaC = epithelial Na^+ channel; MR = mineralocorticoid receptor; NSAIDs = nonsteroidal anti-inflammatory drugs.

conditions, simultaneous use of amiloride may diminish potassium losses by as much as 50%.

Patients who present with unexplained hypokalemia and alkalosis with volume depletion should have urinary electrolytes measured to determine whether the urine chloride is low, as with vomiting or laxative abuse. If the urine contains chloride, a diuretic screen should be considered; Gitelman syndrome and Bartter syndrome are other possibilities.

Hyperkalemic Disorders

In clinical practice, acute hyperkalemia is seen most commonly with renal failure (Chapter 117), acidosis (Chapter 104), and acute muscle damage from rhabdomyolysis (Chapter 99) (Table 103-3). Chronic hyperkalemia is most commonly seen with medications that reduce potassium secretion and with renal tubular disorders.[8]

Hyperkalemic Hypotensive or Normotensive Syndromes

When classic type IV renal tubular acidoses (Chapter 104) are due to hypomineralocorticoidism or adrenal insufficiency, the urine will be able to acidify due to a defect in ammonium production. By comparison, type IV renal tubular acidoses that are associated with an inability to excrete sufficient acid in the urine are caused by diseases that disrupt distal nephron function, including systemic lupus erythematosus (Chapter 245), urinary tract obstruction, amyloidosis (Chapter 174), the nephropathy associated with kidney and bone marrow transplantation (Chapters 117 and 163), and sickle cell nephropathy (Chapter 149). Men who present with hyperkalemia and renal insufficiency of unknown cause should be evaluated for possible prostatic obstruction (Chapter 114). Each of these conditions also may be associated with failure to concentrate the urine (nephrogenic diabetes insipidus) or with a hyperchloremic metabolic acidosis caused by abnormalities in acid secretion.

Primary selective hypoaldosteronism or complete adrenal cortical deficiency (Chapter 209) is associated with elevated renin and low aldosterone. Secondary hypoaldosteronism may be seen in hyporenin states caused by β-blockers, renin antagonists, or nonsteroidal anti-inflammatory drugs (NSAIDs). Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers increase renin and decrease aldosterone. Heparin, including low-molecular-weight and fractionated forms (Chapter 70), can lead to hyperkalemia even in small subcutaneous doses.

Disorders that affect the transepithelial potential difference and can result in hyperkalemia, acidosis, and extracellular volume depletion include inactivating mutations of ENaC (autosomal recessive pseudohypoaldosteronism

type 1), which may be accompanied by high renin and aldosterone levels. The ENaC may also be inhibited by the potassium-sparing diuretics (i.e., amiloride and triamterene) and certain medications secreted by the proximal tubule organic cation transporters, such as trimethoprim and pentamidine, as well as by lithium. Inhibition of the aldosterone receptor may be the result of antagonists such as spironolactone and eplerenone.

Hyperkalemic Hypertensive Syndromes

NSAIDs can cause hyperkalemia, particularly in patients with renal disease, by decreasing sodium delivery, increasing water reabsorption, and decreasing renin and aldosterone. Hypertension with the NSAIDs is most likely caused by renal salt and water retention.

Cyclosporine or tacrolimus may produce a hyperkalemic acidosis. The mechanism may involve inhibition of cyclooxygenase-2 and therefore hyporeninhypoaldosteronism. There may also be a decrease in apical potassium secretion in the collecting duct. Familial hyperkalemic hypertension is a genetic disorder (pseudohypoaldosteronism type 2) associated with hyperkalemia, volume expansion, and metabolic acidosis. It is caused by activation of the thiazide-sensitive distal convoluted tubule NaCl cotransporter related to a dysfunction of the WNK kinase regulatory role.

TREATMENT

It may be difficult to determine the exact state of total body potassium stores from the serum potassium level because as much as 100 to 300 mmol of potassium may be lost from the body with a fall in serum potassium of only 1 mmol/L. As a result, therapy must be guided by careful assessment of the patient as well as the serum potassium level.[9,10]

Hypokalemia

The goal of acute therapy for hypokalemia is to prevent or to manage potentially life-threatening arrhythmias or paralysis. Patients at greatest risk are the elderly, patients with known liver disease or cardiac disturbances, and patients who have had an abrupt fall in serum potassium concentration to less than 2.5 mEq/L. Potassium must traverse the extracellular space before repleting intracellular stores, so it is dangerously easy to replete potassium too quickly. Oral potassium should be given, if possible. If the potassium level is greater than 3 mEq/L, an increase in dietary potassium can be considered, along with removal of the underlying cause of hypokalemia. Usual oral replacement is with potassium chloride at a dose of 40 to 100 mmol/day. The chloride salt has the advantage of treating concomitant metabolic alkalosis, but other available forms include potassium citrate (in the acidotic patient) and potassium phosphate (in patients with a phosphate deficit). Giving potassium with a non-reabsorbable anion, such as gluconate, may not replace the potassium deficit adequately. Intravenous potassium is reserved for patients who are unable to take enteral potassium and patients with symptomatic hypokalemia, paralysis, or cardiac arrhythmias. It is usually given as a solution of 20 to 40 mmol of potassium in 1 L of solution at a rate that does not exceed 10 to 20 mmol/hour. If the potassium level is less than 3 mmol/L or if more than 10 mmol/hour is to be delivered, the patient should be in a monitored setting to observe for cardiac complications. A central venous catheter may be required for these higher concentrations, and it is best to consult with a renal specialist and the pharmacy.

In patients who have prerenal azotemia associated with hyperglycemia or severe metabolic alkalosis, volume expansion with sodium chloride solutions alone can result in life-threatening potassium losses, despite improvement in the extracellular volume. Potassium must be given in anticipation of such events.

In a hypokalemic patient, care must be exercised when glucose-containing solutions are given because the resulting increase in insulin may further decrease the blood potassium level. Attention to the urine output and ongoing losses is crucial. If ongoing losses of potassium are severe, it may be necessary to provide a potassium-sparing diuretic (e.g., amiloride 5 to 10 mg orally) and to treat the cause of the ongoing losses (e.g., diarrhea). Magnesium causes further urinary excretion of potassium and should be repleted, if necessary (Chapter 105).

In the inpatient setting, hypokalemia is a common complication of intravenous fluid administration. In patients with normal renal function, a maintenance dose of intravenous potassium can avoid hypokalemia. In the outpatient setting, hypokalemia is a common side effect of diuretic therapy. Serum potassium should be maintained within the normal range (>3.5 mEq/L), especially in high-risk patients. Addition of 40 to 100 mmol of potassium per day as chloride salt is the usual treatment, depending on the patient's response.

Hyperkalemia

Emergent Treatment

If hyperkalemia is severe, concentration must be reduced rapidly by therapies that stabilize cardiac membranes (intravenous calcium) and shift potassium intracellularly (insulin, bicarbonate), while simultaneously instituting treatments that achieve net potassium loss (diuretics, potassium binders or hemodialysis).[11]

Cardiac Arrhythmias

If hyperkalemia is associated with cardiac arrhythmias, treatment in a monitored setting is warranted before the serum potassium level can be expected to decline, even with aggressive therapy. Calcium gluconate, 10 mL of a 10% solution (8.9 mg calcium) over 10 to 20 minutes, is often indicated to stabilize electrical effects on cardiac excitation. Calcium chloride (3 to 4 mL of a 10% solution) is an alternative, but it should be administered through a central access line because extravasation of the chloride salt may result in tissue necrosis. Gastrointestinal losses of potassium can also be achieved by use of potassium-binding drugs.

Lowering the Potassium Level

The administration of calcium does not lower the potassium concentration. Rapid-acting options to lower the potassium level acutely include an inhaled β_2-agonist or the intravenous combination of insulin plus glucose.

β_2-agonists are usually preferred because epinephrine can initially increase the release of K^+ from the liver. Albuterol by nebulizer (10 to 20 mg in 4 mL of saline during 10 minutes) can redistribute potassium acutely but should not be the sole treatment because some patients are not responsive. In some cases, intravenous β-adrenergic agonists (e.g., albuterol, 0.5 mg in 100 mL of 5% dextrose during 15 minutes) have been used to lower the serum potassium level by about 1 mmol/L within minutes to hours.

If insulin plus glucose is chosen, alternatives include 100 mL of 50% glucose alone or in combination with 10 units of regular insulin; the combination will, on average, provide a significantly greater reduction in the serum potassium level (0.8 mmol/L vs. 0.5 mmol/L) at 60 minutes, but about 20% of insulin-treated patients will develop hypoglycemia. Alternatively, 5 units of regular insulin can be given with 10% glucose solution during 1 hour for a total of 30 to 50 g in the normoglycemic patient. The blood glucose level should be monitored because an abrupt increase in plasma osmolality with glucose may worsen hyperkalemia if it causes potassium to leak from cells with osmotic water flow.

Sodium zirconium cyclosilicate (1.25 to 10 g three times a day), an oral crystalline agent with high binding affinity for potassium within the gastrointestinal tract, can reduce the serum potassium concentration within 1 hour, particularly in patients with heart failure.[A1] This potassium binder has been shown to be effective as an adjunct to glucose and insulin therapy.

Sodium bicarbonate, as an isotonic mixture calculated to correct acid-base status, should be reserved for acidemic patients who otherwise require alkalinization, while being careful to avoid hypocalcemia. Complications of sodium bicarbonate infusions include hypernatremia, volume expansion, and decreased ionized calcium, potentially resulting in tetany. Diabetic patients may be potassium depleted even though they present with hyperkalemia; as they are volume repleted, they typically require potassium replacement (Chapter 210).

If hyperkalemia occurs in the setting of volume contraction and oliguria, extracellular volume expansion with saline to achieve a rise in urine output may be adequate. If a patient is hyperkalemic and volume-expanded and not in renal failure, potassium-losing diuretics (e.g., furosemide 10 to 40 mg intravenously) may be effective.

The hyperkalemia of familial hyperkalemic hypertension is highly responsive to thiazide diuretics. In patients who have advanced or end-stage kidney failure, particularly in a volume-expanded hyperkalemic patient, hemodialysis (Chapter 117) will be required to remove potassium effectively from the body. However, patients who are dialyzed against zero K^+ dialysate may become rapidly hypokalemic.

Chronic Treatment

During the longer term, potassium loss may be sustained by use of cation exchange resins and a low-potassium diet.[12] Patiromer (4.2 to 8.4 g twice daily),[A2] a nonabsorbed calcium-potassium exchange resin that works in the colon, can decrease potassium levels for at least a year. It has been used successfully in patients with diabetic renal disease[A3] and in patients receiving potassium-retaining antihypertensive agents.[A4] Its major side effect is constipation, but hypomagnesemia, diarrhea, nausea, abdominal discomfort, and flatulence can also occur. To avoid potential interaction, no other orally administered medication should be taken at least 3 hours before or after patiromer. Zirconium cyclosilicate at 1.25 to 10 g three times daily[A5,A6] is also effective in managing hypokalemia. Sodium polystyrene sulfonate given orally or as an enema (Chapter 116) at a dose of 30 to 50 g can reduce potassium levels over several hours, but its use is limited by its many adverse effects, so it is now rarely used.

If the patient is volume expanded, furosemide (40 to 100 mg), chlorothiazide (500 mg), or, if the patient is also alkalotic, acetazolamide (250 to 500 mg) may enhance renal potassium clearance. If the patient is volume depleted, isotonic saline expansion may improve urine output and, with it, potassium excretion.

SPECIFIC CLINICAL SYNDROMES

Hypokalemic Periodic Paralysis

Familial hypokalemic periodic paralysis is an autosomal dominant disorder usually caused by mutations in certain voltage-gated skeletal muscle sodium channels or L-type calcium channels. Characteristically, periodic attacks of severe hypokalemia are precipitated by stimuli that usually induce mild hypokalemia by distributing potassium into cells. Precipitating factors include the

increase in insulin levels after the ingestion of carbohydrates or postexercise, when the plasma potassium level falls because of ATPase reuptake of potassium. In affected individuals, these stimuli cause progressive and severe hypokalemia, enough to result in muscle paralysis due to hyperpolarization of the sarcolemma. The cause of the syndrome is an imbalance between outwardly directed K^+ current and inwardly directed cation leaks of Na^+ and Ca^{2+}. In the familial mutations, the cation depolarizing influx, normally very small under hyperpolarizing conditions, is instead increased and, when balanced with the outward K^+ current, results in a paradoxical depolarization. In turn, the depolarization inactivates the sodium channel needed for the rapid action potential, so the muscle cell is unexcitable. In nonfamilial hypokalemic periodic paralysis, a loss in function of outwardly directed potassium channels (Kir) accounts for paradoxical depolarization, inactivation of sodium channels, and decreased excitability.

The clinical presentation of hypokalemic periodic paralysis is usually in the teenage years or early adulthood.[13] In some familial cases, a progressive proximal myopathy (Chapter 389) may develop. Asian patients, usually males with hyperthyroidism (Chapter 207), have a decrease-in-function mutation of an outwardly directed potassium channel that causes them to develop episodic paralysis in response to high-carbohydrate meals or resting after exercise. In Anderson syndrome, which is another form of hypokalemic periodic paralysis, cardiac potassium channels are also affected, and serious cardiac arrhythmias may result.

TREATMENT

Hypokalemic periodic paralysis is treated by a high-potassium diet and cautious use of carbonic anhydrase inhibitors such as acetazolamide (125 to 500 mg/day) and dichlorphenamide (50 to 200 mg/day), which can significantly reduce the frequency of attacks. These medications work in part by creating a hyperchloremic acidosis that offsets the urinary potassium wasting they cause. β_2-Blockers (e.g., propranolol 20 to 40 mg twice daily) also may be used.

Insulin Deficiency

The abnormal distribution of potassium between cells and the extracellular space results in the hyperkalemia that is associated with acidosis, insulin-deficient states, and β_2-adrenergic blockade. Although it is not always possible, it is best to know the levels of serum glucose and potassium in an unconscious diabetic patient before infusing concentrated glucose solutions because of the risk of aggravating hyperkalemia.

Hyperkalemic Periodic Paralysis

Familial hyperkalemic periodic paralysis is a myopathy caused by a genetic defect in voltage-gated sodium channels in skeletal muscle. Exercise or dietary increases in plasma potassium result in mild depolarization of skeletal muscle that then unmasks the sodium channel defect, rendering the cells unexcitable. Treatment is frequent meals and acetazolamide (125 to 500 mg).

Digitalis Overdose

Potassium competes with digoxin-binding sites on the Na^+, K^+-ATPase, so that if hypokalemia coexists, digoxin will have an intensified effect and may lead to drug toxicity. In extreme cases of digitalis overdose (Chapter 96), severe hyperkalemia develops as a result of generalized blockade of Na^+, K^+-ATPase.

PROGNOSIS

The prognosis of patients with hypokalemia and hyperkalemia depends on the severity and underlying illness. Hypokalemia is associated with increased mortality, especially in patients with heart disease,[14] and hyperkalemic patients on renal dialysis have a higher cardiovascular mortality. Hypertensive patients with potassium levels either above or below the range of 4.1 to 4.7 mEq/L also appear to have an increased mortality,[15] but modest hyperkalemia (≤5.5 mEq/L) does not appear to have adverse effects on treated patients with heart failure.[16] Most hypokalemic cases are mild (potassium concentration 3 to 3.5 mEq/L). However, mortality of hospitalized patients with hypokalemia is increased 10-fold. Hyperkalemia is reported in 1 to 10% of hospitalized patients, of whom 10% have severe hyperkalemia (potassium concentration > 6.0 mEq/L). Hyperkalemia is associated with increased mortality (14 to 41%), and it accounts for 2 to 5% of deaths in patients with end-stage renal disease. Patients with electrocardiographic abnormalities are at highest risk, especially in the acute period before the serum potassium level is successfully reduced.

104 ACID-BASE DISORDERS

JULIAN LAWRENCE SEIFTER

DEFINITION

The ability to regulate the H^+ ion concentration, or pH (defined as the negative logarithm of the hydrogen ion concentration), is essential to normal body function. Acid-base balance is assessed by measurements of arterial or venous blood. If arterial pH is below 7.35, *acidemia* is said to exist. If pH is above 7.45, *alkalemia* exists. However, several processes may simultaneously drive the pH upward or downward; these individual processes are known as alkaloses or acidoses, respectively. Because simultaneous alkalosis and acidosis of equal magnitude can coexist, an abnormal pH is not always noted in acid-base disturbances. Also, because pH is a function of the ratio of the blood bicarbonate concentration ($[HCO_3^-]$) to the partial pressure of carbon dioxide (P_{CO_2}), the finding of an abnormal bicarbonate level alone cannot define acidemia or alkalemia.

EPIDEMIOLOGY

An acid-base disturbance should alert the clinician to the possible presence of an important underlying condition. Anion gap acidoses represent serious underlying metabolic disorders, ranging from sepsis (Chapter 94) to uremia (Chapter 116) to diabetic ketoacidosis (Chapter 210) to serious poisonings (Chapter 96). Specific renal abnormalities as well as diarrhea (Chapter 126) can cause hyperchloremic acidosis (Table 104-1). Metabolic alkaloses are commonly caused by diuretics or renal tubular abnormalities or the loss of acid from the stomach due to vomiting or nasogastric suction (Table 104-2). Respiratory acidosis and alkalosis are related to disturbances in ventilation, which is increased by conditions such as sepsis (Chapter 94) and anxiety, and is decreased in many pulmonary conditions and with depression of the central nervous system (CNS) (Chapters 71 and 89).

PATHOBIOLOGY

Growth, cell division, fertilization, and protein and glucose metabolism are examples of pH-sensitive intracellular processes. Acids are generated within cells during metabolism, and each cell must maintain a pH appropriate for its function. For example, cardiac contractility (Chapter 41) is reduced when cardiac myocytes are too acidic. Bone and muscle develop and grow poorly in an acidic environment. Intracellular pH may be lower than extracellular pH because cells are electronegative with respect to extracellular fluid, but they are not as acidic as they would be if H^+ reached electrochemical equilibrium with the extracellular fluid, which means that all cells utilize energy to extrude acid actively. Cells are capable of buffering an acid load, and intracellular vacuoles may use hydrogen adenosine triphosphatases (H^+-ATPases) to sequester excess acid before transport from the cell. The transport processes located on the plasma membranes can protect cells from both acid and alkaline loads. The specific mechanisms may differ from one cell type to another, but they are similar to those used by the excretory organs that finally eliminate the net acid produced by the body into the external world.[1,2]

In severe disease states, arterial pH may fall as low as 6.8 and rise as high as 7.7. Strenuous exercise with the metabolic production of lactic acid may transiently but severely lower pH, even in normal healthy individuals.

increase in insulin levels after the ingestion of carbohydrates or postexercise, when the plasma potassium level falls because of ATPase reuptake of potassium. In affected individuals, these stimuli cause progressive and severe hypokalemia, enough to result in muscle paralysis due to hyperpolarization of the sarcolemma. The cause of the syndrome is an imbalance between outwardly directed K^+ current and inwardly directed cation leaks of Na^+ and Ca^{2+}. In the familial mutations, the cation depolarizing influx, normally very small under hyperpolarizing conditions, is instead increased and, when balanced with the outward K^+ current, results in a paradoxical depolarization. In turn, the depolarization inactivates the sodium channel needed for the rapid action potential, so the muscle cell is unexcitable. In nonfamilial hypokalemic periodic paralysis, a loss in function of outwardly directed potassium channels (Kir) accounts for paradoxical depolarization, inactivation of sodium channels, and decreased excitability.

The clinical presentation of hypokalemic periodic paralysis is usually in the teenage years or early adulthood.[13] In some familial cases, a progressive proximal myopathy (Chapter 389) may develop. Asian patients, usually males with hyperthyroidism (Chapter 207), have a decrease-in-function mutation of an outwardly directed potassium channel that causes them to develop episodic paralysis in response to high-carbohydrate meals or resting after exercise. In Anderson syndrome, which is another form of hypokalemic periodic paralysis, cardiac potassium channels are also affected, and serious cardiac arrhythmias may result.

TREATMENT

Hypokalemic periodic paralysis is treated by a high-potassium diet and cautious use of carbonic anhydrase inhibitors such as acetazolamide (125 to 500 mg/day) and dichlorphenamide (50 to 200 mg/day), which can significantly reduce the frequency of attacks. These medications work in part by creating a hyperchloremic acidosis that offsets the urinary potassium wasting they cause. β_2-Blockers (e.g., propranolol 20 to 40 mg twice daily) also may be used.

Insulin Deficiency

The abnormal distribution of potassium between cells and the extracellular space results in the hyperkalemia that is associated with acidosis, insulin-deficient states, and β_2-adrenergic blockade. Although it is not always possible, it is best to know the levels of serum glucose and potassium in an unconscious diabetic patient before infusing concentrated glucose solutions because of the risk of aggravating hyperkalemia.

Hyperkalemic Periodic Paralysis

Familial hyperkalemic periodic paralysis is a myopathy caused by a genetic defect in voltage-gated sodium channels in skeletal muscle. Exercise or dietary increases in plasma potassium result in mild depolarization of skeletal muscle that then unmasks the sodium channel defect, rendering the cells unexcitable. Treatment is frequent meals and acetazolamide (125 to 500 mg).

Digitalis Overdose

Potassium competes with digoxin-binding sites on the Na^+, K^+-ATPase, so that if hypokalemia coexists, digoxin will have an intensified effect and may lead to drug toxicity. In extreme cases of digitalis overdose (Chapter 96), severe hyperkalemia develops as a result of generalized blockade of Na^+, K^+-ATPase.

PROGNOSIS

The prognosis of patients with hypokalemia and hyperkalemia depends on the severity and underlying illness. Hypokalemia is associated with increased mortality, especially in patients with heart disease,[14] and hyperkalemic patients on renal dialysis have a higher cardiovascular mortality. Hypertensive patients with potassium levels either above or below the range of 4.1 to 4.7 mEq/L also appear to have an increased mortality,[15] but modest hyperkalemia (≤5.5 mEq/L) does not appear to have adverse effects on treated patients with heart failure.[16] Most hypokalemic cases are mild (potassium concentration 3 to 3.5 mEq/L). However, mortality of hospitalized patients with hypokalemia is increased 10-fold. Hyperkalemia is reported in 1 to 10% of hospitalized patients, of whom 10% have severe hyperkalemia (potassium concentration > 6.0 mEq/L). Hyperkalemia is associated with increased mortality (14 to 41%), and it accounts for 2 to 5% of deaths in patients with end-stage renal disease. Patients with electrocardiographic abnormalities are at highest risk, especially in the acute period before the serum potassium level is successfully reduced.

104 ACID-BASE DISORDERS

JULIAN LAWRENCE SEIFTER

DEFINITION

The ability to regulate the H^+ ion concentration, or pH (defined as the negative logarithm of the hydrogen ion concentration), is essential to normal body function. Acid-base balance is assessed by measurements of arterial or venous blood. If arterial pH is below 7.35, *acidemia* is said to exist. If pH is above 7.45, *alkalemia* exists. However, several processes may simultaneously drive the pH upward or downward; these individual processes are known as alkaloses or acidoses, respectively. Because simultaneous alkalosis and acidosis of equal magnitude can coexist, an abnormal pH is not always noted in acid-base disturbances. Also, because pH is a function of the ratio of the blood bicarbonate concentration ($[HCO_3^-]$) to the partial pressure of carbon dioxide (P_{CO_2}), the finding of an abnormal bicarbonate level alone cannot define acidemia or alkalemia.

EPIDEMIOLOGY

An acid-base disturbance should alert the clinician to the possible presence of an important underlying condition. Anion gap acidoses represent serious underlying metabolic disorders, ranging from sepsis (Chapter 94) to uremia (Chapter 116) to diabetic ketoacidosis (Chapter 210) to serious poisonings (Chapter 96). Specific renal abnormalities as well as diarrhea (Chapter 126) can cause hyperchloremic acidosis (Table 104-1). Metabolic alkaloses are commonly caused by diuretics or renal tubular abnormalities or the loss of acid from the stomach due to vomiting or nasogastric suction (Table 104-2). Respiratory acidosis and alkalosis are related to disturbances in ventilation, which is increased by conditions such as sepsis (Chapter 94) and anxiety, and is decreased in many pulmonary conditions and with depression of the central nervous system (CNS) (Chapters 71 and 89).

PATHOBIOLOGY

Growth, cell division, fertilization, and protein and glucose metabolism are examples of pH-sensitive intracellular processes. Acids are generated within cells during metabolism, and each cell must maintain a pH appropriate for its function. For example, cardiac contractility (Chapter 41) is reduced when cardiac myocytes are too acidic. Bone and muscle develop and grow poorly in an acidic environment. Intracellular pH may be lower than extracellular pH because cells are electronegative with respect to extracellular fluid, but they are not as acidic as they would be if H^+ reached electrochemical equilibrium with the extracellular fluid, which means that all cells utilize energy to extrude acid actively. Cells are capable of buffering an acid load, and intracellular vacuoles may use hydrogen adenosine triphosphatases (H^+-ATPases) to sequester excess acid before transport from the cell. The transport processes located on the plasma membranes can protect cells from both acid and alkaline loads. The specific mechanisms may differ from one cell type to another, but they are similar to those used by the excretory organs that finally eliminate the net acid produced by the body into the external world.[1,2]

In severe disease states, arterial pH may fall as low as 6.8 and rise as high as 7.7. Strenuous exercise with the metabolic production of lactic acid may transiently but severely lower pH, even in normal healthy individuals.

ABSTRACT

Measurements of pH, P_{CO_2}, and HCO_3^- in the blood are used in the clinical assessment of acid-base disorders. The constancy of a narrow range of body fluid pH determines many regulatory cellular and extracellular functions. This chapter describes the normal physiologic mechanisms for the metabolic production of volatile carbonic acid, which is eliminated by pulmonary alveolar ventilation, and dietary-derived, nonvolatile acids that require renal mechanisms for urinary excretion. The integrated role of metabolic and renal functions to lessen the severity of or adapt to a specific disorder is known as compensation, and predictable limits exist for both brain-respiratory control and renal responses to achieve these important compensatory responses. Abnormalities in membrane transport, intrinsic diseases of organ function, and hormonal or electrolyte disorders are responsible for the generation and maintenance of simple acid-base disorders. Metabolic acidosis is further characterized as hyperchloremic or anion-gap acidosis depending on the nature of the anion associated with the excessive acid. The consequences and treatments of endogenous acid-base disorders as well as environmental poisonings are emphasized since the prompt recognition, diagnosis, and treatment is often life-saving. The short-term and long-term complications of acid-base disturbances are reviewed, and the integration of pulmonary function, blood pressure, salt, water, potassium, and calcium balance connect intimately to both the initiation and correction of these disorders.

TABLE 104-1 EXAMPLES OF HYPERCHLOREMIC ACIDOSIS

TYPE	CAUSE
Renal with hypokalemia	Proximal RTA, type 2 Distal RTA, type 1 Some anion gap acidoses with high anion clearance
Renal with hyperkalemia	Type 4 RTA Hyporenin-hypoaldosteronism
Nonrenal with hypokalemia	Diarrhea Urinary diversions: ureteroileostomy, ureterosigmoidostomy
Nonrenal with hyperkalemia	NaCl, KCl, NH_4Cl, $CaCl_2$, Arg-HCl, Lys-HCl

RTA = renal tubular acidosis.

TABLE 104-2 EXAMPLES OF METABOLIC ALKALOSIS

TYPE	CAUSES
Renal, hypochloremic alkalosis with hypokalemia: chloride responsive with urine chloride concentration >20 mEq/L	Loop and distal tubule diuretics Bartter syndrome Gitelman syndrome Post-hypercapnic status
Nonrenal, hypochloremic alkalosis: chloride responsive with urine chloride concentration <20 mEq/L	Vomiting, nasogastric suction Congenital chloridorrhea Villous adenoma
Renal, alkalosis with extracellular expansion and hypokalemia: chloride unresponsive with urine chloride concentration >20 mEq/L	Hyperaldosteronism, primary and secondary to unilateral renal artery stenosis Liddle syndrome
Nonrenal alkalosis, chloride unresponsive	$NaHCO_3$, acetate, citrate, lactate. Minimal alkalosis will develop unless accompanied by a process such as hypokalemia or hypovolemia
Renal hypokalemic alkalosis	Excessive excretion of non-reabsorbable anions due to excretion of H^+ and K^+
Nonrenal alkalosis with decreased anion gap	Hypoalbuminemia

At a normal arterial blood pH, the hydrogen ion concentration is in the range of 40 nanoequivalents (nEq) per liter, a very small concentration in comparison to a normal plasma sodium concentration of 140 mEq/L. The hydrogen ion concentration of body fluids is in equilibrium with each of multiple weak acids or buffers, such as proteins and phosphate (the isohydric principle), but acid-base equilibria in the body are often described and analyzed by use of the CO_2/HCO_3^- system and the relationship of the proton concentration (thus pH) to the ratio of HCO_3^- to CO_2. The CO_2/HCO_3^- system is quantitatively the largest buffer system in the body, and it is the system whose parameters are most often measured clinically. The Henderson-Hasselbalch equation is a logarithmic expression of the relationship.

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$
$$pH = pK + \log[HCO_3]/0.03(P_{CO_2})$$

In this equation, p*K*, or the negative log of the dissociation constant for the reaction, is 6.1; 0.03 (mM/mm Hg) is the solubility factor for CO_2 in solution. The product of 0.03 × P_{CO_2} represents dissolved CO_2; the "total CO_2" in plasma is the sum of HCO_3^-, normally about 25 mM, and 0.03 × P_{CO_2}, normally about 1.2 mM in arterial blood. It is important to emphasize that pH is a function of the *ratio* of HCO_3^- to P_{CO_2}. The HCO_3^- concentration in the numerator is regulated by the kidney, and P_{CO_2} is regulated by the lung.

Production of Carbonic Acid and the Elimination of Carbon Dioxide by the Lung

Volatile acid is the term used for the approximately 20,000 mmol/day of CO_2 produced, with an equimolar amount of water, by tissue respiration. This CO_2 is carried from tissues to the lung, where it is eliminated by alveolar ventilation. Steady-state arterial P_{CO_2} is normally 38 to 42 mm Hg.

Oxidation of carbohydrates, fat, and the carbon skeleton of amino acids results in the production of water and CO_2. To maintain a steady state, any acid (or base) produced per day must be equivalent to what is eliminated. If tissue CO_2 production exceeds CO_2 elimination by the lungs, respiratory acidosis characterized by a high P_{CO_2} will develop. If the rate of CO_2 eliminated exceeds production, respiratory alkalosis develops. The inverse relationship between alveolar ventilation (the clearance of CO_2) and P_{CO_2} is demonstrated as

$$\text{alveolar ventilation} \approx CO_2 \text{ elimination rate} \div P_{CO_2}$$

The circulation plays a critical role in transporting tissue CO_2 to the lungs. The process depends not only on cellular respiration but also on tissue capillary flow as well as diffusion of CO_2 into the blood and across red blood cell membranes, where it may react with hemoglobin and proteins to form carbamino compounds or combine with water for conversion to H^+ and HCO_3^- in a reaction catalyzed by carbonic anhydrase. The intracellular H^+ can combine with hemoglobin (the Bohr effect) and the HCO_3^- exchanged with plasma Cl^- through red cell anion exchangers. Most tissue CO_2 is brought to the lung as venous plasma HCO_3^-. Compared with arterial blood, venous blood has the characteristics of a respiratory acidosis. Venous pH is normally approximately 0.05 pH units more acid than arterial pH, its P_{CO_2} is 5 to 6 mm Hg higher than that of arterial blood, and its bicarbonate concentrations are normally greater than arterial concentrations.

In disease, changes in P_{CO_2} are most often caused by changes in alveolar ventilation rather than by production of CO_2. Thus, respiratory acidosis is a consequence of decreased pulmonary ventilation because of lung, skeletal muscle, or CNS disease. However, if alveolar ventilation is compromised, increased production of CO_2 will worsen CO_2 retention. Similarly, respiratory alkalosis develops because of hyperventilation rather than decreased CO_2 production. In either case, when the elimination rate of CO_2 (alveolar ventilation × P_{CO_2}) again equals CO_2 production, a new steady-state P_{CO_2} will prevail, with no net retention or loss of carbonic acid.

Production of Acids and Excretion by the Kidney

Nonvolatile or fixed acid describes noncarbonic acids that are formed primarily from protein metabolism. The usual rate of formation is approximately 1 to 2 mEq of H^+ per kilogram of body weight per day. Most diets that contain animal protein metabolically produce a net positive quantity of nonvolatile acids, primarily sulfuric acid from the sulfur-containing amino acids cysteine and methionine. Other acids are produced in the form of phosphoric acid (from phosphoproteins, phospholipids, and phospho-nucleotides) and nonmetabolizable organic acids (e.g., uric acid), and hydrochlorides are produced from metabolism of the cationic amino acids lysine, arginine, and histidine. Conversely, HCO_3^- is generated from metabolism of organic anions absorbed from the diet (e.g., citrate, acetate).

From the Henderson-Hasselbalch equation, consider the addition of metabolic acid HA (where the anion A^- could be Cl^-, lactate$^-$, sulfite, or mono- or dihydrogen phosphate) to blood that contains Na^+ and HCO_3^-:

$$HA + NaHCO_3 \rightarrow Na^+ + A^- + H^+ + HCO_3^-$$

and

$$H^+ + HCO_3^- \leftrightarrow H_2CO_3 \leftrightarrow CO_2 + H_2O$$

The CO_2 produced by this process will not raise the blood P_{CO_2} if the system is well ventilated because the contribution of metabolic acid is a small part of the daily production of CO_2. Note that the addition of protons to body fluids by these acid end products consumes bicarbonate ("lost bicarbonate"), which then must be replenished by the kidney as it eliminates the proton and A^- in the urine. The process of excreting net H^+ and A^- is equivalent to producing a "new" HCO_3^- to restore the HCO_3^- that is lost by the addition of HA, the metabolic acid. The kidney must excrete any nonvolatile acid (or alkali) load to maintain a steady-state serum HCO_3^- concentration in the 22- to 28-mEq/L range.

When the diet requires the excretion of acids, the urine pH will fall to a value as low as 4.5 to 5.0, and the urine will become nominally free of bicarbonate. With an alkaline load, by comparison, the kidney will excrete excess filtered HCO_3^-, and the urine pH may approach a maximal value of 8.0 to 8.5. In most humans, particularly those who eat animal protein or an "acid-ash" diet, the requirement for net acid *excretion* predominates. However, some vegetarians may have an overall "alkaline-ash" diet, for which net alkali must be excreted to match intake.

Bicarbonate and the Kidney in Acid-Base Balance

The first role of the kidney in achieving acid excretion is to reabsorb all filtered HCO_3^- (E-Fig. 104-1). At a normal glomerular filtration rate (e.g., ≈180 L/day in an adult) and plasma HCO_3^- concentration of 25 mEq/L, about 4500 mEq of HCO_3^- is filtered in 1 day. Loss of even a small fraction of that amount would result in metabolic acidosis if not replaced by alkali (HCO_3^-) intake. Just as reabsorption of all filtered glucose does not add glucose to the body, reabsorption of all filtered HCO_3^- will maintain the status quo but will not fulfill the need to generate new HCO_3^-. Therefore, the kidney must perform two functions: reabsorb all filtered HCO_3^- and eliminate enough additional H^+ (producing HCO_3^- in the process) to replace HCO_3^- losses from acid that is generated by cellular metabolism. Urinary buffers are essential because urinary pH alone cannot be lowered enough to excrete the amount of acid needed for this purpose.

The Proximal Tubule

About 80 to 90% of HCO_3^- reabsorption is accomplished in the proximal tubule by a proton secretory process that renders the luminal fluid more acid (pH ≈ 6.5). The brush border membranes facing the lumen of the proximal tubule cell contain transporters known as Na/H exchangers (NHE3), which carry out the greatest proportion of acidification, and vacuolar H^+-ATPases, which provide a smaller contribution. Through the normal function of basolateral membrane Na^+, K^+-ATPase, cell Na^+ is kept at low concentration so that filtered Na^+ in the lumen will be favored to enter the cell in exchange for H^+ secreted into the lumen. This H^+ rapidly combines with filtered HCO_3^- to form H_2CO_3, which then rapidly dehydrates in the lumen to form CO_2 and H_2O. This process is greatly facilitated by the large surface area of microvillous membranes and by luminal carbonic anhydrase (CA_{IV}). The CO_2 enters the proximal cell by diffusion through apical water channels (aquaporin 1). CO_2 within the cell re-forms HCO_3^-, a reaction catalyzed by intracellular carbonic anhydrase (CA_{II}). The cell, more alkaline by apical H^+ secretion, favors the reaction $OH^- + CO_2$ to form HCO_3^- catalyzed by carbonic anhydrase. The HCO_3^- is then transported back toward the blood by an electrogenic sodium bicarbonate cotransporter (NBCel), which couples 1Na and $3HCO_3^-$, thereby completing net Na^+ and HCO_3^- reabsorption. The 1 : 3 net negative charge transport by NBC allows the inside negative membrane potential to drive outward movement of Na^+ and HCO_3^- against an adverse Na gradient in this reabsorptive process. NBC on the basolateral membrane protects the cell from an alkaline load, accomplishes HCO_3^- reabsorption, and mediates a component of Na^+ reabsorption without further direct requirement for adenosine triphosphate (ATP). The entire process requires a mitochondrial source of ATP for the Na^+/K^+ pump, intact NHE3 and NBC, and two isoforms of carbonic anhydrase. In addition, there must be favorable ion gradients for luminal Na^+ entry, H^+ secretion, and basolateral HCO_3^- transport. An inside negative potential depending on outwardly directed K^+ gradients explains how an increase in blood K^+ decreases the proximal reabsorption of HCO_3^- and the production of NH_4^+. Conversely, hypokalemia tends to stimulate the reabsorption of HCO_3^- and the production of ammonium. A disturbance in any of these factors may disrupt proximal HCO_3^- reabsorption and cause loss of HCO_3^- in urine. It is also clear that the acidifying process in the proximal tubule provides a significant mechanism for Na^+ reabsorption, consistent with the finding that HCO_3^- reabsorption is increased by angiotensin II and the sympathetic nervous system in the defense of extracellular volume.

Another 10 to 15% of filtered HCO_3^- is reabsorbed in the thick ascending limb of Henle, so that only small amounts of the filtered HCO_3^- are normally delivered to more distal nephron segments.

The Cortical Collecting Duct

The cortical connecting tubules and collecting ducts reabsorb less than 10% of the filtered HCO_3^-. In principal cells, Na^+ is reabsorbed from lumen to cell by the epithelial sodium channel (ENaC), driven by the inwardly directed Na^+ gradient and favorable electrical potential. With the reabsorption of Na^+, the lumen becomes electronegative, thereby favoring the secretion of both K^+, through potassium channels, and H^+, through vacuolar H^+-ATPases on the luminal surface of neighboring α-intercalated cells, which are acid-secreting cells. The secreted H^+ will combine with the remaining HCO_3^- in the lumen to generate CO_2, with subsequent reabsorption of CO_2, re-formation of cellular HCO_3^- with the help of cellular carbonic anhydrase (CA_{II}), and then exchange of HCO_3^- from cell to blood for entry of extracellular Cl^- through Cl^-/HCO_3^- exchangers, similar to the erythrocytic anion exchangers (AE1) that participate in blood CO_2 transport. The distal nephron, which has a smaller requirement for bicarbonate reabsorption than the proximal tubule, lacks both brush border and luminal carbonic anhydrase. It is at this distal site that tubular fluid pH starts to fall to levels below pH 6.0.

β-Intercalated cells comprise a population of collecting duct cells that have reverse polarity and secrete HCO_3^- into the lumen in exchange for Cl^- entry into the cell. In these, the H^+-ATPase faces the blood side of the cell. An elevated extracellular HCO_3^- concentration, as seen with an alkaline-ash diet or metabolic alkalosis, will increase HCO_3^- secretion by these cells through pendrin, which is the apical Cl^-/HCO_3^- anion exchanger.

The Medullary Collecting Duct

The medullary collecting duct continues to secrete protons into the luminal fluid, where the pH reaches its lowest values of 4.5 to 5.0. The mechanism is based on continued function of H^+-ATPases. In both the cortical and medullary collecting duct there is an additional role of an ATP-dependent K^+/H^+ exchanger, a member of the family of gastric and colonic ATPases.

Once the filtered HCO_3^- is fully reabsorbed, the kidney is still required to eliminate an additional net amount of acid equivalent to that produced in metabolism. Most of this net acid excretion is in the form of ammonium (NH_4^+), which is derived from the metabolism of glutamine in the proximal tubule and the titration of filtered phosphate to acid phosphate (titratable acidity).

$$NH_3 + H^+ \leftrightarrow NH_4^+ \quad pK\ 9.1$$

and

$$HPO_4^{2-} + H^+ \leftrightarrow H_2PO_4^- \quad pK\ 6.8$$

Urinary Buffers

As the collecting duct cells continue to secrete H^+ into urine with a diminishing luminal HCO_3^- concentration and decreasing pH, H^+ is captured by the urinary buffers. The resulting alkalinization of the cells after H^+ secretion results in the formation of cellular HCO_3^- ready for transport into blood. This process generates "new" HCO_3^- that is not a result of the reabsorption of filtered HCO_3^-. The amount of new HCO_3^- matches the amount of net acid eliminated and is also equal to each of the following: the amount of acid produced; the amount of body buffer consumed by that acid; and the amount of fixed acid anions, such as sulfate, phosphate, and Cl^-, that accompanied the H^+. The result is maintenance of normal acid-base equilibrium.

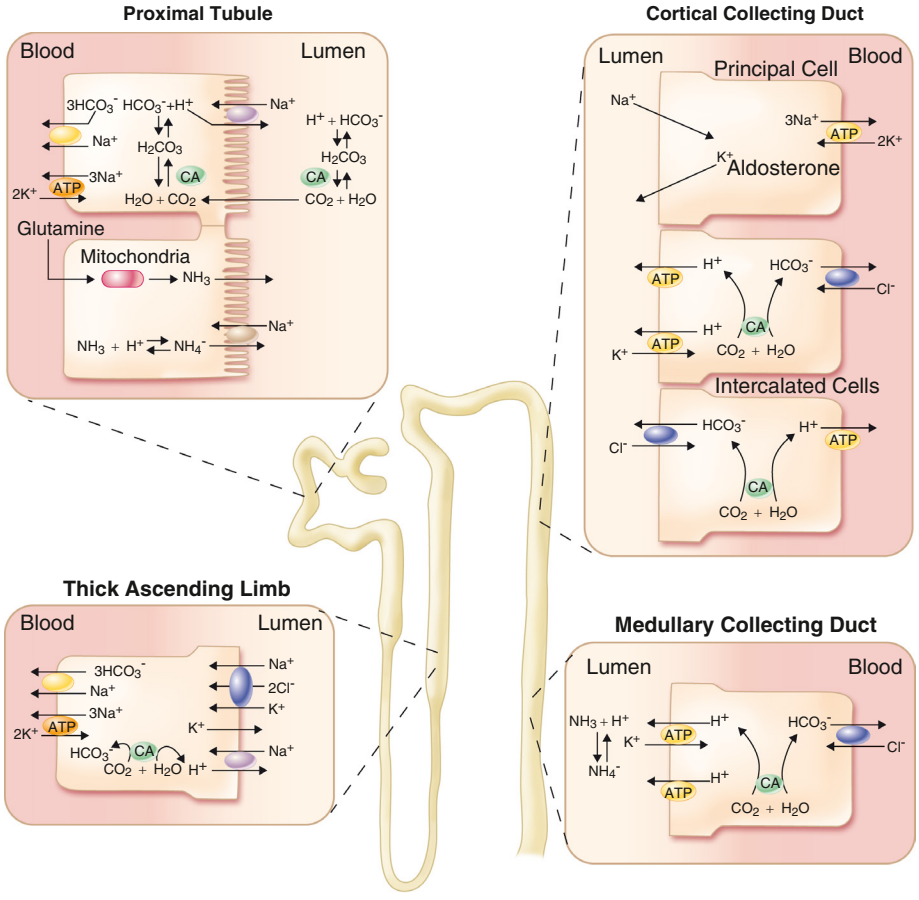
The ability of the kidney to lower urinary pH enables the buffers to capture a proton. Net acid excretion in urine is accomplished not simply by a decrease in urine pH but mostly by titration of these important urinary buffers. For example, a typical daily urine volume of 1 L at pH 5.0 contains only 10^{-5} molar hydrogen ion, or 0.01 mmol, a trivial amount compared with the amount of produced acid (≈1 mmol/kg/day). In chronic kidney disease, the failure to produce sufficient ammonium leads to a poorly buffered urine, thereby causing retention of acid while still consistent with reaching maximal urine acidity with respect to pH.

Regulation of Urinary Acid Secretion

Renal mechanisms of urinary acidification are adaptable. Transport processes such as H^+-ATPases, Na^+/H^+ exchange, and Cl^-/HCO_3^- exchange can increase or decrease their capacity to handle acid-base equivalents, depending on the challenge presented. Renal ammoniagenic mechanisms are also critically regulated to serve the acid-base needs of the individual. Metabolic acidosis and respiratory acidosis increase the capacity to reabsorb HCO_3^-, including increased expression of the transporters involved in acidifying the urine. At the same time, glutamine transport into proximal cells is stimulated, and increased production of ammonium facilitates acid excretion, as well as the generation of new HCO_3^- in the distal nephron. Metabolic alkalosis and respiratory alkalosis have the opposite effects.

Ammoniagenesis, which is a key element in urinary acid excretion, provides the major acceptor for protons. Ammonium is produced predominantly in the proximal tubule cell by mitochondrial glutaminase enzymes. Production is increased by increasing the metabolic acid load in the body, respiratory acidosis, and hypokalemia. NH_4^+ can preserve potassium in the hypokalemic state by serving as a cation needed for anion excretion. In response to metabolic acidosis, the kidney can excrete chloride with ammonium, thereby preserving the ability to retain Na^+.

Metabolic acidosis is a hypercatabolic state with increased cortisol, which increases proteolysis in muscle and increases the release of both glutamine and NH_3 into the circulation. In the liver, acidosis also decreases the activity of the urea cycle, which normally consumes NH_3 and HCO_3^- to form carbamoyl phosphate in the initial regulatory step in ureagenesis. In acidosis, NH_3 is favored to produce hepatic glutamine, which is also delivered to the proximal tubule cell, where mitochondrial enzymes remove NH_4 to assist in urinary net acid excretion. The associated increase in α-ketoglutarate provides



E-FIGURE 104-1. **Renal acidification mechanisms.** As shown, two ammonia molecules are produced per one molecule of glutamine in the mitochondria of the proximal tubule, one each from deamination of glutamine to glutamate (glutaminase) and from the deamidation of glutamate to α-ketoglutarate (glutamate dehydrogenase). HCO_3^- is also generated from metabolism of α-ketoglutarate. ATP = adenosine triphosphate; CA = carbonic anhydrase.

a substrate for gluconeogenesis in the renal proximal tubule and results in the production of HCO_3^-.

Ammonium can be secreted by nonionic diffusion as NH_3 into the proximal fluid, where it will pick up a proton and re-form ammonium (NH_4^+), or it could form ammonium within the proximal tubule cell and be secreted by Na^+/NH_4^+ exchange, a mode of operation of the Na^+/H^+ exchanger. Ammonium is then reabsorbed by the thick ascending limb of Henle on the Na-K-2Cl transporter, where it can substitute for K^+. By countercurrent multiplication, NH_3/NH_4^+ concentrates in the medullary interstitial fluid rather than remaining in the ascending limb fluid as it reaches the highly perfused renal cortex, where it would otherwise dissipate into renal venous blood. The countercurrent mechanism also allows ammonia to diffuse into the medullary interstitium and ultimately the lumen of the medullary collecting duct, where it will be trapped as ammonium in the acid tubular fluid. Diffusion of NH_3 across membranes of collecting duct cells occurs by way of glycoproteins that are in the family of the Rh factor, red blood cell ammonia transporters. The efficient secretion of ammonium in the collecting duct and by acid trapping in the lumen is essential for excretion of acid from the body.

Regulation is accomplished at a number of levels. Hormones such as angiotensin II and catecholamines stimulate Na^+ reabsorption in the proximal tubule by increasing sodium-hydrogen exchange and $NaHCO_3$ cotransport. Aldosterone increases H^+-ATPase in the collecting duct cell and stimulates Na^+ reabsorption, thereby increasing proton secretion. Low extracellular fluid volume increases proximal HCO_3^- reabsorption, as does hypokalemia and high P_{CO_2}. Hyperkalemia (Chapter 103) may limit urinary acidification by decreasing the amount of NH_3 absorbed in the thick limb and, as a result, the amount entering the countercurrent multiplier in the loop of Henle. Hyperkalemia also decreases the secretion of H^+ in the collecting duct as the need to secrete K^+ predominates.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Assessment of clinical acid-base disturbances usually begins with measurement of arterial blood gases (Fig. 104-1 and Table 104-3). In some situations, venous blood can be used as an alternative.

It is useful to conceptualize acid-base disorders by a mass action shift of the variables to the right or left in the following relationship:

$$H^+ + HCO_3^- \leftrightarrow H_2CO_3 \leftrightarrow CO_2 + H_2O$$

The addition of CO_2, as in respiratory acidosis, will increase the hydrogen and bicarbonate concentrations (left shift). Removal of CO_2, as in respiratory alkalosis, will decrease CO_2, protons, and bicarbonate (shift right). The addition of protons with an anion other than HCO_3^-, as in metabolic acidosis, will lead to increased concentrations of protons and a decreased bicarbonate concentration. Removal of HCO_3^- with a cation such as Na^+, also a cause of metabolic acidosis, will increase the proton concentration and lower the HCO_3^- concentration. Metabolic alkalosis might be caused by the addition of $NaHCO_3$ with a resulting decrease in the proton concentration or by removal of H^+ with chloride, thereby leading to a decreased proton concentration and increased HCO_3^-. Because of the relationship of metabolic acidosis and alkalosis to the gain or loss of fluids and electrolytes, acid-base disorders can be considered a consequence of electrolyte imbalance.[3]

Compensatory Changes

Few patients have an isolated acid-base disturbance. In nearly all cases, a respiratory or renal compensation (or both) occurs in response to counteract a primary acid-base process.[4]

When functioning normally, the lungs may maintain a normal pH and P_{CO_2} during changes in volatile acid production. The kidneys will also maintain normal acid-base balance during changes in fixed acid production. Only excesses beyond the capacity to eliminate an acid or alkali load will lead to clinical disturbances. Patients with renal or lung disease may do less well in response to metabolic and respiratory disorders.

When an acid-base disturbance develops, the initial response to modulate its severity depends on the titration of various body buffer pairs. For example, phosphate, hemoglobin, and albumin change their protonated and unprotonated concentrations. The body will further attempt to correct the extracellular pH toward normal but usually not to normal. For metabolic disturbances caused by increased or decreased nonvolatile acid, the response is respiratory; for primary respiratory acidosis and alkalosis, the compensation is renal (Table 104-4). The direction of change in HCO_3^- and P_{CO_2} is the same when the primary disturbance is compensated; the ratio of HCO_3^- to

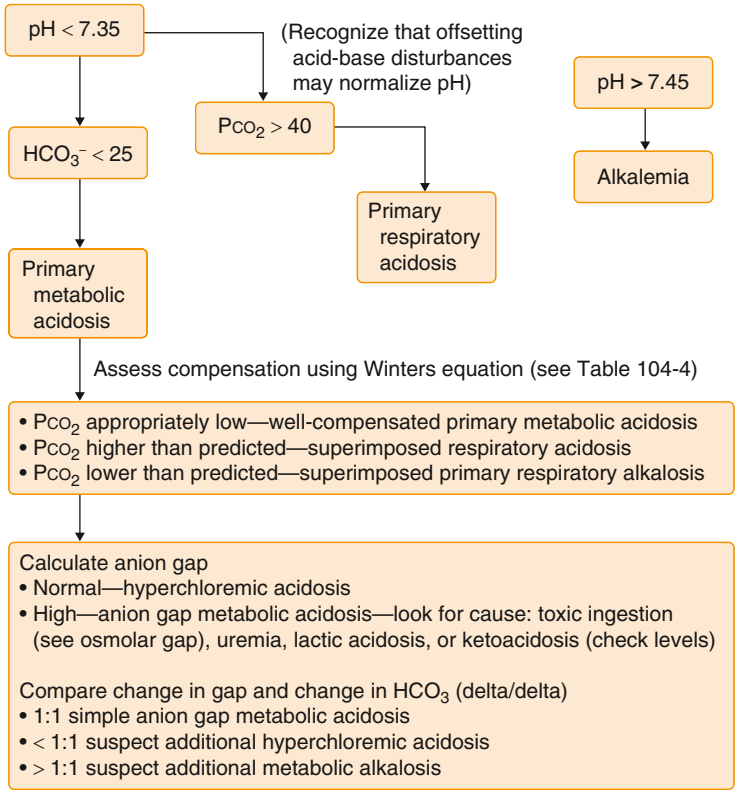


FIGURE 104-1. Evaluation of acidemia. In an anion gap acidosis, a simple 1 : 1 relationship is usually not present because organic anions are variably cleared by organs such as liver and kidney, and because the apparent volume of distribution of organic anions and bicarbonate may differ. In lactic acidosis, a 1 : 1 relationship is usually not present because of clearance of lactic acid from the circulation. In the Cori cycle, muscle lactic acid is taken up by liver cells via monocarboxylic acid transporters, and the lactate goes to re-form glucose via the gluconeogenic pathway. The glucose recycles to the muscle, where it is used for further energy. Another reason the ratio is not 1 : 1 is that lactate anion can be cleared with Na^+ by urinary excretion.

P_{CO_2} and thus pH become closer to normal. These compensations tend to take time, so acid-base disturbances, particularly the respiratory conditions requiring renal compensation, are classified as acute (lasting less than 24 to 48 hours) or chronic.

Peripheral blood does not demonstrate complete compensation for most acid-base disturbances, with the occasional exception of chronic respiratory alkalosis. Full compensation for metabolic acidosis would expend large amounts of respiratory muscle energy, which could limit a prolonged response. Full compensation for metabolic alkalosis would result in excessive hypoventilation and adverse effects on oxygenation. In both situations, the body requires an offset from "normal" to drive continued renal compensation. The degree of offset can be very close, or not that close, to normal. In contrast, the CNS closely regulates its pH, with nearly full correction within 1 to 2 days. Before this compensation occurs, acute alkalemia may be associated with cerebral vasoconstriction and ischemia, whereas acidemia may result in vasodilation and cerebral edema. Rapid changes in blood P_{CO_2} affect the CNS chemosensors more quickly than do changes in HCO_3^- because of more rapid movement of nonionic CO_2 across the blood-brain barrier. Increases in CNS CO_2 lead to acidification of the medullary center interstitial fluid and an increased ventilatory drive. Decreases in CNS CO_2 (alkalinization of the respiratory center) lead to hypoventilation. Acid-base changes are reflected in the composition of the cerebrospinal fluid (CSF).

In metabolic acidosis, peripheral chemosensors in the carotid body stimulate the CNS to increase ventilation to reduce P_{CO_2}. The fall in peripheral P_{CO_2} will lead to dissolved CO_2 leaving the CNS ahead of HCO_3^-; the alkalinization of the medullary center interstitial fluid will then slow the hyperventilatory response until a new steady state of hypocapnia is achieved. Patients may sense dyspnea or air hunger acutely with rapid and shallow respirations. In severe cases of metabolic acidemia, the respirations are deep and gasping, typical of Kussmaul breathing.

When the bicarbonate concentration increases as a result of metabolic alkalosis, a hypoventilatory response, signaled from the peripheral chemosensors, raises P_{CO_2}. As P_{CO_2} rises, the dissolved CO_2 will enter the CSF and acidify

TABLE 104-3 LABORATORY STEPS IN IDENTIFYING ACID-BASE DISORDERS

EVALUATE pH	ACIDEMIC	ALKALEMIC
Elevated P_{CO_2}	Respiratory acidosis	Metabolic alkalosis
Elevated HCO_3	Respiratory acidosis	Metabolic alkalosis
Decreased P_{CO_2}	Metabolic acidosis	Respiratory alkalosis
Decreased HCO_3	Metabolic acidosis	Respiratory alkalosis
EVALUATE FOR EXPECTED COMPENSATION		
Meets expectation: simple disorder with compensation or could be offsetting metabolic alkalosis and acidosis. *Does not meet expectation:* complex disorder, but pH indicates whether acidosis or alkalosis is dominant. *If a metabolic disorder is dominant,* a P_{CO_2} greater than predicted indicates an additional respiratory acidosis. A P_{CO_2} less than predicted indicates an additional respiratory alkalosis. *If a respiratory disorder is dominant,* an HCO_3 concentration greater than predicted indicates additional metabolic alkalosis. An HCO_3 concentration less than predicted indicates an additional metabolic acidosis.		
ASSESS ANION GAP		
Elevated: metabolic acidosis is present whether acidemic or alkalemic. If alkalemic, an additional metabolic or respiratory alkalosis is present. *If the gap is greater than the fall in HCO_3,* consider an additional metabolic alkalosis or respiratory acidosis. *If the gap is less than the fall in HCO_3,* consider an additional nongap acidosis or respiratory alkalosis.		

TABLE 104-4 EXPECTED DEGREES OF COMPENSATION IN ACID-BASE DISORDERS

DISORDER	EXPECTED COMPENSATION
Metabolic acidosis	Steady state in 12-36 hours Expected $P_{CO_2} = 1.5$ (measured HCO_3) + 8 ± 2 (Winters equation)
Metabolic alkalosis	Less predictable Expected P_{CO_2} increases 0.5 – 0.7 mm Hg per 1-mEq/L increase in HCO_3
Respiratory acidosis Acute Chronic, after 24-36 hours	Expected 1-mEq/L increase in HCO_3 per 10-mm Hg rise in P_{CO_2} Expected 3- to 5-mEq/L increase in HCO_3 per 10-mm Hg rise in P_{CO_2}
Respiratory alkalosis Acute Chronic, after 24-36 hours	Expected 1- to 2-mEq/L fall in HCO_3 per 10-mm Hg fall in P_{CO_2} Expected 5-mEq/L fall in HCO_3 per 10-mm Hg fall in P_{CO_2}

the medullary respiratory center. The stimulus to breathe will, in part, antagonize the peripheral signal until a steady state of hypoventilation is reached.

In respiratory acidosis, acute hypoventilation results in hypercapnia, because of the decreased clearance of carbon dioxide. The fall in blood pH and proximal tubular cell acidification results in compensatory ammoniagenesis and increased net renal acid excretion. When the P_{CO_2} reaches a new higher steady-state value, indicating that the production and elimination of carbonic acid have become equal at this low ventilatory rate, no further acid is retained, so further ammoniagenesis and net acid excretion are no longer required. However, the HCO_3^- produced during the period of high acid excretion persists at a high level because the high P_{CO_2} and hypochloremic volume depletion maintain proximal HCO_3^- reabsorption. The hypochloremia, brought about by the compensatory early excretion of NH_4Cl and elevated serum HCO_3^- and then maintained by the high P_{CO_2}, persists until the extracellular volume is replaced with NaCl. An abrupt decrease in P_{CO_2}, such as by mechanical ventilation, cannot correct the high HCO_3^- until chloride returns to its normal level. Reducing the P_{CO_2} before correcting the lost chloride results in post-hypercapnic metabolic alkalosis.

In respiratory alkalosis, the primary event is a fall in P_{CO_2} because of increased alveolar ventilation. On transition from acute to chronic respiratory alkalosis, the compensatory mechanisms that initially maintained a more normal systemic pH are no longer required as CO_2 production and elimination become equal. Thus, the initial compensatory decrease in renal acid excretion brought about by increased loss of filtered $NaHCO_3$ ceases, but low serum HCO_3^- and high serum Cl^- concentrations are maintained because the persistent hypocapnia induces proximal tubule bicarbonaturia. Once a lower steady-state level of HCO_3^- is achieved, net renal acid excretion returns to baseline.

In identifying whether an acid-base disturbance is simple (a single disturbance with its compensation) or complex (multiple primary processes simultaneously present), it is useful to compare the expected compensation for a simple process with the observed parameters of the blood gases (see Table 104-3). For example, if P_{CO_2} is lower than would be predicted by the Winters equation in a patient with a simple, compensated metabolic acidosis, an additional coexistent primary respiratory alkalosis must be driving the P_{CO_2} down. If P_{CO_2} is higher than would be predicted for a low bicarbonate level in a patient with metabolic acidosis, a coexistent respiratory acidosis is present.

METABOLIC ACIDOSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

In metabolic acidosis, the primary change is a fall in serum bicarbonate.[5] The compensatory response is to increase ventilation to reduce P_{CO_2}. Worsening acidosis elicits increasing alveolar ventilation.

Primary metabolic acidosis results from an imbalance between net acid production and net acid excretion in the form of urinary ammonium excretion and acid phosphate excretion. Increased excretion of acid phosphate and other weak acids is called total titratable acidity when measured in the urine. Consider the following relationship, where U_x represents the urinary concentration and the urinary flow rate $\dot{V}$:

$$NAE = (U_{NH4} \times \dot{V}) + (U_{TAphos} \times \dot{V}) - (U_{HCO_3^-} \times \dot{V})$$

In a normal steady-state condition, the rate of excretion of net acid must be equal to the rate of production. The normal production rate depends on diet. If net acid production is normal, metabolic acidosis could occur because of a failure to reabsorb bicarbonate or a failure to secrete adequate net acid, as is the case in renal failure and renal tubular acidosis. An inequality also could develop if net acid production were excessive or if large extrarenal bicarbonate losses were unable to be matched by maximal adaptive increases in net acid excretion. Endogenous sources of acid include ketoacidosis and lactic acidosis, whereas exogenous sources might be acid metabolic products of ingested ethylene glycol or methanol. On occasion, strong inorganic acids may be ingested. When net acid is retained, the serum bicarbonate concentration falls. However, maintenance of a constant low serum HCO_3^- concentration does not guarantee that there is a new steady state in which net acid production is equal to net acid excretion because body buffers such as carbonate salts of bone may become progressively depleted by relentless acid retention, as in chronic kidney disease and distal renal tubular acidosis.

The causes of metabolic acidosis are usually categorized according to the presence of either hyperchloremia or an elevated serum anion gap. The serum anion gap is the net charge difference when the sum of chloride and bicarbonate is subtracted from the serum sodium concentration.

$$\text{Anion gap} = [Na^+] - ([Cl^-] + [HCO_3^-])$$

The normal anion gap is due to the net unmeasured anionic charge associated predominantly with albumin. When acidemia is present, albumin is in a more protonated form, which lowers the normal gap. In alkalemia, the effect of pH is to increase the gap attributed to albumin. Each 1 g/dL of albumin contributes approximately 2.5 mEq/L to the normal anion gap. The anion gap may be low with hypoalbuminemia or with an increase in unmeasured cations, such as immunoglobulin G myeloma paraproteins, calcium, lithium, or magnesium. The anion gap may be high in the presence of unmeasured anions, including sulfates, bromides, iodides, and immunoglobulin A myeloma light

chains. When the anion gap is increased above the normal value of 10 to 12 mEq/L by a non-chloride acid anion, an anion gap metabolic acidosis exists. The accompanying proton is responsible for lowering the serum bicarbonate concentration. The degree of increase in the anion gap, sometimes referred to as the *delta anion gap,* may be estimated by the difference between the observed anion gap and a normal value of 10 to 12 mEq/L. A similar calculation for a change in serum HCO_3^- can be made by subtracting the observed HCO_3^- from the normal value of about 25 mEq/L (the *delta* HCO_3^-). Comparison of the two values (the *delta-delta*) may help identify more complicated acid-base disorders. If the increase in the anion gap is larger than the decrease in serum HCO_3^-, an additional process is raising the HCO_3^- level. The patient may have a coexisting metabolic alkalosis or be compensating for chronic respiratory acidosis. If the decrease in serum HCO_3^- is larger than the increase in the anion gap, it is a sign of another process that raises the Cl^- while lowering the HCO_3^- level, such as an additional hyperchloremic acidosis or respiratory alkalosis. In most anion gap acidoses, the increase in anion gap and the decrease in HCO_3^- is not usually greater than 1 : 1 because the excretion of urinary anions with Na^+ results in a hyperchloremic component to the acidosis. (See Fig. 104-1 and its legend.) Conversely, any buffering of H^+ with non-HCO_3^- buffers will decrease the drop in HCO_3^- compared with the increase in anion gap. In severe cases of anion gap acidosis, Cl^- may be displaced into cells, thereby resulting in a higher anion gap compared with the decrease in HCO_3^-—a hypochloremic anion gap acidosis.

CLINICAL MANIFESTATIONS

The effects of metabolic acidosis depend on its rapidity of onset and severity. Patients often complain of fatigue, nausea, vomiting, shortness of breath, and dyspnea on exertion. Acutely, deep respirations, often labored with the use of accessory muscles, may be detected, but hyperventilation may be less notable with chronic metabolic acidemia. Metabolic acidemia also may be associated with vasodilation, tachycardia, and hypotension (Chapter 92). The negative inotropic effect of acidemia on the heart can exacerbate septic shock (Chapter 94). The stress of an underlying illness or an increase in adrenergic and corticosteroid activity associated with acidemia may elevate the peripheral white blood cell count and cause hyperglycemia. Other findings can include hyperkalemia (Chapter 103), hyperphosphatemia (Chapter 105), and hyperuricemia (Chapter 252) as well as hypocalcemia (Chapter 227) and markers of bone injury as a result of decreased renal synthesis of 1,25-dihydroxyvitamin D.

ANION GAP METABOLIC ACIDOSES

A variety of abnormalities can cause anion gap acidoses.[6] One mnemonic for the common ones is *gold mark,* for *g*lycols (ethylene and propylene), *o*xoproline, L-lactate, D-lactate, *m*ethanol, *a*spirin, *r*enal failure, and *k*etoacidosis. Because some causes are life-threatening, a rapid diagnosis is required. The osmolar gap should be calculated in all cases of anion gap acidosis (Table 104-5) because unmeasured toxic, nonionic alcohols will contribute to body osmolality but not to acidity. Although not acidic themselves, these alcohols oxidize to dangerous unmeasured organic acids with anions that contribute only to the anion gap. The osmolar gap is defined as the difference between the measured and the calculated serum osmolality. The serum osmolality should be measured by a freezing point depression technique and compared with the calculated osmolality.

$$\text{Calculated osmolality} = 2(Na^+) + (\text{Glucose [mg/dL]} \div 18) + (\text{Blood urea nitrogen [mg/dL]} \div 2.8)$$

UREMIC ACIDOSIS

The metabolic acidosis of advanced chronic kidney disease (Chapter 116) may be due to tubular leakage of HCO_3^-, but it is usually present when inadequate production of ammonium is unable to facilitate excretion of the normal metabolic acid load.[7] Because, of the low buffering capacity in the urine, many patients with renal failure maintain the ability to acidify their urine maximally. Many organic and inorganic anions, such as phosphate and sulfates, are retained at glomerular filtration rates of less than 25 mL/minute and constitute an increased anion gap in association with the metabolic acidosis. The magnitude of the gap is usually less than 20 mEq/L consisting of poorly filtered sulfates and phosphates and retention of anions that are suboptimally secreted. The renal patient who is maximally producing NH_3 to stay in balance with daily acid production may be unable to accommodate any further acid production, such as a metabolic or respiratory acidosis, that would require increased ammoniagenesis. The patient with poor glomerular filtration and an alkaline load will retain HCO_3^-, thereby worsening both metabolic and respiratory alkalosis. For example, metabolic alkalosis commonly occurs instead of urinary alkalinization when HCO_3^- is used in the attempt to alkalinize the urine in a patient with kidney failure. The systemic acid-base disturbance in renal diseases with prominent tubular dysfunction is attributable to the kidney's inability to secrete hydrogen and to reabsorb and generate HCO_3^-. It is particularly pronounced in oliguric acute kidney injury and is exacerbated by hypercatabolic states such as infection. A significant metabolic acidosis disproportionate to the severity of chronic kidney disease of unknown cause should raise the possibility of tubular dysfunction due to urinary tract obstruction or chronic tubulointerstitial diseases (Chapter 108), including amyloidosis (Chapter 174), myeloma (Chapter 173), autoimmune disorders (Chapter 236), and analgesic nephropathy (Chapter 108).

It is important to treat the metabolic acidosis of chronic kidney disease.[8] Maintaining the serum HCO_3^- concentration above 20 to 22 mEq/L, by administering $NaHCO_3$ at a rate of 1 mEq HCO_3^-/kg/day, will slow the progression of chronic kidney disease, delay end-stage renal failure, and improve nutritional status.

TABLE 104-5 CAUSES OF INCREASED ANION AND OSMOLAR GAPS

ANION GAP METABOLIC ACIDOSIS	OSMOLAR GAP
Uremia	No
Lactic acidosis	Variable/no
D-Lactic acidosis	No
Diabetic ketoacidosis	No
Starvation ketoacidosis	No
Alcoholic ketoacidosis	If ethanol is present
Ethylene glycol	Yes
Methanol	Yes
Salicylates	No
5-Oxoprolinuria (acetaminophen)	No

PROGNOSIS

In population studies, a low serum bicarbonate level is associated with higher all-cause mortality. The relative risk of death is about 2.6-fold higher in patients with chronic kidney disease and about 1.7-fold higher even without it.

OVERPRODUCTION OF ENDOGENOUS ACIDS

Lactic Acidosis

EPIDEMIOLOGY AND PATHOBIOLOGY

Overproduction of lactic acid may occur with severe exertion, but true lactic acidosis (lactate level >4 mmol/L or >36 mg/dL) is frequently associated with critical illness, multiorgan failure, and increased mortality. Lactic acid, which is the final product in the anaerobic pathway of glucose metabolism, is produced from pyruvate in a reaction catalyzed by lactate dehydrogenase:

$$NADH + \text{pyruvate} + H^+ \rightarrow \text{lactate} + NAD^+$$

A high reduced nicotinamide adenine dinucleotide (NADH)/NAD ratio will favor the formation of lactate. Conversion of ethanol to acetaldehyde and conversion of β-hydroxybutyrate to acetoacetate use NAD and produce NADH. Alcohol metabolism may be associated with excessive β-hydroxybutyrate and lactic acidosis.

Lactic acidosis is caused by an imbalance in the rates of lactate production and its clearance, primarily in the liver. Lactic acidosis, which increases the anion gap, is most often due to circulatory failure, hypoxia, sepsis, and mitochondrial dysfunction that each increase anaerobic glycolysis and the rate of conversion of pyruvate to lactate (Table 104-6).[9] Sepsis (Chapter 94) is associated with an elevated lactate level because of poor clearance and impaired gluconeogenesis.[10] Lactic acidosis can also result from seizure activity (Chapter 372) when lactate is released from muscle cells that have sustained a period of anaerobic metabolism. Other causes include thiamine deficiency (Chapter 199), hypophosphatemia (Chapter 105), isoniazid toxicity (Chapter 96), and hypoglycemic states (Chapter 211). Metformin may cause lactic acidosis, particularly in elderly patients with cardiac, hepatic, or renal dysfunction.

TABLE 104-6 CAUSES OF LACTIC ACIDOSIS

Shock (Chapter 92): septic (Chapter 94), cardiogenic (Chapter 93), or hypovolemic
Advanced heart failure (Chapters 45 and 46)
Severe trauma (Chapter 97)
Severe hypoxemia (Chapter 90) with Pao_2 <30 mm Hg
Carbon monoxide poisoning (Chapter 82)
Severe anemia (Chapter 144) with hemoglobin level <5 g/dL
Vigorous exercise, seizures (Chapter 372), or shivering (Chapter 95)
Diabetes mellitus (Chapter 210), usually in association with ketoacidosis
Cancer (especially lymphomas [Chapters 171 and 172], leukemias [Chapters 168,169 and 170], and solid tumors)
Liver disease with decreased lactate clearance (Chapter 140)
High plasma metformin levels
Nucleoside reverse-transcriptase inhibitors
Cocaine (Chapter 365)
Toxic alcohols, methanol, ethylene glycol, diethylene glycol (Chapter 96)
Propylene glycol (Chapter 96)
Salicylates (Chapter 70)
Cyanide (Chapter 96)
β_2-Agonists (Chapter 75)
Propofol (after prolonged high-dose infusion; Chapter 400)
Thiamine deficiency in children or adults receiving parenteral nutrition or those with fulminant beriberi (Chapters 198 and 199)

Adapted from Kraut JA, Madias NE. Lactic acidosis. *N Engl J Med*. 2014;371:2309-2319.

Nucleoside antivirals (Chapter 357), including zidovudine, may cause lactic acidosis and abnormal liver function as a result of toxic mitochondrial effects. Abnormal mitochondrial function is also a feature of aspirin overdose (Chapter 70) or toxicity with hypoglycin from ingestion of the unripe ackee fruit (Jamaican vomiting sickness). The antibiotic linezolid is another cause of lactic acidosis.

Lactic acidosis also can be caused by the overproduction of the acid, which may occur with severe exertion and malignant neoplasms, particularly with a large tumor burden from lymphoma or widely metastatic cancer. Malignant cells can upregulate glycolytic activity, which may increase their uptake of glucose and decrease their dependence on mitochondrion-derived energy. These tumors can use large amounts of available glucose and inorganic phosphate, thereby leading to a syndrome of hypoglycemia, hypophosphatemia, and lactic acidosis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Lactic acidosis typically presents with a blood pH of 7.35 or lower and a serum HCO_3^- 20 mEq/L or lower. To make the diagnosis, however, the serum lactate level should be directly measured in any patient with an anion gap acidosis. Glucose, creatinine, and blood urea nitrogen levels also should be obtained. In cases in which a toxic ingestion is suspected (see Table 104-5), a screen for such toxins in the serum should be performed.

TREATMENT

Treatment of lactic acidosis is aimed at correction of the underlying cause. Central venous oxygen saturation should be increased, with a goal of at least 70%, by restoring tissue perfusion and ventilation. In general, the mean arterial pressure should be maintained at 65 to 70 mm Hg, the heart rate below 100 beats/minute, and the hemoglobin level over 7 g/dL.

Sodium bicarbonate can be considered when the arterial pH is below 7.0 or when acidemia has resulted in decreased cardiac inotropy or systemic vasodilation and shock. It is preferable to give $NaHCO_3$ as an isotonic mixture in 5% dextrose and water rather than as a hypertonic bolus, because the latter carries the risk of pulmonary edema and hypernatremia. The quantity of administered sodium bicarbonate to raise arterial pH to 7.2 should be estimated by multiplying the desired bicarbonate concentration minus the observed bicarbonate concentration by 50% of body weight. The calculated amount in patients with severe acidosis may require continuous dialytic methods to administer adequate amounts of bicarbonate without causing volume overload. Full correction should be avoided.

In patients with a metabolic acidosis after seizures (Chapter 372), the lactate is quickly metabolized to HCO_3^- by the liver and kidneys, and the acidosis often resolves within 60 minutes. The administration of HCO_3^- is usually unnecessary and may precipitate an overshoot metabolic alkalosis as the lactate is metabolized, which lowers the seizure threshold.

In patients with intestinal bacterial overgrowth (Chapter 126), a syndrome of disorientation, ataxia, and anion gap metabolic acidosis may develop after a carbohydrate meal because of bacterial production of D-lactate. This isomer of the mammalian L-lactate can be measured only by a specific D-lactate assay. The condition is treated with oral antibiotics and appropriate diet.

PROGNOSIS

Lactic acidosis, when severe, is associated with a high early mortality. When the pH is less than 7.2, only 17% of patients who are admitted to an intensive care unit are ultimately discharged from the hospital.

Diabetic Ketoacidosis

EPIDEMIOLOGY AND PATHOBIOLOGY

Diabetic ketoacidosis is defined as hyperglycemia with metabolic acidosis resulting from generation of the acids of the anions β-hydroxybutyrate (a hydroxy acid) and acetoacetate (a ketoacid) in response to insulin deficiency and elevated counter-regulatory hormones such as glucagon.[11] It is most commonly seen in cases of type 1 diabetes mellitus but can occasionally be seen in type 2 diabetes mellitus (Chapter 210). Diabetic ketoacidosis is more common in vulnerable populations with less access to quality medical care.

The lack of insulin increases lipolysis in adipose tissue; free fatty acids are transported to the liver, where hepatic mitochondria produce ketoacid anions, including acetoacetate, from acetyl coenzyme A. In the presence of high NADH/NAD ratio, the more reduced form of β-hydroxybutyrate is produced.

CLINICAL MANIFESTATIONS

Symptoms include nausea, vomiting, anorexia, polydipsia, and polyuria. Patients often exhibit Kussmaul respirations and volume depletion. Neurologic symptoms include fatigue and lethargy with depression of the sensorium. CSF exhibits a change in acid-base status with treatment of diabetic ketoacidosis. Even without bicarbonate administration, CSF pH falls as a result of the ventilatory response to the correction of acidosis and the sudden rise in Pco_2. However, no correlation between decreased CSF pH and depression of sensorium has been established. Ketoacidosis is also seen in cases of starvation, in which it is generally mild and not associated with hyperglycemia.

Ketoacid anions in the urine may be accompanied by cations, including sodium and potassium, thereby contributing to an osmotic diuresis with depletion of volume and potassium. The overall electrolyte status in diabetic ketoacidosis may be relative chloride retention, a mixed anion gap, and hyperchloremic acidosis. The delta HCO_3^- may exceed the delta anion gap, especially if the glomerular filtration rate and the filtered load of ketoacid anions are high, thereby facilitating their excretion with sodium and potassium. The serum anion gap in general will be greatest when renal failure is present because the additional anions cannot be cleared from extracellular fluid.

DIAGNOSIS

The urinary dipstick nitroprusside test for ketones may underestimate the degree of ketosis because it does not detect β-hydroxybutyrate; in fact, the ketone test result may become more positive as treatment helps metabolize β-hydroxybutyrate to acetoacetate. This problem should be addressed by direct measurement of serum β-hydroxybutyrate. Diabetic patients also are more prone to lactic acidosis because an increase in NADH favors the formation of lactate from pyruvate, and pyruvate dehydrogenase is inhibited in the absence of insulin.

TREATMENT

Treatment of diabetic ketoacidosis (Chapter 210) consists of volume repletion, insulin administration with dextrose if necessary to avoid hypoglycemia, and potassium replacement (Chapter 103). Bicarbonate administration should be considered only if ketoacidosis is accompanied by shock or if arterial pH is less than 7.0 or 7.1, and bolus infusion should be avoided. The administration of bicarbonate occasionally results in cerebral edema significant enough to lead to loss of consciousness and even death.

PROGNOSIS

Most patients with diabetic ketoacidosis recover. In the less than 0.5% of patients who present with coma from cerebral edema, the mortality rate ranges from 20% to as high as 90%. The cerebral edema may be exacerbated by bicarbonate administration, which is discouraged in this situation.

Salicylate Intoxication

EPIDEMIOLOGY AND PATHOBIOLOGY

Salicylate intoxication can be caused by accidental overdose, therapeutic overdose, or a suicide attempt (Chapters 70 and 96).[12] Salicylate functions as an

uncoupler of oxidative phosphorylation and consequently results in increased oxygen consumption and production of CO_2, as well as production of mixed organic acid, thereby causing an anion gap metabolic acidosis. However, the increase in alveolar ventilation resulting from stimulation of central chemoreceptors overcomes this increase in CO_2.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common clinical manifestation is a combined anion gap metabolic acidosis and respiratory alkalosis, although the condition also can be manifested as either one or the other only. Children are often seen with metabolic acidosis, whereas adults often have predominant respiratory alkalosis. Hypoglycemia, ketoacidosis, and lactic acidosis may result. Other manifestations of intoxication include hemorrhage, fever, nausea and vomiting, hyperventilation, diaphoresis, tinnitus, and occasionally polyuria followed by oliguria. Severe cases may lead to seizures, respiratory depression, and coma. Noncardiogenic pulmonary edema is sometimes seen in adults.

Respiratory alkalosis is the result of a direct stimulatory effect of salicylate on the medullary respiratory control center. Salicylate intoxication also increases the metabolic rate. Diagnosis is suspected by the clinical presentation and confirmed by the salicylate level (Chapters 70 and 96).

Treatment of salicylate intoxication (Chapter 96) is aimed at correction of the metabolic acidosis and removal of salicylate. Bicarbonate as a sodium salt should be administered according to an estimated calculation of the deficit if metabolic acidosis predominates. Salicylates are removed by alkaline diuresis because the less reabsorbable salicylate anion will predominate when the urine pH increases. Urinary alkalinization with acetazolamide should be used cautiously because carbonic anhydrase inhibition may impair CO_2 transport from tissue to blood and potentially worsen acidosis in the respiratory center. In severe intoxication (salicylate concentrations greater than 35 80 mg/dL) or when renal failure is present, dialysis may be required.

PROGNOSIS

The prognosis of salicylate toxicity is better with early diagnosis and prompt management, in which case most patients do well. Patients who ingest oil of wintergreen (methyl salicylate) may have more severe deterioration because of the high lipid solubility of the drug.

Alcoholic Ketoacidosis

EPIDEMIOLOGY AND PATHOBIOLOGY

Alcoholic ketoacidosis occurs in a patient who has been drinking very heavily without eating.[13] The pathophysiologic mechanism is based on the overproduction of the acids of β-hydroxybutyrate and, to a lesser extent, acetoacetate because of an increased production of free fatty acids from adipose tissue. Alcohol inhibits the conversion of lactate to glucose in the liver. The oxidation of ethanol increases the ratio of NADH to NAD^+ and favors the production of β-hydroxybutyrate from acetoacetate. Damage to mitochondria by alcohol can further elevate the ratio of β-hydroxybutyrate to acetoacetate by preventing reoxidation of NADH to NAD. The oxidative metabolism of ethanol favors the reaction of dehydrogenase enzymes to form β-hydroxybutyrate and lactate (opposing glucose production).

CLINICAL MANIFESTATIONS

Alcoholic ketoacidosis usually follows binge drinking and may be associated with withdrawal symptoms (Chapters 364 and 384) and the associated hyperadrenergic state. Alcoholic ketoacidosis is associated with abdominal pain, vomiting, starvation, and volume depletion. In contrast to diabetic ketoacidosis, coma is rare. Blood glucose levels are generally low or normal, and the insulin level is frequently low, with elevated glucagon (favoring ketogenesis) and cortisol levels. Some patients have hyperglycemia because of the increased catecholamine response.

DIAGNOSIS

Initially, patients typically have a high osmolar gap from ethanol or acetone. When serum alcohol or acetone levels become zero, the osmolar gap should disappear. A clue to the diagnosis of toxic alcohol ingestion is the simultaneous presence of an anion gap metabolic acidosis and an osmolar gap. The osmolar gap, if due to ethanol, should equal the ethanol concentration in milligrams per deciliter divided by 4.6. If this calculation does not yield the expected gap based on the ethanol level, ingestion of another alcohol, such as methanol, isopropanol, or ethylene glycol, should be suspected (see Table 104-2).

If possible, ethanol, ethylene glycol, propylene glycol, and methanol levels should be measured directly; each is associated with a metabolic acidosis. In contrast, isopropanol metabolizes to acetone and causes ketosis without acidosis. An osmolar gap may be present.

TREATMENT

Treatment of alcoholic metabolic acidosis consists of volume repletion with normal saline in dextrose; administration of thiamine (50 to 100 mg); treatment of hypoglycemia; and the correction of any hypophosphatemia (Chapter 105), hypokalemia (Chapter 103), and hypomagnesemia (Chapter 105) that may be present. The acid-base disturbance usually resolves after several hours. Both hypophosphatemia and thiamine deficiency, which may not be apparent until 12 to 24 hours after the initiation of treatment in an undernourished patient, are exacerbated by glucose administration and may contribute to an associated lactic acidosis.

PROGNOSIS

The prognosis of alcoholic ketoacidosis is usually favorable. The long-term outlook is more closely tied to other complications of continued alcohol abuse.

5-Oxoprolinuria

5-Oxoprolinuria, which is an acquired form of anion gap metabolic acidosis, is increasingly recognized in patients who have glutathione depletion associated with underlying chronic illness, malnutrition, diabetes, alcoholism, or cancer, especially in the context of a high therapeutic level or overdose of acetaminophen. It has been observed without concomitant hepatic failure. Glutathione, which is a tripeptide consisting of glutamate, cysteine, and glycine, has many functions, including protection from cellular toxins, combating of oxidative stress, and shuttling of amino acids into the cytosol by the γ-glutamyl transpeptidase pathway. Hereditary forms of 5-oxoprolinuria are associated with γ-glutamyl transpeptidase cycle enzyme deficiencies (5-oxoprolinase and glutathione synthase). The usual production of 5-oxoproline is by release of the transported amino acid from the γ-glutamyl–amino acid dipeptide. The enzyme 5-oxoprolinase re-forms glutamate to re-enter the cycle as glutamylcysteine. Acetaminophen causes further depletion of glutathione due to binding of an acetaminophen metabolite, *N*-acetyl-*p*-benzoquinone imine (NAPQI), to glutathione. Treatment with *N*-acetylcysteine, in doses similar to those used for acetaminophen toxicity (Chapter 96), should be considered to decrease further glutathione depletion.

Poisonings

A variety of acute poisonings (Chapter 96) can present as an anion gap acidosis.[14]

Ethylene Glycol

Ethylene glycol (Chapter 96) is commonly found in antifreeze and is used as an industrial solvent. It has a sweet taste, and patients occasionally ingest it as a substitute for ethanol. Although ethylene glycol itself is not particularly damaging, its highly toxic metabolites include the acids of glyoxylate and glycolate, oxalic acid, and ketoaldehydes. Glycolic acid appears to be primarily responsible for the metabolic acidosis observed in this condition. Further, glycolic acid may register as lactic acid in point-of-care measurements of whole blood by the lactic oxidase method, producing an artifactual high lactate level. However if an assay of lactate is performed in the laboratory by lactate dehydrogenase, the true lactate will be significantly less than the value from the lactic acid oxidase method. The difference between these two values, known as the lactate gap, represents glycolic acid.

Intoxication is characterized by profound CNS symptoms, including diplopia, seizures and coma, severe metabolic acidosis, cardiac failure, pulmonary failure, and renal failure. Patients are often dehydrated and hypernatremic because of osmotic diuresis from the renal excretion of the alcohol.

An increased anion gap is attributable to ethylene glycol metabolites. A high osmolar gap also will be present because of the uncharged alcohol. However, an osmolar gap may not be present if all of the alcohol has been converted to the toxic anionic forms. Calcium oxalate crystals in the urine may cause intratubular obstruction and inflammation with acute kidney injury. Treatment is aimed at rehydration with saline and correction of acidosis with $NaHCO_3$ based on an estimate of the bicarbonate deficit. When an osmolar gap exists, competitive inhibition of alcohol dehydrogenase should be initiated with fomepizole at a loading dose of 15 to 20 mg/kg intravenously in 100 mL normal saline

during 30 minutes to 1 hour, followed by a maintenance dose of 10 mg/kg every 12 hours (Chapter 96). If ethanol is used, a solution of 10% ethanol in 5% dextrose can be given as a loading dose of 0.6 g/kg intravenously followed by a maintenance dose of 150 mg/kg per hour in alcoholic patients or 65 mg/kg per hour in nonalcoholic patients. The ethanol level should be maintained at 100 to 200 mg/dL. The goal of therapy is early recognition to prevent metabolism of the uncharged glycol to acidic products. Hemodialysis is required in severe cases. If the diagnosis is made promptly and appropriate therapy is instituted, outcomes are favorable. Renal failure may be reversible.

Methanol

Methanol, wood alcohol, is a component of shellac and windshield wiper fluid and is highly toxic to the CNS after metabolism to formaldehyde and formic acid. Some automotive fluids now contain the less toxic propylene glycol. Optic papillitis may cause blindness. Detection may be made easier if fluorescein has been added to the methanol-containing fluid.

Treatment consists of competitive inhibitors for alcohol dehydrogenase, including ethanol and fomepizole, in similar amounts as for ethylene glycol poisoning, to reduce the formation of acid anions and the anion gap while maintaining a higher level of methanol in the blood (Chapter 96). Hemodialysis may be necessary to increase elimination. Early diagnosis and treatment are associated with a favorable outcome, but visual loss may be permanent. Late presentation is associated with a poor prognosis, particularly if the amount consumed exceeds 30 mL. As with ethylene glycol, the simultaneous presence of ethanol on presentation may help slow the metabolism of methanol and improve outcome.

Isopropyl Alcohol

Toxic ingestion of isopropyl alcohol (Chapter 96), as in rubbing alcohol, does not cause an increased anion gap or ketoacidosis because the metabolite is acetone, but test results for ketones are positive, and a high osmolal gap will be present.

Propylene Glycol

On occasion, patients in the intensive care unit setting are given high doses of intravenous benzodiazepines, such as lorazepam or diazepam, that contain propylene glycol as a diluent. Other intravenous medications that also contain this diluent include phenobarbital, phenytoin, nitroglycerine, and esmolol. Propylene glycol also has been used as a less toxic substitute for methanol in windshield wiper fluid. A high osmolal gap may develop because of the propylene glycol and lead to a clinical picture of sedation, failure to be weaned from the respirator, and an increased lactate level. Propylene glycol can cause a severe lactic acidosis, and patients with this disorder can have a massive osmotic diuresis. Propylene glycol, a 3-carbon glycol, oxidizes to the acids of lactate and pyruvate. Treatment, which consists of early recognition and withdrawal of the offending agent, usually results in a favorable prognosis.

HYPERCHLOREMIC (NORMAL ANION GAP) ACIDOSIS

Hyperchloremic metabolic acidoses (see Table 104-1) can be caused by renal or nonrenal mechanisms and can be associated with an elevated, normal, or low serum potassium level (Fig. 104-2).

HYPERCHLOREMIC METABOLIC ACIDOSIS OF NONRENAL ORIGIN ASSOCIATED WITH NORMAL OR INCREASED POTASSIUM LEVEL

Hyperchloremic metabolic acidoses with a normal or elevated potassium concentration can develop with the administration of chloride salts such as NaCl, KCl, $CaCl_2$, NH_4Cl, arginine and lysine hydrochlorides, or HCl itself. If the quantity of Cl^- introduced exceeds the ability of the kidney to eliminate Cl^- salts in urine, hyperchloremia will develop. Electroneutrality is maintained by a decrease in the serum HCO_3^- concentration, and a hyperchloremic acidosis ensues. Renal production of NH_3 increases in an attempt to improve HCl (NH_4Cl) excretion. Hyperkalemia can occur because the acidemia favors the exit of K^+ from cells. Acidemia also inhibits K^+ secretion in the renal collecting duct.

HYPERCHLOREMIC METABOLIC ACIDOSIS OF NONRENAL ORIGIN ASSOCIATED WITH HYPOKALEMIA

Hypokalemic, hyperchloremic acidosis may result from loss of a body fluid that is low in Cl^- relative to Na^+ and K^+ compared with the ratio of Cl^- to Na^+ in extracellular fluid. For example, stool losses of Na^+, K^+, and HCO_3^- in small bowel diarrhea or organic acid anions of bacterial origin, such as butyrate, in colonic diarrhea lead to hyperchloremic acidosis (Chapter 126). Pancreatic secretions (Chapter 213) or heavy losses from ileostomy sites may lead to loss of bicarbonate-containing fluids. Secretagogues such as vasoactive intestinal peptide (VIP), which is associated with neoplasms of the pancreas or sympathetic chain (Chapter 213), cause large losses of HCO_3^- in stool, with a resulting hypokalemic, hyperchloremic metabolic acidosis. Concomitant gastric achlorhydria is part of the syndrome known as *watery diarrhea, hypokalemic, hypochlorhydric acidosis*. Urinary diversions, such as ureterosigmoidostomies and ileal loops, may increase chloride absorption in exchange for bicarbonate in the intestinal segment and lead to hyperchloremic acidosis. In the presence of urea-splitting bacteria, the net absorption of NH_4Cl can result in both hyperchloremic acidosis and hyperammonemia.

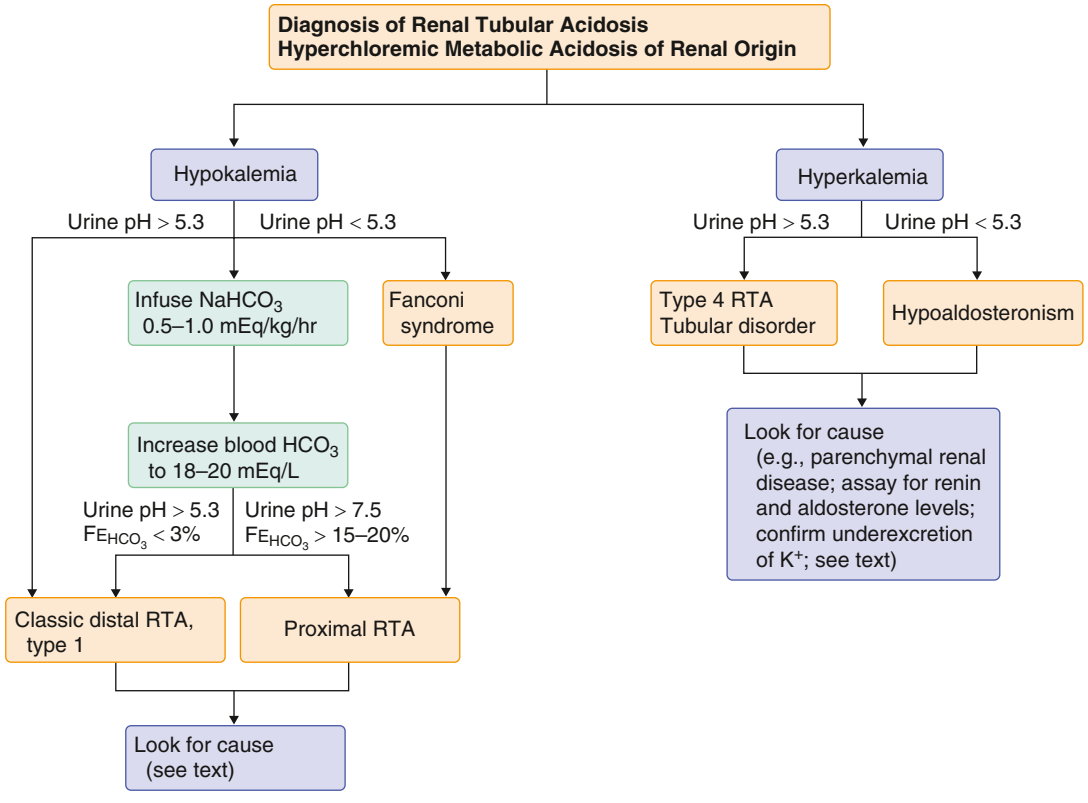

FIGURE 104-2. Evaluation of the patient with suspected renal tubular acidosis, hyperchloremic metabolic acidosis of renal origin. $FeHCO_3$ = fractional excretion of HCO_3^-; RTA = renal tubular acidosis.

RENAL TUBULAR ACIDOSIS TYPES 1 AND 2

Proximal Renal Tubular Acidosis

Renal tubular acidosis causes the cations Na^+ and K^+ to be lost in the urine with HCO_3^- rather than with Cl^-, thereby leading to hyperchloremia.[15] Proximal renal tubular acidosis (type 2) is characterized by a decreased threshold for bicarbonate reabsorption. HCO_3^- wasting and concomitant urinary losses of potassium occur until a lower level of serum bicarbonate reduces the filtered HCO_3^- to a level that the combined function of the dysfunctional proximal tubule and distal nephron can completely reabsorb. At that point, the urine becomes acid (pH < 5.3), and net acid production equals net acid excretion, with a steady-state low plasma HCO_3^-.

Isolated proximal renal tubular acidosis may result from mutations of specific transporters of the proximal tubule, such as the $NaHCO_3$ cotransporter, or from hereditary deficiency of carbonic anhydrase. More commonly, proximal renal tubular acidosis is associated with the Fanconi syndrome or generalized proximal tubule dysfunction. Causes (Table 104-7) include genetic diseases such as glucose-6-phosphatase deficiency (Chapter 147), cystinosis (Chapter 113), hereditary fructose intolerance (Chapter 189), and Wilson disease (Chapter 195). Multiple myeloma (Chapter 173) and Sjögren syndrome (Chapter 247) should be considered in an adult patient. Primary hyperparathyroidism (Chapter 227) results in proximal renal tubular acidosis and hypophosphatemia secondary to inhibition of Na^+/H^+ exchange and sodium phosphate cotransport in the proximal tubule by parathyroid hormone through cyclic adenosine monophosphate. Hyperparathyroidism is one of the few causes of metabolic acidosis with hypercalcemia. The Cl^-/phosphate ratio in plasma may be elevated. Drug toxicity with aminoglycosides, cisplatin, and ifosfamide may cause proximal tubule dysfunction. The antiretroviral drug tenofovir, a nucleotide analogue reverse transcriptase inhibitor, is a cause of the Fanconi syndrome. The syndrome also may be seen after kidney transplantation (Chapter 117).

Distal Renal Tubular Acidosis

In distal renal tubular acidosis (type 1), failure to excrete ammonium leads to an inability to excrete adequate net acid, thereby leading to continuous retention of acid in the body. The degree of acidemia is often severe, with pH reaching values as low as 7.2, whereas urine pH usually exceeds 5.3.[16]

Kindreds have been described in which mutations in genes for the distal vacuolar H^+-ATPase cause an autosomal recessive distal renal tubular acidosis with deafness. Mutations resulting in defective Cl^-/HCO_3^- exchange protein (AE1) have been linked to an autosomal dominant form of distal renal tubular acidosis.[17]

Distal renal tubular acidosis (see Table 104-7) is also associated with autoimmune disorders, including systemic lupus erythematosus (Chapter 245) and Sjögren syndrome (Chapter 247), and genetic diseases, including sickle cell anemia (Chapter 149), Wilson disease (Chapter 195), Fabry disease (Chapter 192), cystic kidney diseases (Chapter 112), and hereditary elliptocytosis (Chapter 147). Hypercalciuria and hyperoxaluria may cause distal renal tubular acidosis; nephrocalcinosis and nephrolithiasis may be present. Increased proximal tubular citrate reabsorption, as a consequence of the chronic acidosis, also leads to hypocitraturia, which is a risk factor for calcium nephrolithiasis (Chapter 111). A chronically alkaline urine is a risk for pure $CaHPO_4$ brushite stones and other calcium phosphate mixtures. Amyloidosis (Chapter 174) may be manifested as severe acidemia and other tubular dysfunction, including nephrogenic diabetes insipidus. Chronic tubulointerstitial diseases of the kidney (Chapter 108), including reflux nephropathy (Chapter 113) and urinary obstruction, may result in renal tubular acidosis with hypokalemia or hyperkalemia. Acute tubulointerstitial nephritis also may result in renal tubular acidosis. Drugs such as amphotericin B can cause hypokalemic distal renal tubular acidosis. Topiramate, used for migraines, is a carbonic anhydrase inhibitor that may cause mixed proximal and distal renal tubular acidosis.

HYPERCHLOREMIC METABOLIC ACIDOSIS OF RENAL ORIGIN ASSOCIATED WITH HYPERKALEMIA

Hyperkalemic, hyperchloremic acidosis (type 4) suggests dysfunction of the cortical collecting duct, where acidification of urine and disorders in potassium secretion may occur. Some patients with high blood potassium and hyperchloremic acidosis can lower urinary pH below 5.3, whereas others appear to have defects in both potassium balance and urinary acidification. Hyperkalemia itself may worsen metabolic acidosis by decreasing NH_3 accumulation by countercurrent multiplication in the medullary interstitium.

Causes include hyporenin-hypoaldosteronism, as seen in diabetic renal disease (Chapter 109); other tubulointerstitial diseases (Chapter 108), usually with some renal impairment; sickle cell anemia (Chapter 149); and the use of drugs such as β-blockers and nonsteroidal anti-inflammatory drugs. Low renin and aldosterone levels also can be found in cases of volume expansion with hypertension. Cyclosporine and tacrolimus may lead to decreased electrical driving forces for K^+ and H^+ secretion. Hyperkalemic acidosis with elevated renin and low aldosterone is found in adrenal insufficiency (Chapter 208), in isolated hypoaldosteronism (Chapter 208), and with the use of angiotensin-converting enzyme inhibitors, renin inhibitors, and angiotensin II receptor blockers. High renin and aldosterone levels are anticipated when the renal collecting duct cell is insensitive to aldosterone, as in urinary tract obstruction, sickle cell anemia, amyloidosis, and systemic lupus erythematosus. Inhibition of aldosterone action with spironolactone or eplerenone may cause hyperkalemic acidosis, as does ENaC inhibition by amiloride, triamterene, trimethoprim, and lithium.

Autosomal recessive pseudohypoaldosteronism type 1 is due to inactivating mutations of the sodium channel ENaC, whereas autosomal dominant pseudohypoaldosteronism type 1 is due to mutations of the mineralocorticoid receptor. Both cause hypovolemia, metabolic acidosis, and hyperkalemia with secondary increases in renin and aldosterone. In Gordon syndrome

TABLE 104-7 CAUSES OF RENAL TUBULAR ACIDOSIS*

HYPOKALEMIC DISTAL (TYPE 1) RTA
Hereditary tubule disorders
Vacuolar H^+-ATPase β-subunit gene mutations
Carbonic anhydrase type II deficiency
Cl^-/HCO_3^- exchanger (AE1) mutations
Genetic causes
Sickle cell anemia
Fabry disease
Wilson disease
Elliptocytosis
Paroxysmal nocturnal hemoglobinuria
Medullary cystic kidneys
Autoimmune disorders
Systemic lupus erythematosus
Sjögren syndrome
Multiple myeloma and amyloidosis
Drugs: amphotericin, cisplatinum, aminoglycosides
Nephrocalcinosis and hypercalcemic disorders
Tubulointerstitial diseases
Acute tubulointerstitial nephritis
Reflux nephropathy
Analgesic nephropathy
PROXIMAL (TYPE 2) RTA
Hereditary tubule disorders
$NaHCO_3$ cotransport (NBC) mutations
Carbonic anhydrase deficiency
Generalized proximal tubular dysfunction
Hereditary Fanconi syndrome
Genetic diseases: cystinosis, glycogen storage disease (glucose-6-phosphatase deficiency), Wilson disease
Hormonal: hyperparathyroidism, vitamin D deficiency
Multiple myeloma
Lysozymuria
Sjögren syndrome
Renal transplantation
Heavy metals: cobalt, mercury, lead
Drugs: ifosfamide, outdated tetracycline, tenofovir, tacrolimus, aminoglycosides
HYPERKALEMIC (TYPE 4) RTA
Renal diseases—aldosterone resistance
Diabetes mellitus
Amyloidosis
Systemic lupus erythematosus
Urinary tract obstruction
Hyporeninism
Autonomic neuropathy (diabetic)
Sickle cell anemia
Primary hypoaldosteronism
Adrenal insufficiency: Addison disease
Genetic disorders: pseudohypoaldosteronism
Drugs: potassium-sparing diuretics, amiloride, triamterene, spironolactone, nonsteroidal anti-inflammatory drugs, lithium, trimethoprim, cyclosporine, tacrolimus, renin inhibitors, angiotensin-converting enzyme inhibitors, angiotensin II receptor antagonists

*Type 3 renal tubular acidosis (RTA) is not listed separately because it is an overlap of proximal and distal dysfunction. Pure aldosterone deficiency will decrease the secretion of H^+ and K^+, thereby causing hyperkalemic acidosis. Also, renal diseases involving tubular cells may result in decreased urinary secretion of acid and potassium.

(pseudohypoaldosteronism type 2), increases in Na^+ and Cl^- reabsorption through increased activity of the distal thiazide-sensitive NaCl transporter lead to hypertension, hyperkalemic acidosis, volume expansion, and consequently low renin and aldosterone.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The urinary anion, or charge, gap helps distinguish renal tubular acidosis from extrarenal bicarbonate loss (e.g., from diarrhea).[18] Because the normal renal response to metabolic acidosis is an increase in ammoniagenesis, the urine should contain large amounts of NH_4Cl while the kidney retains sodium and potassium; the urinary charge gap, which is $(Na^+ + K^+) - Cl^-$, should be strongly negative because of the unmeasured NH_4^+.

In renal diseases such as distal renal tubular acidosis, however, the urinary anion gap will be zero or positive because of either inadequate excretion of ammonium or the excretion of sodium plus potassium with bicarbonate. With type 2 (proximal) renal tubular acidosis, patients often have Fanconi syndrome with glycosuria, phosphaturia, aminoaciduria, and uricosuria. In proximal renal tubular acidosis, the steady-state urine pH is usually less than 5.3, the acidosis is not severe (i.e., HCO_3^- usually not less than 16), and acid excretion may balance acid production at this new steady state.

In contrast to proximal renal tubular acidosis, distal renal tubular acidosis (type 1) is generally a more severe metabolic disorder that may be accompanied by hypercalciuria, nephrocalcinosis, calcium phosphate kidney stones (Chapter 111), and bone disease that includes rickets in children and osteomalacia in adults. Proximal and distal renal tubular acidoses usually can be distinguished by a careful clinical evaluation (see Fig. 104-2). Helpful findings include the presence of a urine pH greater than 5.3 in distal but not in proximal renal tubular acidosis during acidemia; a fractional excretion of bicarbonate as high as 10 to 15% in proximal renal tubular acidosis treated with alkali supplementation; and the lowering of serum potassium on correction of proximal but not of distal tubular acidosis.

In patients with an elevated serum anion gap, unmeasured anions such as keto acids and lactate, rather than NH_4^+, are present in urine, so a positive urinary anion gap does not indicate renal tubular acidosis. On occasion, the prompt renal excretion of organic anions with sodium and potassium may minimize the increase in the serum anion gap. In the metabolic acidosis of glue sniffers, hippurate, which is a product of toluene, is rapidly excreted, thus giving the appearance of a nongap metabolic acidosis with a positive urinary anion gap and mimicking a renal tubular acidosis. Similarly, if keto acids are completely cleared into the urine, ketoacidosis may be manifested as a hyperchloremic acidosis rather than as an anion gap acidosis.

TREATMENT

If possible, treatment of metabolic acidosis should focus on correction of the underlying cause, such as discontinuation of an offending drug, permitting the body's homeostatic mechanisms to correct the acid-base disturbance.[19]

Patients whose pH is less than 7.2 are typically treated with infusions of sodium bicarbonate,[20] guided by the estimated base deficit in milliequivalents, calculated by the serum HCO_3^- concentration in milliequivalents per liter:

$$\text{Amount of } HCO_3^- = (25 - [HCO_3^-]) \times \text{wt (kg)}/2$$

Such treatment appears to be especially beneficial in patients with acute kidney injury.[A1] In general, the correction of metabolic acidemia should be based on a calculated amount, with not more than 50% of the estimate given before recalculation. Moreover, this equation is used for deficit correction only; the ongoing losses of 1 to 2 mEq/kg per day, equivalent to the daily acid load, should be replaced in distal renal tubular acidosis with $NaHCO_3$ or $KHCO_3$, (depending on whether the patient has hypokalemia or hyperkalemia). Citrate salts (e.g., potassium citrate 60 to 90 mEq/day in divided doses) may be used to achieve a goal serum bicarbonate level of 22 to 24 mEq/L. Hypokalemia may accompany distal renal tubular acidosis and may improve with treatment. Citrate should be avoided as an alkalinizing salt in patients with low glomerular filtration rates because it may increase the gastrointestinal absorption of aluminum.

Proximal renal tubular acidosis in children may affect growth and require large quantities of bicarbonate in excess of 1 to 2 mEq/kg per day to correct the acidosis because ingested alkali is promptly excreted in alkaline urine. In adults, treatment is often deferred because the steady-state acidosis allows a normal acid excretion rate. Hypokalemia may worsen with bicarbonate treatment of proximal tubular acidosis.

In type 4 renal tubular acidosis, treatment of hyperkalemia with a low-potassium diet, thiazide or loop diuretics, or potassium-binding resins often improves urinary acidification without the use of bicarbonate salts. However, base supplements in the form of sodium bicarbonate or sodium citrate (0.5 to 0.8 mEq/kg, or 30 to 60 mEq per day) plus a diuretic aid in the excretion of potassium.

PROGNOSIS

The prognosis of renal tubular acidosis generally depends on the presence of an underlying systemic disease, such as myeloma (Chapter 173). In children, disorders such as medullary cystic kidney disease (Chapter 112) and cystinosis (Chapter 113) usually result in renal failure by the teenage years. These patients are candidates for renal replacement therapy, including transplantation. Chronic metabolic acidosis in children, if not well treated, is associated with rickets (Chapter 226) and short stature.

METABOLIC ALKALOSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

In metabolic alkalosis, the primary event is elevation of the plasma bicarbonate concentration. In response to increased systemic pH, alveolar ventilation is decreased to increase P_{CO_2} and thereby decrease pH.[21] However, respiratory compensation is generally less effective in cases of metabolic alkalosis than in cases of metabolic acidosis. Contributing factors may include the fact that hypoventilation also decreases P_{O_2}, which is a potent stimulus for the peripheral chemoreceptors to increase alveolar ventilation when P_{O_2} falls below about 60 mm Hg. A second mechanism that may blunt respiratory compensation is intracellular acidosis in the brain in the setting of hypokalemia. In acute metabolic alkalosis, an initial paradoxical acidotic shift in CSF pH secondary to a sudden increase in P_{CO_2}, analogous to the alkaline shift in CSF pH in acute metabolic acidosis, may activate central chemoreceptors and increase ventilatory drive despite peripheral stimulation to decrease alveolar ventilation. In chronic metabolic alkalosis, CSF pH may return to normal, so respiratory drive is controlled entirely by the peripheral chemoreceptors. The result is that the ventilatory response to metabolic alkalosis is highly varied: many patients with metabolic alkalosis maintain nearly normal P_{CO_2} levels, and the level rarely rises above 60 mm Hg.

In the normal state, the renal response to metabolic alkalosis is greater filtration of bicarbonate, less proximal reabsorption of bicarbonate, and bicarbonate secretion in exchange for chloride. Metabolic alkalosis requires a generation phase, in which new HCO_3^- is added to the extracellular fluid, and a maintenance phase, in which the new elevated serum HCO_3^- concentration is sustained. Without the maintenance phase, a kidney with normal filtration and tubular function has a high capacity to excrete HCO_3^-, thereby preventing alkalosis. Maintenance of a high HCO_3^- concentration usually occurs because of volume depletion, reduced glomerular filtration rate, hypokalemia, or low chloride levels.

METABOLIC ALKALOSIS OF RENAL ORIGIN ASSOCIATED WITH VOLUME DEPLETION

Generation of metabolic alkalosis by the kidney can result from reduced renal tubular NaCl reabsorption due to diuretics or inherited disorders (e.g., Bartter or Gitelman syndromes). Metabolic alkalosis is usually associated with high urinary chloride levels, especially when diuretics inhibit reabsorption of Cl^- salts. The Cl^- loss results in hypochloremia, with a compensatory increase in plasma HCO_3^- to maintain electroneutrality. Extracellular volume depletion stimulates the renin–angiotensin–aldosterone pathway, and high aldosterone levels superimposed on increased distal Na delivery and urinary flow rates result in increased secretion of K^+, H^+, and $NH4^+$, with hypokalemia and hypokalemic metabolic alkalosis. The volume depletion and hypokalemia enhance proximal reabsorption of HCO_3^-, thereby maintaining the alkalosis, and the prerenal fall in the glomerular filtration rate limits the filtration of HCO_3^-.

Genetic syndromes characterized by urinary sodium chloride wasting include Bartter syndrome and Gitelman syndrome (Chapter 113). Bartter syndrome is an autosomal recessive salt-losing state associated with extracellular volume depletion and excessive urinary chloride loss that results in hypokalemia and hypochloremic metabolic alkalosis. Secondary increases of plasma renin and aldosterone occur, as does renal juxtaglomerular cell hyperplasia. The syndrome resembles the effects of furosemide on the thick ascending limb of Henle; gene mutations in the Na-K-2Cl cotransporter, the renal outer medullary potassium channel (ROMK), and voltage-gated CLC-Kb chloride channels mediating NaCl reabsorption have been described. Because calcium reabsorption occurs in the thick ascending limb of Henle, Bartter syndrome (Chapter 113), like furosemide, causes hypercalciuria and nephrocalcinosis as well as polyuria due to decreased urinary concentrating ability.

Gitelman syndrome is an autosomal recessive cause of extracellular volume depletion, urinary wasting of sodium chloride, and hypokalemic metabolic alkalosis. It is due to inactivating mutations in the *SLC12A3* gene encoding the thiazide-sensitive NaCl cotransporter of the renal distal tubule. Urinary concentrating ability is preserved, and patients are hypocalciuric because decreased

NaCl reabsorption in the distal tubule and volume depletion enhance the reabsorption of Ca^+ in the proximal tubule. Hypomagnesemia also may be severe owing to defective Mg^{2+} reabsorption in the distal convoluted tubule.

METABOLIC ALKALOSIS OF NONRENAL ORIGIN WITH EXTRACELLULAR VOLUME DEPLETION

Metabolic alkalosis may develop as a result of gastrointestinal loss of Cl^- or gain of HCO_3^- owing to vomiting, nasogastric suctioning, or some causes of secretory diarrhea. In such cases, extracellular volume is usually contracted, hypochloremia develops, and the urinary chloride level is usually less than 20 mEq/L.

In Zollinger-Ellison syndrome (Chapter 213), excessive gastrin-induced gastric acid secretion may result in an acidic stool with high chloride content. Diarrhea does not cause metabolic alkalosis unless the electrolyte relationship $[(Na^+ + K^+) - Cl^-]$ in the stool is less than plasma HCO_3^-.

Infectious gastroenteritis, congenital chloridorrhea, and villous adenomas also cause chloride losses in stool. Congenital chloridorrhea is an autosomal recessive disorder of defective intestinal apical Cl^-/HCO_3^- exchange associated with the downregulated adenoma *(DRA)* gene.

With vomiting, the initiating event is loss of HCl. This secretion of HCl into the stomach lumen by the parietal cell is coupled to the absorption of HCO_3^- in exchange for chloride at the basolateral membrane. When gastric acid is normally secreted, a mild increase in serum HCO_3^- spills into urine and causes an "alkaline tide." With vomiting, however, the net loss of HCl generates the alkalosis. With vomiting, the increased HCO_3^- is filtered by the glomeruli and excreted in urine, accompanied by Na^+ and K^+; volume and K^+ begin to be depleted. As vomiting continues, extracellular volume depletion worsens, glomerular filtration falls, HCO_3^- filtration is limited, the renin–angiotensin II–aldosterone system is stimulated, proximal reabsorption of fluid and HCO_3^- increases, distal reabsorption of Na^+ increases under the influence of aldosterone, and greater secretion of H^+ enhances the reabsorption of HCO_3^-. These effects reduce renal Na^+ loss but at the expense of maintaining the metabolic alkalosis. Significant urinary K^+ losses, which occur as a result of the bicarbonaturia and hyperaldosteronism, lead to hypokalemia, which is actually due to renal, not gastrointestinal, losses as a consequence of attempts to maintain extracellular volume. The hypokalemia further increases the proximal reabsorption of $NaHCO_3$, the distal secretion of H^+, and the reabsorption of K^+, all at the expense of further reabsorption of HCO_3^-. In the new steady state after vomiting or nasogastric suctioning ceases, the paradoxical aciduria of metabolic alkalosis develops as the reabsorption of HCO_3^- is complete, and the urine contains low levels of Na^+, K^+, and Cl^-. The patient may be hypovolemic, hypokalemic, and alkalemic, but because Na^+, K^+, and acid-base balance are intrinsically linked, life-threatening volume depletion, potassium depletion, and alkalemia are usually avoided.

Most nonrenal metabolic alkaloses with volume depletion are due to gastrointestinal losses. However, some patients with cystic fibrosis (Chapter 77) may develop hypochloremic alkalosis as a consequence of excessive sweat chloride related to the *CFTR* gene mutation.

The sweat gland, like the principal cell in the kidney, contains the aldosterone-sensitive epithelial sodium channel, so Na^+ absorption from the glandular duct renders the lumen electronegative. When the absorption of Cl^- is decreased in cystic fibrosis (Chapter 77), the lumen becomes more negative, thereby decreasing the absorption of Na^+, Cl^-, and fluid, as well as leading to salty sweat; the proportionally large Cl^- loss generates a hypochloremic metabolic alkalosis.

METABOLIC ALKALOSIS OF RENAL ORIGIN WITH VOLUME EXPANSION AND HYPERTENSION

The renal conditions that cause metabolic alkalosis and volume expansion are due to a proportionately greater increase in Na^+ reabsorption above what is required to maintain a steady state of Na^+ balance, rather than primary loss of the Cl^- anion. As Na^+ is reabsorbed, electroneutrality is maintained by an increase in plasma HCO_3^-. Cl^- appears in urine, but hypochloremia is not present except in cases of significant metabolic alkalosis. In the kidney, the loss of net acid as NH_4Cl in excess of the acid produced generates a metabolic alkalosis, in which the new bicarbonate generated is due to proton secretion by the distal nephron through H^+-ATPases. The H^+ then combines with NH_3 to form NH_4^+ in urine.

Na^+ is reabsorbed independently of Cl^- in the cortical collecting duct through the aldosterone-sensitive cells containing the ENaC. When Na^+ is reabsorbed by the principal cells of the cortical collecting duct, the tubular lumen becomes electronegative and stimulates the secretion of both K^+ and H^+ by the electrogenic H^+-ATPases. To the extent that HCO_3^- remains in the lumen, the secreted protons complete the reabsorption of HCO_3^-. Additional secreted protons combine with NH_3 and phosphates to lead to net acid excretion. Any increase in the distal H^+ secretory mechanism will produce more urinary net acid; more new HCO_3^- will be generated and returned to the now expanded extracellular fluid, and metabolic alkalosis will develop. The increased plasma HCO_3^- will be filtered, but in the absence of a stimulus to increase proximal HCO_3^- reabsorption, the HCO_3^- will flow distally to be reabsorbed by the increased secretion of H^+ in the collecting duct. At first, the alkalosis is mild, but increased Na^+ reabsorption in the cortical collecting duct will also lead to increased K^+ secretion and hypokalemia. Hypokalemia increases the capacity for the proximal reabsorption of HCO_3^-, thereby opposing the effect of volume expansion, so that the distal delivery of HCO_3^- decreases. The higher than normal distal H^+ secretion titrates urinary buffers, so further new HCO_3^- is formed in the presence of the high ENaC activity, thereby allowing the alkalosis to worsen. The alkalosis is maintained at a new steady state only when the distal secretion of H^+ results in the reabsorption of the remaining amount of filtered HCO_3^- in the collecting duct. Metabolic alkalosis in the hypermineralocorticoid syndromes is sustained by hypokalemia. The metabolic alkalosis in these syndromes is only mild if the patient is K^+ replete.

METABOLIC ALKALOSIS OF NONRENAL ORIGIN ASSOCIATED WITH NORMAL OR EXPANDED VOLUME

If an alkalotic patient is not hypochloremic, electroneutrality must be maintained either by depletion of an alternative anion or by an excessive concentration of a cation. An example of a metabolic alkalosis associated with depletion of a non-chloride anion is hypoproteinemic alkalosis, with hypoalbuminemia and a small anion gap. Chloride balance is normal and chloride appears in urine.

Alkalosis also may result from the administration of alkali salts of HCO_3 or metabolizable organic anions. The normal response to the ingestion of $NaHCO_3$ is rapid urinary alkalinization because of an unaltered threshold for the reabsorption of HCO_3^-. However, a marked excess of HCO_3^-, as may be administered in an attempt to alkalinize a patient's urine, expands volume and causes an alkalemia, especially in the presence of volume depletion or low glomerular filtration. Milk-alkali syndrome, usually seen when patients in renal failure ingest milk, excess vitamin D, or calcium antacids, is associated with hypercalcemia and alkalemia. Other situations in which intake of alkali salts results in metabolic alkalosis include infusion of large quantities of sodium salts of metabolizable organic anions, such as acetate, citrate, lactate, or bicarbonate; hyperalimentation with acetate salts; chronic peritoneal dialysis with acetate or lactate dialysate; and excessive transfusions or plasmapheresis, in which large quantities of citrate, used as an anticoagulant, are delivered.

CLINICAL MANIFESTATIONS

Mild metabolic alkalosis up to a pH of 7.50 is usually asymptomatic. When the pH exceeds 7.55, however, the alkalosis itself and the compensatory hypoventilation are frequently associated with metabolic encephalopathy. Symptoms include confusion, obtundation, delirium, and coma. The seizure threshold is lowered. Because more Ca^{2+} is protein-bound and less is ionized Ca^{2+}, tetany, paresthesias, muscle cramping, and other symptoms of low calcium are seen (Chapter 227). In patients with preexisting hypocalcemia, these signs may be seen at pH values above 7.45. Other findings include cardiac tachyarrhythmias and hypotension. The production of lactate increases as a result of the increased anaerobic glycolysis.

DIAGNOSIS

Measurement of urinary Cl can be very helpful in the diagnosis of the cause of metabolic alkalosis, and it is important to distinguish whether the condition is chloride responsive or chloride unresponsive. (See Table 104-2 and Fig. 104-3.) Chloride-responsive metabolic alkalosis with low urinary Cl^- is associated with depletion of extracellular fluid and chloride and is seen with loss of gastric fluid and prior use of diuretics. Chloride-responsive metabolic alkalosis with high urinary Cl^- is associated with Bartter or Gitelman syndrome or ongoing diuretic use. Chloride-unresponsive metabolic alkalosis with high urinary Cl^- is seen in volume-expanded states, such as primary hyperaldosteronism when metabolic alkalosis is primarily maintained by depletion of K^+. A diagnostic clue comes from the serum electrolytes. The HCO_3^- concentration is increased with a corresponding fall in serum chloride (hypochloremic alkalosis). Chloride-unresponsive metabolic alkalosis is seen in patients with extracellular fluid expansion in conditions such as primary aldosteronism and hypokalemia.

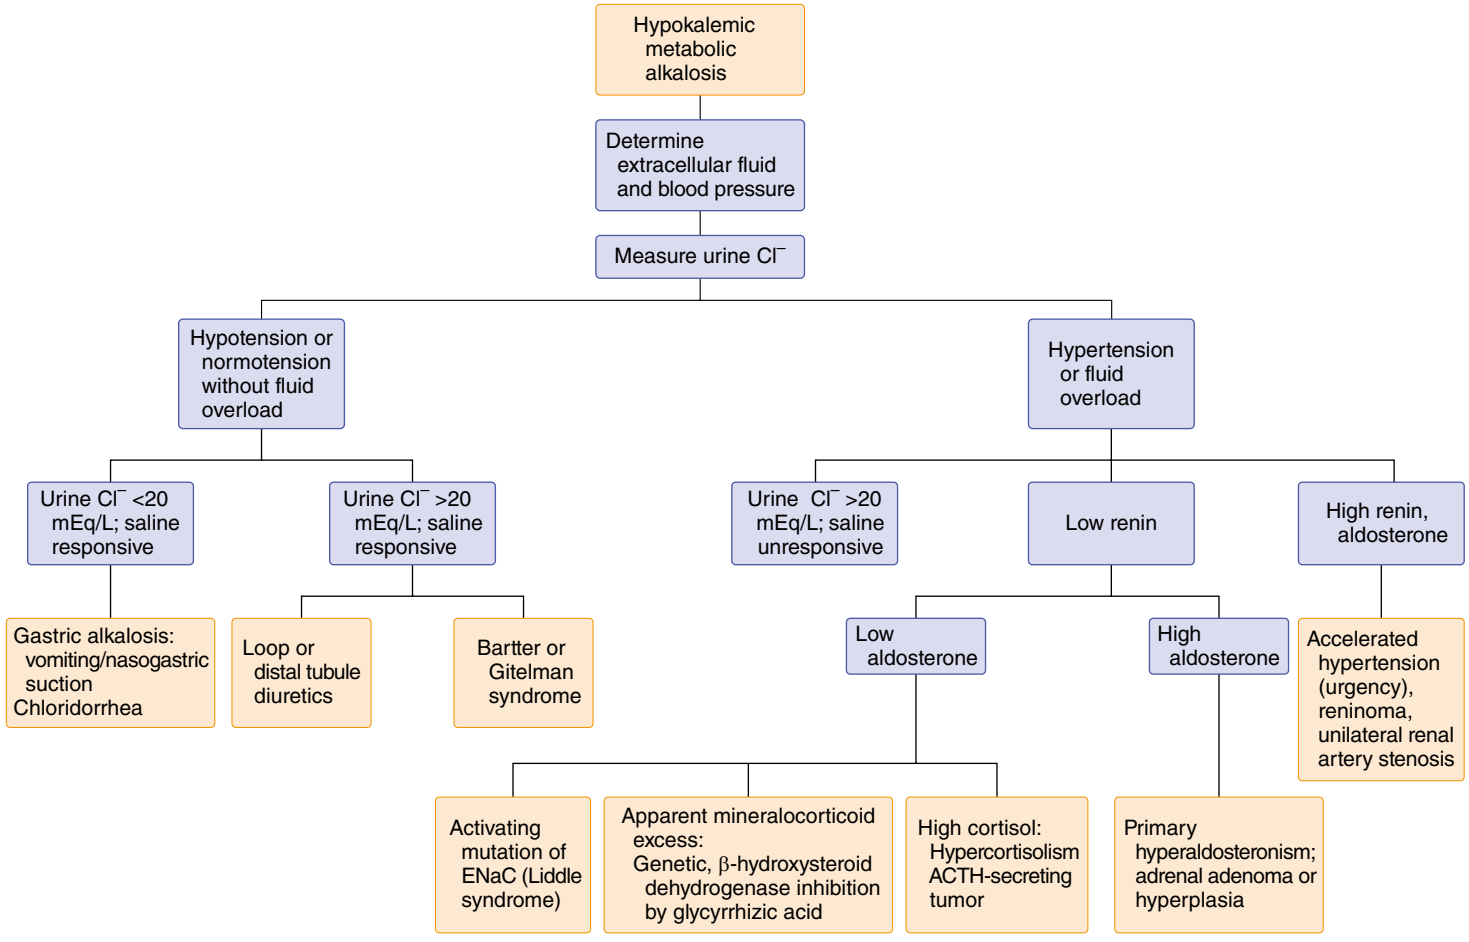

FIGURE 104-3. **Evaluation of the patient with hypokalemic metabolic alkalosis.** ACTH = adrenocorticotropic hormone; Cl = chloride; ENaC = epithelial sodium channel.

Vomiting, nasogastric suction, and diarrhea are usually obvious sources of metabolic alkalosis. However, the Zollinger-Ellison syndrome (Chapter 213), villous adenomas (Chapter 179), and VIPomas (Chapter 213) may be more difficult to diagnose unless the index of suspicion is high.

Patients who present with hypokalemic metabolic alkalosis (Fig. 104-3) with normal or low blood pressure and have urinary chloride concentrations above 25 mEq/L may be taking diuretics such as furosemide or thiazides surreptitiously; a diuretic screen can document the presence of the drug. If the screen is negative, Bartter or Gitelman syndrome (Chapter 113) should be considered. Bartter syndrome is less common, is usually more severe, and presents in young patients. The presence of hypercalciuria favors Bartter syndrome, whereas hypocalciuria and hypomagnesemia suggest Gitelman syndrome.

Specific causes of renal alkalosis with volume expansion and hypertension can be classified according to levels of renin and aldosterone. Primary increases in renin with secondary increases in aldosterone can be seen in patients with unilateral renal artery stenosis (Chapter 110), renin-secreting tumors of the kidney (Chapter 64), and malignant hypertension (Chapter 64). Low renin and elevated aldosterone levels are characteristic of primary hyperaldosteronism from an adrenal adenoma or hyperplasia (Chapter 208). A high cortisol level with volume expansion is seen in hypercortisolism and adrenocorticotropic hormone–secreting tumors (Chapter 208). Inhibition of the intracellular enzyme 11β-hydroxysteroid dehydrogenase type 2 will also result in low renin levels, low aldosterone levels, and hypokalemic alkalosis. Both genetic mutations (the apparent mineralocorticoid excess syndrome) and an excess consumption of glycyrrhizic acid found in licorice and anisette are causes of this enzymatic block. Another cause of hypertension with hypokalemic alkalosis but with low renin and aldosterone levels is Liddle syndrome (Chapter 113), in which an activating mutation in the cortical collecting duct sodium channel (ENaC) leads to increased Na^+ reabsorption.

Metabolic alkalosis may also develop without volume expansion when a non-reabsorbable anion is presented to the cortical collecting duct lumen. Nitrates, sulfates, and certain antibiotics such as nafcillin, carbenicillin, and ticarcillin may obligate the secretion of K^+ and H^+ as Na^+ is reabsorbed. Topical administration of silver nitrate to burn victims may result in alkalosis.

TREATMENT

In chloride-responsive patients who are volume-depleted, chloride-depleted, and most likely potassium-depleted (see Table 104-2), treatment is directed at ameliorating the factors that are maintaining the alkalosis. Providing saline and potassium chloride will increase bicarbonaturia and correct the metabolic alkalosis.[22] In patients with mild to moderate alkalosis, liberalizing NaCl intake and administering potassium chloride (20 to 80 mEq per day in divided doses) is effective in increasing the renal excretion of HCO_3^-. The K^+ deficit, though difficult to estimate from plasma [K^+], is likely to be at least 100 mEq for every 1 mEq/L decrease in plasma [K^+]. Unless potassium deficits are replenished simultaneously with extracellular volume expansion, the combination of increased bicarbonate filtration rate and an ongoing hypokalemia-induced increase in proximal tubular reabsorption of bicarbonate may severely worsen hypokalemia as bicarbonaturia develops and aldosterone's residual effects remain. Complete resolution of alkalosis will not occur until volume is restored and K^+ is normalized.

In a patient with renal failure and vomiting, the elevation in [HCO_3^-] may be more severe because of poor renal filtration of HCO_3^- and may require the administration of HCl or dialysis. If conditions such as volume expansion with decreased effective volume make the administration of NaCl unwise, potassium-sparing diuretics (Chapter 102) may help correct the alkalosis without increasing edema or potassium wasting. In the absence of renal failure, intravenous acetazolamide (250 to 500 mg every 8 hours) may be effective but may greatly increase renal losses of K^+. In patients who have edema and renal failure, acetazolamide treatment may be unsuccessful, so cautious administration of dilute solutions of HCl (0.1 N HCl) may be required. The amount of H^+, in milliequivalents, to be given may be calculated as the product of the desired change in serum HCO_3^- concentration (mEq/L) multiplied by 0.5 of body weight in kilograms. This calculation will likely overestimate the amount of acid needed for correction, so no more than one third of the amount should be given before recalculating to avoid metabolic acidosis. Full correction of HCO_3^- should not be the goal.

Chloride-unresponsive patients (see Table 104-2) include patients who have mineralocorticoid excess. In these patients, the metabolic alkalosis can be lessened by potassium replacement or by blocking Na^+ reabsorption with aldosterone antagonists such as spironolactone (starting with 25 mg orally) or amiloride (beginning with 5 mg orally). Indomethacin (75 mg per day) effectively treats Bartter syndrome (Chapter 113) by interfering with prostaglandin E_2 to allow greater reabsorption of NaCl in the thick ascending limb. Gitelman and Bartter syndromes are best treated with combinations of potassium chloride (40 to 160 mEq per day depending on the severity of the hypokalemia), a potassium-sparing diuretic (e.g., spironolactone 100 to 300 mg per day or eplerenone 150 mg per day), and magnesium if needed.

RESPIRATORY ACIDOSIS

Respiratory acidosis is characterized by a primary elevation in P_{CO_2} as reflected by reduced arterial pH with variable elevations in the HCO_3^- concentration. Respiratory acidosis is most frequently caused by a decrease in alveolar ventilation owing to pulmonary disease (Chapter 90), respiratory muscle fatigue, musculoskeletal abnormalities of the chest wall, or abnormalities in ventilatory control (Chapter 74).

CLINICAL MANIFESTATIONS

Clinical findings in respiratory acidosis are related to the degree and duration of the respiratory acidosis and whether hypoxemia is present. A precipitous rise in P_{CO_2} can lead to confusion, anxiety, psychosis, asterixis, seizures, and myoclonic jerks, with progressive depression of the sensorium and coma at an arterial P_{CO_2} greater than 60 mm Hg (CO_2 narcosis). Hypercapnia, which increases cerebral blood flow and volume, can lead to symptoms and signs of elevated intracranial pressure, including headaches and papilledema. Other findings in acute respiratory acidosis include signs of catecholamine release, such as skin flushing, diaphoresis, and increased cardiac contractility and output. Symptoms of chronic hypercapnia include fatigue, lethargy, and confusion, in addition to the findings seen in acute hypercapnia.

The slow time course of many of these diseases allows the kidney to compensate adequately by increasing its excretion of hydrogen ion as ammonium as well as by generating and reabsorbing bicarbonate to restore systemic pH toward normal values. This compensatory process is not maximal until 3 to 5 days after the onset of respiratory acidosis. Hypoxemia, hypercapnia with resulting chronic $NaHCO_3$ retention, and edema (cor pulmonale) often accompany chronic respiratory acidosis.

DIAGNOSIS

Disorders that cause a respiratory acidosis include central effects of drugs, strokes, and infections; airway obstruction; primary parenchymal processes, such as chronic obstructive pulmonary disease (Chapter 76) and acute respiratory distress syndrome (Chapter 90); disorders of ventilation (Chapter 74); and neuromuscular diseases, such as myasthenia gravis (Chapter 390) and muscular dystrophies (Chapter 389).

TREATMENT

Treatment of both chronic and acute respiratory acidosis aims primarily to correct the underlying cause and to ensure adequate ventilation. In acute respiratory acidosis, measures to relieve severe hypoxemia and acidemia should be instituted immediately, including intubation and assisted mechanical ventilation (Chapter 91) if necessary. Patients with myxedema coma require thyroid replacement (Chapter 207).

In patients with compensated chronic respiratory acidosis, rapid and complete correction of hypercapnia can result in post-hypercapnic metabolic alkalosis. Patients who are chronically hypercapnic and hypoxemic should receive necessary oxygen even though their P_{CO_2} will rise. The rise is not necessarily due to loss of a hypoxic drive to ventilation but may instead be because of release of CO_2 from hemoglobin in the presence of oxygen or because oxygen-induced pulmonary arteriolar vasodilation increases perfusion to poorly ventilated alveoli. Patients recovering from an acute-on-chronic respiratory acidosis should be monitored carefully to correct hypokalemia, hypochloremia, and hypovolemia so that adequate renal excretion of bicarbonate can occur.

Bicarbonate therapy is not indicated for respiratory acidosis unless the pH falls below 7.0 and the patient is about to be intubated.[23] Bicarbonate therapy has no role in patients with renal failure (Chapter 116), in whom adequate compensatory acid excretion cannot occur.

RESPIRATORY ALKALOSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

In respiratory alkalosis, a primary decrease in P_{CO_2} is reflected by increases in the arterial pH and variable decreases in the plasma bicarbonate concentration. The most common cause is alveolar hyperventilation, not underproduction of CO_2.

Acute hypocapnia results in an initial increase in the pH of both the CSF and the brain's intracellular environment. The increased intracellular pH stimulates glycolysis, vasoconstriction, hypoxia, and an increased affinity of hemoglobin for oxygen, thereby offsetting the metabolic alkalosis by producing lactic acid. However, this increase in lactic acid is quickly offset because the renal compensation for decreased bicarbonate reabsorption will result in a lower blood bicarbonate level. The combination of increased oxygen demand and decreased oxygen delivery may contribute to adverse clinical outcomes in hypocapnic alkalosis.

Cerebral blood flow is significantly decreased by hypocapnia, which is a potent vasoconstrictor. As in respiratory acidosis, the CNS is immediately affected because of the blood-brain barrier's permeability to CO_2. In addition, as in respiratory acidosis, CSF and intracellular pH show an initial short-lived response that parallels the systemic increase in pH.

Renal compensation for sustained hypocapnia is complete in 36 to 72 hours. The mechanism rests primarily in the kidney's net reduction of hydrogen ion excretion, which is accomplished largely by decreasing the excretion of ammonium and titratable acid. The threshold for bicarbonate excretion is also lowered, and bicarbonaturia develops. As a result, systemic bicarbonate levels decrease, and arterial pH returns toward normal values.

Acute exposure to high altitude (Chapter 82) results in hypoxia-induced hyperventilation. Compensation requires several days and is characterized by a gradual further increase in hyperventilation, a steadily decreasing P_{CO_2}, and a recovering P_{O_2}. The effect of the hypoxic stimulus to ventilate is initially modulated by the effects of alkalosis, both peripherally and centrally. However, as HCO_3^- falls in the CSF, inhibition of the central stimulus to ventilate decreases. Once a steady state is achieved, the drive to ventilate is determined by the effects of hypoxemia and alkalemia on the peripheral chemoreceptors.

CLINICAL MANIFESTATIONS

The clinical manifestations of respiratory alkalosis depend on the degree and duration of the condition but are primarily those of the underlying disorder. Chronic hypocapnia does not appear to be associated with any significant clinical symptoms.

Symptoms of acute hypocapnia with P_{CO_2} below 30 mm Hg are largely attributable to the alkalemia and include dizziness, perioral or extremity paresthesias, confusion, asterixis, hypotension, seizures, and coma. Shortness of breath and chest wall pain, which frequently accompany hyperventilation because of pain or anxiety, do not appear to be related to hypocapnia itself.

DIAGNOSIS

Alveolar hyperventilation leading to respiratory alkalosis is seen with hypoxemia from pulmonary disease (Chapter 71), heart failure (Chapter 45), high altitudes (Chapter 82), or anemia. Mechanical ventilation (Chapter 91) is also a common cause of respiratory alkalosis. Rarely, patients have chronic hyperventilation syndrome without any detectable underlying disease.[24]

Another common cause of respiratory alkalosis is primary stimulation of the central chemoreceptor, as seen in sepsis (Chapter 94), hepatic cirrhosis (Chapter 139), salicylate intoxication (Chapters 70 and 96), correction of metabolic acidosis, hyperthermia (Chapter 95), and pregnancy, as well as cortical hyperventilation from anxiety and pain. In these situations, central signals override peripheral chemoreceptors until the primary stimulus is removed.

Primary neurologic diseases that can stimulate alveolar hyperventilation include acute stroke, infection, trauma, and tumors. Two patterns of respiration are seen: central hyperventilation and Cheyne-Stokes respiration (Chapter 74). Central hyperventilation, which is associated with lesions at the pontine-midbrain level, is regular but with an increased rate and tidal volume. Cheyne-Stokes breathing, which is characterized by periods of hyperventilation alternating with apnea, is seen in patients with bilateral cortical and upper pontine lesions and in patients with heart failure.

TREATMENT

Treatment of respiratory alkalosis must address the underlying cause of the disturbance. Hyperventilation syndrome is a diagnosis of exclusion, but patients who exhibit symptoms such as tetany and syncope and who do not have more serious causes of hyperventilation can be treated with a rebreathing mask. Hypophosphatemia can be seen, but usually improves with treatment of the alkalosis. Patients with respiratory alkalosis associated with mountain sickness can be pretreated with acetazolamide to induce metabolic acidosis (Chapter 82), thereby preventing extreme elevations in pH, but care must be taken to ensure adequate intake of K^+ to avoid hypokalemia.

105 DISORDERS OF MAGNESIUM AND PHOSPHORUS

ALAN S.L. YU

MAGNESIUM METABOLISM

Magnesium is an important mineral component of the bony skeleton, a cofactor for many metabolic enzymes, and a regulator of ion channels and transporters in excitable tissues.[1]

NORMAL MAGNESIUM METABOLISM

The majority of total body magnesium is intracellular or in bone, with only 1% in extracellular fluid. The normal serum magnesium concentration is 1.8 to 2.3 mg/dL (1.5 to 1.9 mEq/L). The average daily intake of magnesium is 300 mg, the main sources of which are green vegetables, nuts, whole grain cereals, milk, and seafood. Magnesium is absorbed mainly in the jejunum and ileum. In the kidney, 70 to 80% of serum magnesium is filtered at the glomerulus, with the majority being reabsorbed along the length of the tubule, particularly in the thick ascending limb of Henle. In states of magnesium deficiency or excess, renal tubule reabsorption is tightly regulated so that magnesium excretion is adjusted accordingly.[2]

MAGNESIUM DEFICIENCY

PATHOBIOLOGY

Magnesium deficiency is usually detected when hypomagnesemia becomes evident. However, because magnesium is stored primarily intracellularly, substantial depletion of total body magnesium can occur before serum magnesium levels drop appreciably.

Magnesium deficiency may be due to nutritional deficiency, intestinal malabsorption, redistribution into bone, or losses via cutaneous, lower gastrointestinal, or renal routes (Table 105-1). The recommended daily allowance of magnesium is 420 mg for males and 320 mg for females. Approximately 25% of alcoholics are chronically hypomagnesemic because of a combination of poor nutritional intake and increased renal loss. Magnesium deficiency can occur, rarely, in protein-calorie malnutrition and may be associated with acute hypomagnesemia during refeeding because of rapid cellular magnesium uptake. Fat malabsorption in conditions such as celiac disease, Crohn disease, and small intestinal resection causes magnesium deficiency because free fatty acids accumulate in the intestinal lumen, where they combine with magnesium to form insoluble soaps. Proton pump inhibitors also cause hypomagnesemia by inhibiting intestinal absorption, primarily in patients who are concurrently using diuretics.[3] Lower gastrointestinal tract secretions are rich in magnesium, so diarrhea of colonic origin is a common cause of hypomagnesemia. Sweat contains significant amounts of magnesium, and transient hypomagnesemia can occur after prolonged, intense exercise such as marathon runs. Magnesium is also lost from burned skin surfaces, and 40% of patients with severe burns (Chapter 97) are hypomagnesemic.

In patients with severe hyperparathyroidism (Chapter 227) and high bone turnover, continued sequestration of minerals within bone after parathyroidectomy causes transient hypocalcemia, hypomagnesemia, and hypophosphatemia. Renal magnesium losses can occur in the recovery phase of acute tubular necrosis or urinary tract obstruction. Hypomagnesemia is common in diabetes mellitus (Chapter 210), in which it is thought to be due to a combination of poor intestinal absorption, osmotic diuresis, and decreased renal tubule reabsorption. Inhibition of sodium reabsorption in the thick ascending limb of Henle by loop diuretics and in the distal convoluted tubule by thiazide diuretics inhibits tubular magnesium reabsorption and leads to urinary magnesium wasting. Tubular toxins that are common causes of renal magnesium wasting include cisplatin, carboplatin, amphotericin B, and aminoglycosides, which are often associated with hypokalemia and rarely with renal tubule acidosis, as well as calcineurin inhibitors such as cyclosporine and tacrolimus, which also cause hyperkalemia. Antibodies to the epidermal growth factor receptor, such as cetuximab and panitumumab, which are used to treat metastatic colorectal cancer, downregulate a distal tubule magnesium channel and cause isolated severe hypomagnesemia.

Inherited hypomagnesemia is usually caused by renal magnesium loss and can be subdivided into three main types, depending on the coexistence of other electrolyte disturbances: Bartter and Gitelman syndromes, which are associated with renal salt wasting and hypokalemic metabolic alkalosis; familial hypomagnesemia with hypercalciuria and nephrocalcinosis; and isolated hypomagnesemia, which is usually associated with hypocalcemia.

CLINICAL MANIFESTATIONS

Mild-to-moderate hypomagnesemia or magnesium deficiency is frequently asymptomatic. Manifestations of increased neuronal excitability are the most common symptoms, including paresthesias, tetany, and seizures. These may be associated with Chvostek sign (twitching of the cheek muscles in response to tapping the facial nerve in front of the ear) or Trousseau sign (carpal spasm induced by compressing the upper arm with a tourniquet or blood pressure cuff). Cardiac disturbances range from mild electrocardiographic abnormalities (nonspecific T wave changes, U waves, prolonged QT interval, and repolarization alternans) to ventricular tachycardia, torsades de pointes, and ventricular fibrillation (Chapter 53).

Coexistent hypokalemia is very common for two reasons: many of the causes of hypomagnesemia are also causes of potassium loss, and hypomagnesemia itself causes renal potassium wasting. Severe hypomagnesemia also impairs parathyroid hormone secretion and induces tissue resistance to its actions, thereby leading to hypocalcemia.

DIAGNOSIS

The cause of the magnesium deficiency is often obvious from the history. In difficult diagnostic cases, a random urine sample should be collected and the fractional excretion of magnesium (FE_{Mg}) determined.

$$FE_{Mg} = \frac{\text{Urine magnesium} \times \text{Serum creatinine}}{0.7 \times \text{Serum magnesium} \times \text{Urine creatinine}}$$

With extrarenal magnesium loss (usually diarrhea, malabsorption or laxative abuse), the FE_{Mg} is appropriately suppressed (<4%). Higher FE_{Mg} levels indicate renal magnesium wasting, often secondary to surreptitious diuretic use or one of the familial magnesium-wasting disorders.

TREATMENT

It is unclear whether mild, asymptomatic hypomagnesemia needs to be treated. Magnesium repletion is recommended in hypomagnesemic patients if they are symptomatic, have underlying cardiac or seizure disorders, exhibit concurrent severe hypocalcemia or hypokalemia, or have severe hypomagnesemia (<1.4 mg/dL). In mild cases or in the outpatient setting, oral magnesium salts such as magnesium oxide (250 to 500 mg four times daily) can be used for repletion, but these substances frequently cause diarrhea, particularly at high doses. In the inpatient setting, intravenous magnesium sulfate (1 to 2 g every 6 hours) can be used for repletion. Because the redistribution of magnesium

ABSTRACT

Magnesium and phosphate are important components of bone, but they also play important roles within cells. Disorders of magnesium and phosphate homeostasis—especially hypomagnesemia, hypophosphatemia, and hyperphosphatemia in the setting of kidney disease—are common and most often asymptomatic. This chapter reviews the causes of magnesium and phosphate disorders, tests and algorithms to diagnose the underlying cause, and treatment options, including replacement regimens.

KEYWORDS

magnesium
hypomagnesemia
phosphate
hypophosphatemia
hyperphosphatemia

from extracellular to intracellular compartments is relatively slow, the serum magnesium concentration may normalize before total body magnesium stores are replete. It is therefore prudent to continue intravenous magnesium for an additional 1 to 2 days after restoration of normomagnesemia. In patients with normal renal function, any excess magnesium is simply excreted renally. Adverse effects from intravenous magnesium administration are primarily due to transient hypermagnesemia and include flushing, hypotension, and flaccid paralysis. Amiloride (10 to 20 mg PO once daily) abrogates renal magnesium wasting in some patients.

PROGNOSIS

Hospitalized patients with hypomagnesemia have a higher 1-year mortality, presumably because it is a marker of more severe illness.[4] Low serum magnesium levels (<1.7 mg/dL) are also associated with about a 35% increase in all-cause mortality in the general population.[5] In patients with a self-limited cause of magnesium deficiency, repletion is easily accomplished. However, in patients with persistent magnesium wasting, such as in Gitelman syndrome (Chapter 113), it can be difficult to keep up with the ongoing losses with oral therapy. Fortunately, these individuals tend to adapt to their chronic hypomagnesemia and tolerate it fairly well.

HYPERMAGNESEMIA

Transient hypermagnesemia can occur in patients given large doses of intravenous magnesium, for example, in the setting of preeclampsia. It has also been reported in individuals taking large doses of magnesium-containing antacids or cathartics, particularly in settings in which intestinal absorption is enhanced, such as inflammatory bowel disease and intestinal obstruction. However, the kidney has a very large capacity to excrete excess magnesium. Thus, persistent hypermagnesemia is seen almost exclusively in patients who have a reduced glomerular filtration rate, as in chronic kidney disease (Chapter 116), and who are also taking excessive amounts of magnesium in the form of antacids, cathartics, or enemas.

CLINICAL MANIFESTATIONS

Magnesium toxicity is a serious and potentially fatal condition. Mild hypermagnesemia (serum magnesium level > 4 to 6 mg/dL) causes hypotension, nausea, vomiting, facial flushing, urinary retention, and ileus. Above serum levels of 8 to 12 mg/dL, flaccid skeletal muscle paralysis and hyporeflexia may ensue, along with bradyarrhythmias, respiratory depression, coma, and cardiac arrest. A low or even negative serum anion gap is sometimes seen.

TREATMENT

Mild hypermagnesemia in a patient with good renal function usually requires no treatment because renal clearance is rapid and the normal serum half-life of magnesium is approximately 1 day. In the event of serious toxicity, the effects of magnesium can be temporarily antagonized by the administration of intravenous calcium salts (5 to 10 mL of 10% calcium chloride). Renal magnesium excretion can be enhanced by administering furosemide (20 to 40 mg every 4 hours) together with a saline infusion (0.9% NaCl at 150 mL/hour, titrated to replace urinary losses). In patients with advanced renal insufficiency, the most effective method of magnesium removal is hemodialysis.

PROGNOSIS

Severe hypermagnesemia is potentially fatal. Lesser degrees of hypermagnesemia usually respond well to treatment, but hypermagnesemia at the time of hospital admission is associated with an increased 1-year mortality.[6]

PHOSPHORUS METABOLISM

Phosphorus has many critical roles. It is a major component of bone mineral, of phospholipids in cell membranes, and of nucleic acids. It forms high-energy phosphate bonds in compounds such as adenosine triphosphate (ATP), is post-translationally bound to proteins as an intracellular signal, and acts as a major pH buffer in serum and urine.

NORMAL PHOSPHORUS METABOLISM

Of the total body phosphorus content, 85% is in bone, 14% is in intracellular compartments, and only 1% is in extracellular fluid. The normal concentration of phosphorus in plasma is 3 to 4.5 mg/dL (1 to 1.5 mM). Daily intake of phosphorus is 800 to 1500 mg. Phosphorus is present in many foods, including dairy products, meats, and grains, and it is absorbed in the small intestine. The kidneys excrete excess phosphorus, which is the principal mechanism by which the body regulates extracellular phosphate balance. Ninety percent of serum phosphate is filtered at the glomerulus, of which 80 to 97% is reabsorbed along the nephron, primarily in the proximal tubule. Parathyroid hormone and fibroblast growth factor 23 increase renal phosphate excretion by inhibiting the sodium-phosphate cotransporter in the proximal tubule, whereas vitamin D enhances intestinal phosphate absorption.

HYPOPHOSPHATEMIA

PATHOBIOLOGY

Hypophosphatemia may be caused by decreased intake, impaired intestinal absorption, redistribution into cells or bone, and renal losses (Table 105-2, Fig. 105-1). Phosphate is frequently depleted in alcohol use disorder (Chapter 364) because of the intake of a carbohydrate-rich, phosphate-poor diet, as well as renal phosphate wasting. Divalent cation-containing antacids bind phosphate in the intestinal lumen to form insoluble salts, thereby preventing their absorption. Vitamin D deficiency also leads to decreased intestinal phosphate absorption and hence to hypophosphatemia. Acute respiratory (but not metabolic) alkalosis (Chapter 104), including that due to salicylate intoxication, may cause transient hypophosphatemia. In this disorder, intracellular pH is increased, thereby stimulating glycolysis, which depletes the intracellular inorganic phosphate pool and leads to a shift of phosphate into cells.

Insulin is also a strong stimulus for shifting phosphate into cells. Patients with diabetic ketoacidosis (Chapter 210) are often hyperphosphatemic because of a shift of phosphate out of cells under insulinopenic conditions, but their total body phosphate is actually depleted as a result of urinary losses. Subsequent treatment with insulin may uncover severe hypophosphatemia. Similarly, in malnourished patients (Chapter 197), whose total body phosphate stores may be depleted, overzealous intravenous refeeding with carbohydrate-rich fluids may stimulate insulin release and cause acute hypophosphatemia.[7] The tyrosine kinase inhibitors imatinib, sorafenib, and nilotinib, which are used in the treatment of various cancers (Chapters 164 and 170), can cause profound hypophosphatemia, which appears to be due either to inhibition of bone resorption or a partial Fanconi syndrome.

Renal phosphate wasting is usually due to impaired proximal tubule phosphate reabsorption. In primary hyperparathyroidism (Chapter 227), hypercalcemia is typically associated with hypophosphatemia. Fanconi syndrome is a generalized proximal tubule disorder characterized by hypophosphatemia in association with glycosuria, aminoaciduria, hypokalemia, and type II renal tubular acidosis; it can be caused by a variety of inherited metabolic disorders, multiple myeloma (Chapter 173), heavy metal intoxication (Chapter 20), intravenous iron therapy (Chapter 144),[8] and drugs such as ifosfamide, cidofovir, and tenofovir. Phosphaturia also can occur with diuretics, particularly carbonic anhydrase inhibitors, and with antimicrobial agents such as pentamidine and foscarnet.

*Common causes.

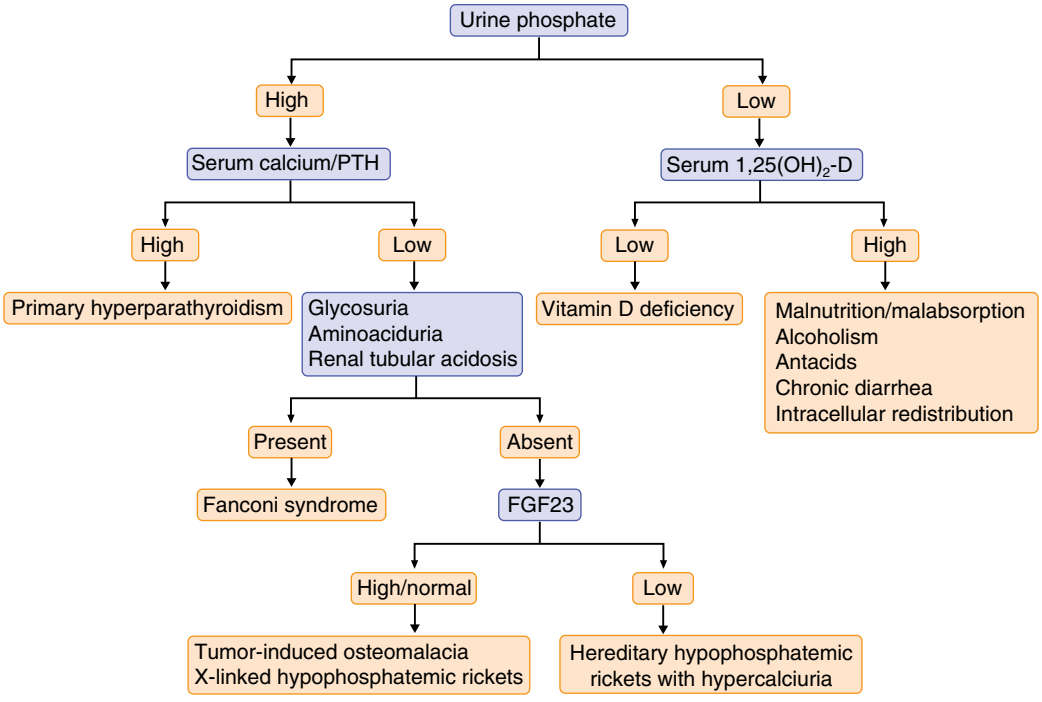

FIGURE 105-1. Diagnostic approach to chronic hypophosphatemia. $1,25(OH)_2$-D = 1,25-Dihydroxyvitamin D; FGF23 = fibroblast growth factor 23; PTH = parathyroid hormone.

Oncogenic osteomalacia is a paraneoplastic syndrome (Chapters 164 and 226) associated primarily with mesenchymal tumors that secrete a variety of phosphaturic factors, including fibroblast growth factor 23, that are collectively known as phosphatonins.[9] A similar phenotype is found in X-linked, autosomal dominant and autosomal recessive hypophosphatemic rickets (Chapter 226), which are inherited disorders that are characterized by an increase in the levels or activity of fibroblast growth factor 23. Fibroblast growth factor 23 inhibits both renal tubular phosphate reabsorption and 1α-hydroxylation of 25-hydroxycholecalciferol, thereby leading to hypophosphatemia, rickets, or osteomalacia (Chapter 226) and inappropriately low serum levels of 1,25-dihydroxycholecalciferol. Finally, patients undergoing renal replacement therapy by continuous venovenous hemodiafiltration (Chapter 117) often become phosphate depleted and need ongoing replacement.

CLINICAL MANIFESTATIONS

Clinical complications, which are usually observed only with severe hypophosphatemia (<1 mg/dL), are thought to be due to the disruption of cell membrane composition, depletion of ATP (which particularly affects high energy–consuming tissues such as skeletal and cardiac muscle), and depletion of 2,3-diphosphoglycerate in erythrocytes, with impaired tissue oxygen delivery. Manifestations of severe hypophosphatemia include encephalopathy, dilated cardiomyopathy, generalized muscle weakness that can lead to respiratory failure, rhabdomyolysis, and hemolysis. Hypophosphatemia also impairs renal ammoniagenesis and reduces the availability of urinary buffer, thereby impairing renal acid excretion and causing metabolic acidosis. Chronic hypophosphatemia leads to resorption of bone and osteomalacia.

DIAGNOSIS

The cause of hypophosphatemia is often evident from the history and physical examination. If not, measurement of either 24-hour urinary phosphate excretion or fractional excretion of phosphate (FE_{PO4}) in a spot urine sample is often helpful.

$$FE_{PO4} = \frac{\text{Urine phosphate} \times \text{Serum creatinine}}{\text{Serum phosphate} \times \text{Urine creatinine}}$$

In the setting of hypophosphatemia, the normal response of the kidney is to reduce urinary phosphate excretion to less than 100 mg/day or to reduce FE_{PO4} to less than 5%. Higher values suggest one of the causes of renal phosphate wasting.

TREATMENT

Patients with asymptomatic mild-to-moderate hypophosphatemia, normal total body phosphorus stores, and minimal ongoing phosphorus losses (e.g., hypophosphatemia caused by acute respiratory alkalosis) do not require treatment. Phosphate should be repleted in patients who are symptomatic, are suspected of having severely depleted intracellular phosphorus stores (malnourished or alcoholic patients), have ongoing gastrointestinal or renal losses, or have severe hypophosphatemia (<1 mg/dL).[10] Oral repletion can be accomplished with sodium or potassium phosphate salts (1 to 2 g/day) or with skim milk. Intravenous phosphorus repletion at a dose of 0.16 to 0.64 mmol/kg over 4 to 8 hours is recommended for severe hypophosphatemia but is contraindicated in patients with renal insufficiency or hypercalcemia. Hypophosphatemia in patients on continuous venovenous hemodiafiltration can also be ameliorated by the use of phosphate-containing dialysate and replacement solutions. Complications of phosphate therapy include hypocalcemia, metastatic calcification, hypotension, acute renal failure, and arrhythmias, as well as concomitant hypernatremia or hyperkalemia, depending on which salt is administered.

PROGNOSIS

Most patients with hypophosphatemia respond well to treatment. However, hypophosphatemia is a marker of the severity of disease in patients who require intensive care.[11]

HYPERPHOSPHATEMIA

PATHOBIOLOGY

Pseudohyperphosphatemia may occur in blood specimens that are hemolyzed or hyperglobulinemic, such as in multiple myeloma (Chapter 173). True hyperphosphatemia is caused by excessive phosphate intake, increased intestinal absorption, redistribution from intracellular stores, or impaired renal excretion (Table 105-3 and Fig. 105-2). Overzealous phosphate repletion also can cause hyperphosphatemia. The phosphorus in some laxatives and enemas may be absorbed and cause hyperphosphatemia. Intoxication with vitamin D or its analogues increases intestinal absorption of both calcium and phosphorus. Conditions associated with massive cell lysis, such as rhabdomyolysis (Chapter 99) and tumor lysis syndrome (Chapter 164), release intracellular phosphate into the extracellular fluid, where it can bind calcium and result in hypocalcemia (Chapter 227). Patients with diabetic ketoacidosis (Chapter 210) are often hyperphosphatemic at initial evaluation because of the redistribution of phosphate out of cells in the insulin-deficient state. Decreased phosphate

*Common causes.

TREATMENT

Acute hyperphosphatemia in an asymptomatic patient with normal renal function often resolves spontaneously as excess phosphate is excreted. In symptomatic patients and those with impaired renal function, phosphate can be removed by extracorporeal therapy. Because of the slow rate of phosphate mobilization from intracellular stores, continuous venovenous hemodiafiltration is considerably more effective than intermittent hemodialysis. Chronic hyperphosphatemia (Chapter 116) can be managed by minimizing the dietary intake of phosphorus and administering oral phosphate binders with meals. Current guidelines recommend minimizing the use of calcium salts in chronic kidney disease (Chapter 116), based on evidence that non–calcium-based phosphate binders and especially sevelamer (800 mg three times daily)[A1] may reduce all-cause mortality compared with calcium-based binders.[A2] Tenapanor (starting at 5 mg twice daily and titrating to as high as 30 mg twice daily if needed), which is an inhibitor of the paracellular absorption of phosphorus from the intestine, can lower serum phosphate levels.[A3] Cinacalcet (starting at 30 mg daily and titrated as high as 180 mg daily as needed), which is a calcimimetic used in patients with chronic kidney disease to treat secondary hyperparathyroidism, also reduces the serum phosphate concentration modestly and can be considered in refractory cases.

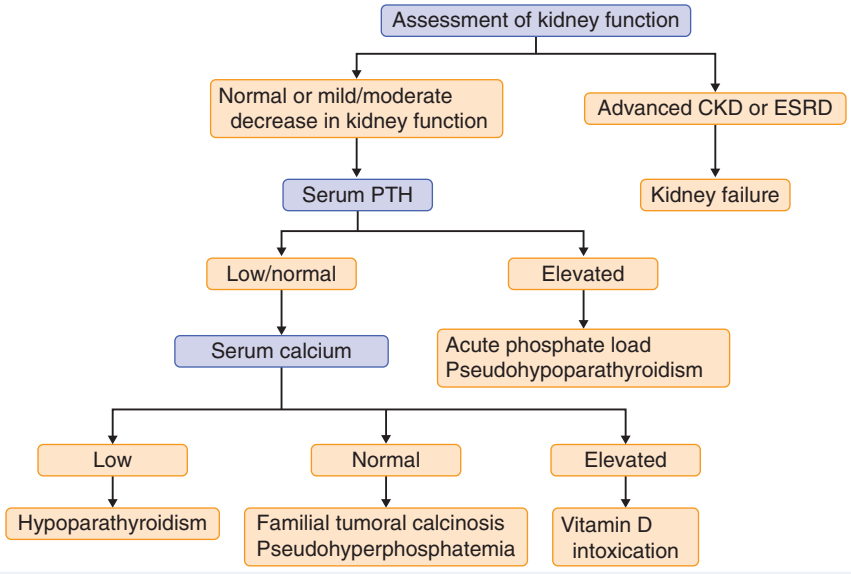

FIGURE 105-2. Diagnostic approach to chronic hyperphosphatemia, a parathyroid hormone (PTH)–based diagnostic algorithm. CKD = chronic kidney disease; ESRD = end-stage renal disease; PTH = parathyroid hormone. (Redrawn from Leaf DE, Wolf M. A physiologic-based approach to the evaluation of a patient with hyperphosphatemia. *Am J Kidney Dis.* 2013;61:330-336.)

excretion is most commonly due to acute or chronic kidney disease (Chapter 116). With a normal diet, serum phosphate levels can be maintained within the normal range until the glomerular filtration rate falls below 25 mL/minute. However, even mild degrees of renal insufficiency may predispose to hyperphosphatemia if there is a concurrent excessive intake of phosphate-containing compounds such as laxatives. Parathyroid hormone stimulates the excretion of phosphate in the proximal tubule, so primary hypoparathyroidism (Chapter 227) is often associated with mild hyperphosphatemia as well as hypocalcemia.[12] Oncologic drugs that inhibit fibroblast growth factor receptors (Chapters 164 and 166) also can cause hyperphosphatemia by antagonizing fibroblast growth factor 23.[13]

CLINICAL MANIFESTATIONS

Acute hyperphosphatemia increases the risk for the precipitation of calcium phosphate and subsequent metastatic calcification in soft tissues, including the kidney, in which it can cause acute kidney injury (Chapter 106).[14] For example, acute hyperphosphatemia is an independent risk factor for acute kidney injury in patients with rhabdomyolysis (Chapter 99).[15] The resultant hypocalcemia (Chapter 227) can cause tetany, hypotension, seizures, and cardiac arrhythmias. Hyperphosphatemia in chronic kidney disease (Chapter 116) is a risk factor for coronary and other vascular calcification and for increased mortality.

PROGNOSIS

Severe acute hyperphosphatemia can be life-threatening owing to metastatic calcification and multiorgan failure, but it generally responds well to prompt therapy. Chronic hyperphosphatemia in patients with chronic kidney disease (Chapter 116) is often fairly resistant to treatment, particularly in poorly compliant individuals, and is associated with increased long-term mortality.

106 ACUTE KIDNEY INJURY

ANUPAM AGARWAL AND JONATHAN BARASCH

DEFINITION

Acute kidney injury (AKI), which is a clinical syndrome, is defined by a clinically evident defect in the kidney's clearance of waste materials within approximately 1 week after an injurious stimulus. Although formal definitions vary somewhat, the components include an increase in the serum level of the muscle metabolite creatinine by 0.3 mg/dL or greater (within 48 hours), an increase in the creatinine level to 1.5 times higher than a baseline value within 7 days or a fall in urine volume to less than 0.5 mL/kg/hour for 6 hours or longer (Table 106-1). The degree of the rise in serum creatinine or fall in urine output is typically reported in stages that describe progressive functional loss (Table 106-1).

EPIDEMIOLOGY

About 20 to 25% of hospitalized adults have an elevated serum creatinine level. Among patients admitted to the hospital from an emergency department, up to 45% present with an elevated serum creatinine level, and the rate is even higher (55 to 65%) among patients who are admitted to the intensive care unit (ICU). Because the serum creatinine level is insensitive for detecting tubular or vascular damage, the true incidence of acute kidney injury is probably even higher.[1] In contrast, community-acquired acute kidney injury is uncommon and estimated to have an annual incidence of less than 1%. The serum creatinine level can be elevated for a variety of reasons, including prerenal, intrarenal, and postrenal subtypes that are impossible to distinguish on the basis of a single measurement of the serum creatinine level (Fig. 106-1).

Prerenal azotemia, which is the most common cause of an elevated serum creatinine level, is found in 15% of patients admitted from the emergency department. Prerenal azotemia accounts for about 40% of hospital-acquired cases of acute kidney injury and as much as 60 to 70% of community-acquired cases, depending on its precise definition. Intrinsic acute kidney injury, defined as 7 days or longer of azotemia, is present in 5 to 6% of patients who are admitted from the emergency department in the United States and in as many as 60% of patients in the intensive care unit. Acute kidney injury is also common and underdiagnosed in low-resource settings worldwide.[2] Intrinsic acute kidney injury requiring dialysis has increased substantially over the past three decades. For postrenal acute kidney injury, the incidence depends on the patient's age and sex. Prostatic hypertrophy in older men (Chapter 114) is the leading cause.

TABLE 106-1 KIDNEY DISEASE IMPROVING GLOBAL OUTCOMES (KDIGO) ACUTE KIDNEY INJURY DEFINITIONS

STAGE	SERUM CREATININE	URINE OUTPUT
1	1.5-1.9 times baseline OR ≥0.3 mg/dL (≥26.5 µmol/L) increase	<0.5 mL/kg/hour for 6 to 12 hours
2	2.0-2.9 times baseline	<0.5 mL/kg/hour for ≥12 hours
3	3.0 times baseline OR Increase in serum creatinine to ≥4.0 mg/dL (≥353.6 µmol/L) OR Initiation of renal replacement therapy OR In patients <18 years of age, decrease in eGFR to <35 mL/min per 1.73 m^2	<0.3 mL/kg/hour for ≥24 hours OR Anuria for ≥12 hour

eGFR = estimated glomerular filtration rate.

Prerenal Azotemia/Hypoperfusion

Prerenal azotemia is caused when hypoperfusion of the kidney reduces the clearance of serum creatinine and water, thereby limiting urine output. In prerenal azotemia, kidney function, including the serum creatinine level and urine output, can be corrected within hours of infusing volume, thereby stimulating cardiac output, or withdrawing vasoconstrictors (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs], cyclosporine, radiocontrast agents). Although evidence of tubular injury may be limited, even 1 day of prerenal azotemia can result in hyponatremia, hyperkalemia, acidosis, and hence increased mortality (Fig. 106-2). Urinary biomarkers of acute kidney injury are not particularly elevated.

The causes of prerenal azotemia include true intravascular volume depletion because of limited oral intake, fever and sweating, burns, diarrhea, diuretic agents, and bleeding, as well as effective volume depletion from heart failure (Chapter 45) or liver failure (Chapter 140). In addition, a number of medications potentially reduce glomerular perfusion and raise the serum creatinine level, including NSAIDs, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor blockers. These medications can have a dramatic effect on the serum creatinine level when renal perfusion is compromised by volume depletion or other insults.

Intrinsic Acute Kidney Injury

Intrinsic acute kidney injury can involve any portion of the kidney or its vasculature. Central to the pathobiology is an abrupt decline in kidney function that cannot be restored for a number of days or even weeks owing to slow resolution of intensive vasoconstriction, tubular damage, and cell death, as well as interstitial inflammation with edema. Urinary biomarkers of tubular damage are particularly elevated. In contrast to prerenal azotemia, molecular

ABSTRACT

Acute kidney injury, which occurs frequently in hospitalized patients, is defined as a rapid decline in kidney function within 1 week of an injury, such as from a toxin, medication, sepsis, or hemodynamic perturbance. Acute kidney injury includes prerenal, intrarenal, and postrenal subtypes, which differ in their pathogenesis and can be distinguished by imaging studies and by urine and serum biomarkers. Treatments involve removal of offending stimuli, correcting any obstruction, and supportive care to address volume depletion and electrolyte disturbances. Hemodialysis is warranted when prolonged acute kidney injury is associated with volume overload, electrolyte disturbances, or uremic symptoms. Prognosis varies depending on the underlying injury and preexisting comorbid conditions, but acute kidney injury is associated with significant morbidity and mortality. Prevention relies on the identification of high-risk patients and limiting the use of potential nephrotoxins.

analysis demonstrates the activation of inflammatory, ischemic, and coagulation pathways.

The causes of intrinsic acute kidney injury[3] include ischemic hypoperfusion that results in cellular injury, septic injury,[4] inflammatory injury, and a myriad of renal toxins (Table 106-2), including intrinsic toxins (e.g., myoglobin, hemoglobin, calcium oxalate, uric acid, and endogenous pancreatic enzymes) and exogenous toxins (e.g., radiocontrast agents, antibiotics, and metals). Acute kidney injury does not develop in all patients who are exposed to potentially toxic agents, but patients with prior functional defects, such as elderly patients with chronic kidney disease or volume-depleted patients (e.g., due to diuretics, burns, heart failure, cirrhosis, or hypoalbuminemia), are more likely to suffer toxic tubular injury. For example, the risk of developing antibiotic nephrotoxicity is 10-fold higher in high-risk patients.

Injury to the renal interstitium or acute interstitial nephritis (Chapter 108) is found in about 15% of biopsy samples of patients who have an intrinsic acute kidney injury.[5] Implicated medications include sulfonamides, penicillins, cephalosporins, proton pump inhibitors, and NSAIDs (Table 106-3). In addition, checkpoint inhibitors trigger acute interstitial nephritis in about 5% of treated patients. Bacteria and viruses that can cause interstitial injury include *Legionella,* leptospirosis, *Yersinia,* streptococcus, *Mycobacterium tuberculosis,* Epstein-Barr virus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), and cytomegalovirus. Fungal infections, including histoplasmosis and coccidioidomycosis, as well as tuberculosis, are implicated in granulomatous acute interstitial nephritis. Interstitial nephritis also can be seen in patients who have systemic autoimmune diseases, including systemic lupus erythematosus (Chapter 245), Sjögren syndrome (Chapter 247), cryoglobulinemia (Chapter 173), and primary biliary cirrhosis (Chapter 141). Intratubular crystallization of compounds such as uric acid, calcium oxalate, acyclovir, sulfonamides, methotrexate, and myeloma light chains can result in tubular obstruction.

Postrenal Acute Kidney Injury

Postrenal acute kidney injury refers to obstruction of urinary outflow. Both kidneys (or a single solitary kidney) must be obstructed in order to cause postrenal acute kidney injury, because the serum creatinine level is too insensitive to detect kidney damage from partial or unilateral obstruction. Obstruction can occur in the lower tract owing to the constriction of the urethra or the base of the bladder by prostatic hypertrophy (Chapter 114) or cancer of the prostate (Chapter 186), cervix (Chapter 184), or bladder (Chapter 182). Patients with spinal cord disease or diabetes also can develop an elevated serum creatinine

level because of functional obstruction from a neurogenic bladder. Obstruction of both ureters at the bladder trigone or along their course from the kidneys can be seen in retroperitoneal fibrosis (Chapter 246), endometriosis (Chapter 218), metastatic colon cancer (Chapter 179), and lymphomas (Chapters 171 and 172). Intraluminal blockade occurs when renal calculi (Chapter 111), papillary necrosis (Chapter 100), or blood clots obstruct both ureters.

PATHOBIOLOGY

Molecular processes that cause acute kidney injury can be categorized according to the principal site of disease activity. Such processes include decreased kidney perfusion, which can reduce the glomerular filtration rate (GFR) regardless of whether it causes acute cellular injury, a primary glomerular disease, an injury (toxic, septic, ischemic) to the nephron, or inflammation and edema of the tubules or interstitium (Fig. 106-3).

Prerenal Acute Kidney Injury

A reduction in extracellular or intravascular volume, commonly termed effective arterial volume, affects many segments of the kidney by activating the catecholamine–renin–angiotensin–aldosterone–antidiuretic hormone systems. These regulators determine afferent and efferent arteriolar tone in the glomerulus and hence the concentration of albumin and the reabsorption of Na^+ and water in the postglomerular capillary and in the nephron. The hormonal cascade is most active in the inner medulla, where the final capture of salt and water prevents further volume depletion. In addition, Na^+ recovery is a critical pro-inflammatory signal that defends the kidney from urinary infections during periods when urine flow rate is reduced.

In addition to regulating gene transcription via the hormonal axis, volume depletion also regulates oxygen tension in the medulla. Volume depletion reduces and volume expansion increases medullary partial pressure of oxygen (pO_2), without changing cortical pO_2. Severe and prolonged prerenal azotemia can damage the inner medullary tubules by hypoxia (Table 106-4). Conversely, volume resuscitation is needed to protect the kidney when a second insult, such as a nephrotoxic agent or radiologic contrast, may damage the kidney.

Prerenal acute kidney injury may also result from heart failure, called cardiorenal acute kidney injury. Both right-sided congestion, which can involve the renal vein, and left-sided failure with a decreased cardiac output, can reduce the effective arterial volume and, as a result, the filtration of creatinine.

Early in the course of heart failure (Chapter 45) and early in prerenal azotemia, the GFR remains relatively preserved, with only small increases in the serum creatinine level, because kidney hypoperfusion triggers a cascade of hormonal responses that dilate afferent arterioles and constrict efferent arterioles to maintain glomerular perfusion pressure and that stimulate the tubules to retain Na^+ and water. At later stages, however, intravascular volume expansion does not further improve kidney perfusion; rather, removal of volume

TABLE 106-4 CONDITIONS THAT LEAD TO ISCHEMIC ACUTE KIDNEY INJURY

MECHANISM	CONDITION
Severe volume depletion and hypotension	Severe hemorrhage; gastrointestinal, renal, and dermal losses
Severely decreased effective intravascular volume	Severe heart failure and cirrhosis, hepatorenal syndrome, peritonitis
Systemic vasodilation, renal vasoconstriction	Sepsis, hepatorenal syndrome
Large-vessel renal vascular disease	Renal artery thrombosis or embolism, intraoperative arterial cross-clamping, renal artery stenosis, cholesterol emboli
Small-vessel renal vascular disease	Sepsis, vasculitis, atheroembolism, hemolytic-uremic syndrome, malignant hypertension, scleroderma, preeclampsia, sickle cell anemia, hypercalcemia, transplant rejection
Impaired renal blood flow	Cyclosporine, tacrolimus, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, nonsteroidal anti-inflammatory drugs, radiocontrast agents

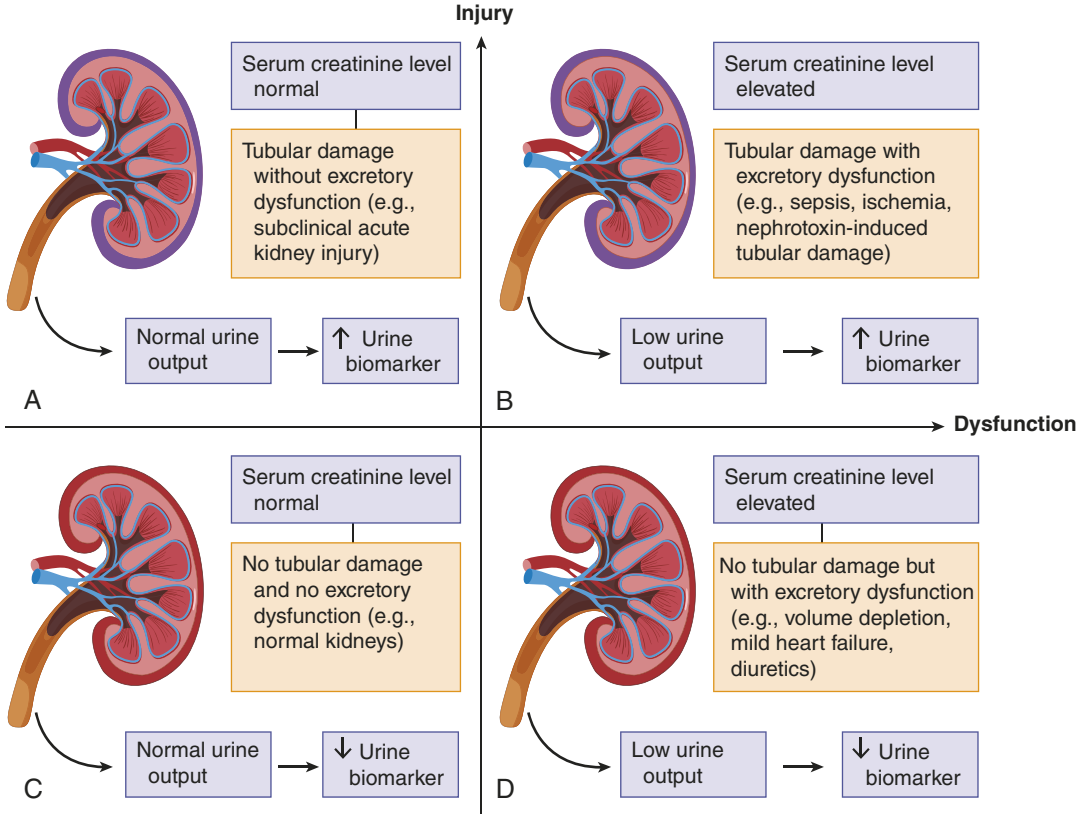

FIGURE 106-3. Three forms of acute kidney injury based on the intersection of an elevated serum creatinine level and urinary biomarkers. (A) Partial damage is detected by biomarkers but not by the serum creatinine level. **(B)** Extensive damage detected by both biomarkers and the serum creatinine level. **(C)** Normal kidney. **(D)** Volume depletion detected by an elevated serum creatinine level without biomarker elevation. (Adapted from Desanti De Oliveira B, Xu K, Shen TH, et al. Molecular nephrology: types of acute tubular injury. *Nat Rev Nephrol*. 2019;15:599-612.)

and reducing congestion in the pulmonary and renal veins is beneficial even as the serum creatinine level rises if tubular damage is not also present.

Progression of Prerenal to Intrinsic Acute Kidney Injury

Prerenal and intrarenal azotemia are distinct conditions, with different molecular pathways, including gluconeogenesis, lipid metabolism, and anti-inflammatory regulators in the prerenal state as compared with coagulation, inflammation, and epithelial remodeling in the intrarenal state. However, when a second insult, such as an inflammatory or toxic stimulus, is superimposed, volume depletion exacerbates the damage.[6] Without early volume repletion, prerenal azotemia may contribute to tubular epithelial injury.

Intrarenal Acute Kidney Injury

Intrinsic acute kidney injury can be classified by the primary site of injury: tubules, interstitium, vasculature, or glomerulus. Renal tubular injury, previously termed *acute tubular necrosis* (ATN) and now *acute tubular injury* (ATI), is typically found in the S3 segment of the proximal tubule and the medullary thick ascending limb of Henle, which are two segments that are located in the outer stripe of the medulla, where oxygen tension is limited. Different forms of ischemia preferentially target these segments: warm ischemia targets the proximal (S3) tubule, whereas cold ischemia, vasoconstrictors, contrast agents, gram-negative sepsis, myoglobinuria, and obstruction target the medullary thick ascending limb of Henle. The balance of injury may depend on the degree of injury-induced hypoxia (the proximal tubule is dependent on aerobic metabolism, whereas the medullary thick ascending limb of Henle can utilize anaerobic metabolisms) and on segmental variations in the activation of mitogen-activated protein kinases.

A very common cause of intrinsic acute kidney injury is sepsis. The initiation stage of sepsis-associated tubular injury is not fully elucidated, but lipopolysaccharide accumulates in proximal tubules and then in distal tubules. The uptake of lipopolysaccharide correlates with broadening of the distribution of toll-like receptors (TLRs), including TLR4, the lipopolysaccharide receptor, and its coreceptor (CD14) from distal tubules to proximal tubules in response to injury.

Tubular toxins initiate damage by binding endocytic receptors (megalin and cubilin) and trafficking to tubular lysosomes in the proximal tubule, similar to the pathway taken by lipopolysaccharide. The many endocytic toxins that may also undergo endocytosis by the megalin pathway include cadmium, aminoglycoside antibiotics, and other medicinal toxins such as intravenous radiocontrast agents and cisplatin (see Table 106-2).[7] The most important endocytic toxin is the endogenous molecule myoglobin (Chapter 99), which contains heme and iron and triggers ferroptosis and necroptosis. Tubular toxins also exacerbate kidney injury by inducing vasoconstriction. This phenomenon is linked to radiocontrast agents, NSAIDs, cyclosporine, and combinations of these agents with renin-angiotensin system inhibitors and diuretics.

In addition to direct cell toxicity and vasoconstriction, many toxins and metabolites can precipitate and thereby block tubular function. Endogenous compounds that can cause crystal nephropathy include calcium oxalate (both the common enteric form and the primary hyperoxaluric form), and uric acid. Exogenous compounds that create intratubular obstruction include acyclovir, sulfonamides (sulfadiazine and sulfamethoxazole), ciprofloxacin, vitamin C, ethylene glycol, methotrexate, protease inhibitors (e.g., indinavir, darunavir), and the light chains of multiple myeloma (Chapter 173).

Cellular Damage

Cellular dysfunction is typical in the proximal tubule, particularly in the S3 segment. In the initiation phase of renal ischemia, the apical membrane with the brush border sheds in blebs from the cells. Subsequently, the polarity of membrane proteins is lost, due to loss of function of cellular tight junctions. Retraction of tight junctions and loss of the epithelial cell barrier allow the back-leak of the glomerular filtrate into the interstitium, thereby reducing clearance of metabolic wastes. As the injury progresses, both live and necrotic proximal cells detach from the basement membrane and enter the tubular lumen, where they ultimately form casts in the distal tubule. Casts contribute to a reduction in GFR by obstructing the tubular flow of urine at the S3-thin limb of Henle junction,[8] thereby preventing further filtration into that nephron. The clearance of casts is necessary for recovery; it is mediated by proteases and by phagocytic proteins that bind intratubular casts. By day 3 after injury, casts are cleared from most of the nephron, but obstructing casts can linger at the S3 segment or descending limb of Henle.

During the phase of cellular death, endothelial dysfunction and an inflammatory endothelial response, particularly in the corticomedullary junction of the kidney, result from extensive signaling between the proximal tubular cells and adjacent endothelial cells. Leukocytes can block blood flow via cellular adhesion and rouleaux formation. Damage to the microvasculature in turn can generate coagulation abnormalities. When proximal tubular cells dedifferentiate, proliferate, and restore the nephron,[9] the kidney recovers and the GFR begins to improve.

In interstitial and vascular acute interstitial nephritis (Chapter 108), interstitial edema comprises an inflammatory infiltrate with T lymphocytes, eosinophils, monocytes, and macrophages invading the tubular basement membrane. In chronic interstitial nephritis, the characteristic findings are interstitial fibrosis and tubular atrophy, but inflammation can persist. Surprisingly, a greater degree of inflammation may portend a higher likelihood of resolution.[10]

Vascular Disease

Microvascular diseases (e.g., sepsis [Chapter 94], the hemolytic-uremic syndrome [Chapter 158], thrombotic thrombocytopenic purpura [Chapter 158], and the HELLP syndrome [*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelet count; Chapters 132 and 221]) can also cause acute kidney injury by producing fibrin clots in the glomerulus and microvasculature. Acute kidney injury related to macrovascular disease is seen with embolism, including embolism of cholesterol plaques that occur especially after invasive vascular procedures (Chapter 110), and larger thromboembolism as in atrial fibrillation (Chapter 52). Vascular infarcts also can be seen with hypercoagulable states such as the nephrotic syndrome, antiphospholipid syndrome, and homocysteinemia, as well as with the use of oral contraceptive agents. Acute kidney injury also occasionally can be caused by glomerulonephritis (Chapter 107). Sometimes the glomerular injury is part of a systemic disease such as systemic lupus nephritis (Chapter 245), granulomatosis with polyangiitis (Chapter 249), polyarteritis nodosa (Chapter 249), Goodpasture syndrome (Chapter 107), Henoch-Schönlein purpura (Chapters 107 and 249), or the hemolytic-uremic syndrome (Chapter 158).

Postrenal Acute Kidney Injury

Postrenal acute kidney injury is caused by obstruction to luminal flow of the glomerular filtrate. In this condition, the GFR initially remains largely preserved because the glomerular afferent arteriole is dilated. If, however, the obstruction is not rapidly relieved, the release of angiotensin II and thromboxane causes vasoconstriction and reduces the GFR. If the obstruction persists for more than 12 to 24 hours, renal blood flow and intratubular pressure decline, and the GFR declines because of large underperfused areas of renal cortex. Subsequently, the kidney is invaded by macrophages, which stimulate fibrosis.

Acute Kidney Injury in the Setting of SARS-CoV-2

The SARS-CoV-2 virus that causes coronavirus disease 2019 (COVID-19) induces systemic responses, including a cytokine storm, immune and metabolic dysfunction, endothelial injury, coagulopathy, and microangiopathy (Chapter 336).[11] SARS-CoV-2 can directly infect kidney cells, where it causes dedifferentiation and activation of profibrotic pathways in the organoids.[12] Pathology reveals proximal tubular cell injury with loss of apical membrane and intracellular inclusions. In addition, nonviral mechanisms include hemodynamic factors, cardiac dysfunction, high levels of mechanical ventilation, hypovolemia, use of nephrotoxic drugs, and nosocomial sepsis.

CLINICAL MANIFESTATIONS

Acute kidney injury is usually clinically silent, and no specific symptoms are present in early stages of the injury. Some patients will rarely note a change in urine volume or color. Obstructive acute kidney injury due to a stone (Chapter 111) or papillary necrosis (Chapter 100) may result in hematuria and in flank pain radiating to the ipsilateral groin, but they also can be silent. Distal-type renal tubule acidosis (Chapter 104) is a common sequela of obstructive uropathy. In advanced states of acute kidney injury, uremic symptoms (Chapter 116) develop with anorexia, fatigue, nausea and vomiting, pruritus, and reversal of the sleep-wake cycle. Examination of the patient may reveal pulmonary edema and peripheral edema (Chapter 45), inflammatory complications such as a pericardial or pleural friction rub, and neurologic complications of uremia such as myoclonus and asterixis.

DIAGNOSIS

The diagnosis of acute kidney injury is based on a rise in the serum creatinine level and subsequently on elucidating the cause of the injury. Despite the utility of a single measurement of serum creatinine to demonstrate kidney dysfunction, a single elevated serum creatinine level measurement cannot

accurately measure functional loss because it lacks the kinetic properties required to determine function in the absence of steady state. In addition, the serum creatinine level and urine output fail to detect kidney tubule injury in real time, to detect injury that involves less than one entire kidney, or to distinguish different clinical syndromes that elevate serum creatinine levels. Finally, serum creatinine levels are influenced by muscle mass, muscle damage, nutritional status, and medications that block the tubular transport of serum creatinine (e.g., cimetidine, trimethoprim, pyrimethamine, and salicylates), thereby raising serum creatinine in the absence of injury.[13]

All patients with an acutely elevated serum creatinine level should be evaluated with serum measurements of electrolytes, calcium, phosphorus, and a blood urea nitrogen level, as well as a complete blood count with differential. Urine dipstick and microscopy (Table 106-5) can detect blood, cells, and casts that are typical of different forms of intrarenal damage (Chapter 100). The urine and serum Na^+ and serum creatinine levels should be measured simultaneously to determine the fractional excretion of sodium (FE_{Na}), which measures the ability of the tubules to reabsorb Na^+, normalized for water reabsorption by measuring urine creatinine (Table 106-6).

$$FE_{Na} = \frac{\text{Urine Na} \times \text{Plasma Cr}}{\text{Plasma Na} \times \text{Urine Cr}} \times 100$$

In the setting of oliguria, an elevated FE_{Na} suggests tubular damage. Fractional excretion of chloride (FE_{Cl}) can substitute for FE_{Na} because urinary sodium can be elevated by systemic alkalosis when a high urinary bicarbonate level obligates the loss of sodium.

Prerenal azotemia can be diagnosed by evidence of dehydration and by its rapid resolution after a fluid challenge (e.g., 100 mL intravenously in 1 minute or up to 3 to 4 mL/kg over 5 minutes). In early true acute kidney injury, urine output of 100 mL within 1 hour after administering intravenous furosemide (1 or 1.5 mg/kg) can evaluate residual tubular function and can predict the subsequent rise in serum creatinine levels and mortality.[14] A renal ultrasound is key to exclude postrenal azotemia caused by stones, anatomic malformations, and bladder outlet obstruction.

TABLE 106-5 COMMON URINALYSIS FINDINGS IN ACUTE KIDNEY INJURY

CAUSE OF ACUTE KIDNEY INJURY	URINALYSIS
Prerenal	Normal or hyaline casts
Intrarenal	
Tubular cell injury	Muddy-brown, granular, epithelial casts
Interstitial nephritis	Pyuria, hematuria, mild proteinuria, granular and epithelial casts, eosinophils
Glomerulonephritis	Hematuria, marked proteinuria, red blood cell casts, granular casts
Vascular disorders	Normal or hematuria, mild proteinuria
Postrenal	Normal or hematuria, granular casts, pyuria

Adapted from Molitoris BA. Acute kidney injury. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Saunders; 2020.

TABLE 106-6 FE_{Na} VALUES FOR THE VARIOUS CAUSES OF ACUTE KIDNEY INJURY

CAUSE OF ACUTE KIDNEY INJURY	FE_{Na}	BUN-TO-SERUM CREATININE RATIO
Prerenal	<1%	>20
Intrarenal		<10-15
Tubular necrosis	≥1%	
Interstitial nephritis	≥1%	
Glomerulonephritis (early)	<1%	
Vascular disorders (early)	<1%	
Postrenal	≥1%	>20

FE_{Na} = fractional excretion of sodium.
Adapted from Molitoris BA. Acute kidney injury. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Saunders; 2020.

When the diagnosis appears to be true acute kidney injury, urine protein measurements for biomarkers (e.g., tissue inhibitor of matrix metalloproteinase 2–insulin-like growth factor–binding protein 7 [TIMP2-IGFBP7], kidney injury molecule 1 [KIM-1], neutrophil gelatinase–associated lipocalin [NGAL], and interleukin 18) can detect cell stress and damage that are typical of tubular injury rather than simple prerenal azotemia, even when the serum creatinine level has just started to rise because of a falling GFR.[15] Based on their sensitivity and specificity for tubular injury, some of these biomarkers may help guide the characterization of acute kidney injury (see Fig. 106-3), but their actual use in clinical practice has been limited.

Prerenal Azotemia

Prerenal azotemia is suggested by history of vomiting, diarrhea, hemorrhage, or poor oral intake. Heart failure indicates hypoperfusion either because of progressive disease or because of volume depletion due to diuretics. Medications such as NSAIDs, ACE inhibitors, and angiotensin-receptor blockers, can cause prerenal azotemia. Physical examination includes findings typical of underperfusion such as systemic or orthostatic hypotension, flat jugular veins, dry mucous membranes, and reflex tachycardia. Laboratory studies in patients with prerenal azotemia demonstrate elevated serum creatinine and blood urea nitrogen (BUN) levels. In prerenal azotemia, patients will typically have a ratio of BUN to serum creatinine of greater than 20 : 1. FE_{Na} is typically less than 1%. The FE_{Na} can provide reliable diagnostic information regarding acute kidney injury only if it is less than 1%, because elevated levels of FE_{Na} are seen in many diseases. In patients who are taking diuretics or in the presence of nonreabsorbable solutes such as glucose, a fractional excretion of urea (FE_{urea}) below 35% suggests prerenal acute kidney injury.

Intrarenal Acute Kidney Injury

In intrarenal acute kidney injury, significant hypotension, sepsis, and exposure to nephrotoxins (see Tables 106-2 and 106-3) are common. Physical examination is usually not revealing except for evidence of hypervolemia (Chapters 39 and 45). The skin examination may reveal embolic phenomenon or a rash consistent with allergic interstitial nephritis.

Laboratory testing will show elevated serum creatinine and BUN levels. Unlike prerenal azotemia, in which the elevation of the serum creatinine level tends to be modest and to plateau below 4 mg/dL, the serum creatinine level in intrarenal acute kidney injury may rise rapidly each day. The FE_{Na} is usually above 1 in acute injury, whereas it typically is below 1 in early sepsis, glomerulonephritis, radiocontrast-induced acute kidney injury, and vascular disorders. The urinalysis also can be helpful in making the diagnostic (see Table 106-6). In rare cases, acute interstitial nephritis may be associated with peripheral and urinary eosinophilia, but eosinophilia can also accompany cholesterol microemboli (Chapter 110). Urinary interleukin (IL)-9 and tumor necrosis factor (TNF)-α may be better markers for acute interstitial nephritis than are urinary findings.[16] Biomarkers can help detect intrarenal tubular injury within hours of the injury, and their levels in the urine can distinguish intrarenal (biomarkers are very elevated) from prerenal (biomarkers are not particularly elevated) forms of acute kidney injury.

Postrenal Acute Kidney Injury

Postrenal acute kidney injury should be suspected in patients who have a history of prostatic hypertrophy (Chapter 114), prostate cancer (Chapter 186), lymphoma (Chapter 171), cervical cancer (Chapter 184), or retroperitoneal disease. However, postrenal acute kidney injury also should be considered when patients have marked oliguria (urine output < 450 mL/day) or anuria (urine output < 100 mL/day). Renal ultrasound can diagnose bladder and upper tract disease, whereas a bladder catheterization showing a large residual is the best way to diagnose lower tract disease.

TREATMENT

Fluids and Supportive Care

The treatment of acute kidney injury initially focuses on optimizing intravascular volume and withdrawing any offending agents. Because the majority of cases of elevated serum creatinine levels result from reversible volume depletion, prompt volume resuscitation during the early phases of acute kidney injury provides the greatest opportunity for minimizing kidney injury (Fig. 106-4) and is critical to avoid progression to tubular damage (Chapter 92). However, aggressive volume resuscitation must be carefully monitored in elderly patients, patients who have a history of heart failure or cirrhosis, or septic patients because of the possibility of precipitating pulmonary and/or peripheral edema. Fluid status can be monitored by an estimation of central venous pressure on physical examination

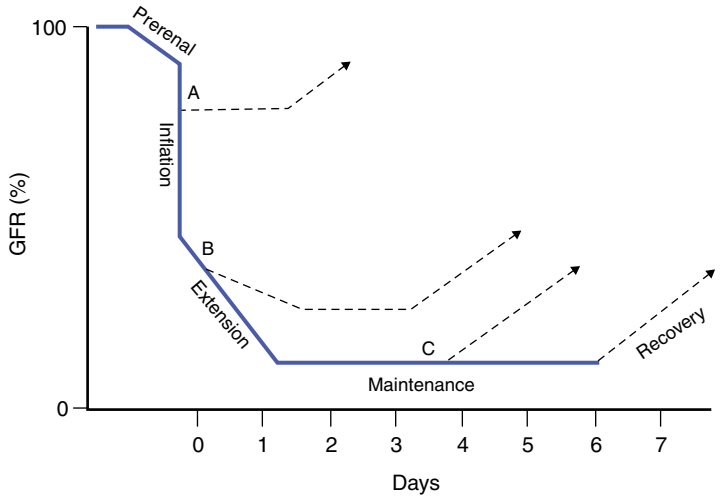

FIGURE 106-4. Phases of acute kidney injury. GFR = glomerular filtration rate. (From Sutton TA, Fisher CJ, Molitoris BA. Microvascular endothelial injury and dysfunction during ischemic acute renal failure. *Kidney Int*. 2002;62:1539-1549.)

(Chapters 39 and 45) as well as by monitoring the return of urine output and echocardiography (Chapter 43).

Postrenal obstructive uropathy from prostatic hypertrophy (Chapter 114) frequently can be corrected by insertion of a catheter into the bladder, often followed by definitive surgery. However, when outlet obstruction is caused by a tumor, a ureteral stent or a percutaneous nephrostomy tube usually is required.

For ischemic or septic tubular damage, no specific therapies are available, but general supportive measures include avoiding nephrotoxins, maintaining fluid balance, treating electrolyte abnormalities (with diets low in sodium, potassium, protein), and treating any comorbid or precipitating conditions aggressively. Volume overload is treated with daily diuretics (e.g., furosemide 40 to 80 mg intravenously) and a low-sodium diet. Hyperkalemia is generally treated with sodium zirconium cyclosilicate/lokelma or patiromer (see Chapter 103) and a low-potassium diet. Hyperphosphatemia is treated with oral binders (Chapter 105), hypocalcemia is treated with calcium tablets (Chapter 227), and acidosis is treated with $NaHCO_3$ tablets (Chapter 104). Intriguing experimental studies suggest that a deficiency of lipid β-oxidation and the production of β-hydroxybutyrate worsen the damage, and that treatment with niacinamide may prove to be beneficial.[17]

Immunosuppression

Intrarenal acute kidney injury resulting from glomerulonephritis (Chapter 107), vasculitis (Chapters 249), or systemic disease typically requires immunosuppressive therapy. For acute interstitial nephritis, an empiric trial of prednisone (often starting with 1 mg/kg for several days, followed by a gradual taper over 1 month) is usually tried (Chapter 108).

Dialysis

Acute hemodialysis is indicated in the setting of marked volume overload, hyperkalemia, acidosis, and uremic symptoms (e.g., changes in mentation, frank encephalopathy, myoclonus, asterixis, seizures, pleuritis, and pericarditis) that are unresponsive to dietary changes and other treatments.[18] Dialysis (Chapter 117) is generally begun when the serum creatinine level reaches about 10 mg/dL in symptomatic patients because starting it sooner is not of incremental benefit[A1,A2] and may result in unnecessary dialysis in some patients.[A3] In fact, delaying dialysis even longer (until the onset of important hyperkalemia, metabolic acidosis, or pulmonary edema) is as safe as initiating dialysis at a blood urea nitrogen level of 112 mg/dL or after 72 hours of oliguria.[A4,A5] The dose and modality of dialysis do not appear to affect the outcomes.

PREVENTION

Prevention begins with recognizing patients who are at the highest risk for developing acute kidney injury because they have known prior kidney disease or predisposing conditions, such as diabetes, atherosclerosis, hypertension, or heart failure. Consultation with a nephrologist before a potentially nephrotoxic exposure can reduce these risks. Key steps include maintaining adequate intravascular volume, avoiding nephrotoxic medications (e.g., NSAIDs and aminoglycosides), minimizing the use of radiocontrast material, and carefully monitoring urinary output and serum creatinine levels after interventions that might cause/induce acute kidney injury.

To prevent contrast-associated acute kidney injury, hydration with intravenous sodium chloride may be helpful, and the use of rosuvastatin (40 mg on admission then 20 mg/day or 10 mg/day for 2 days before and 3 days after the procedure) can reduce the risk of acute kidney injury in patients who have diabetes and chronic kidney disease.[A6] By comparison, neither intravenous sodium bicarbonate nor oral acetylcysteine reduces this risk.[A7-A9] In the intensive care unit, balanced crystalloid therapy (e.g., lactated Ringer solution) reduces the risk of acute kidney injury compared with normal saline[A10] but a similar benefit has not been demonstrated for noncritically ill adults.[A11]

PROGNOSIS

Prerenal acute kidney injury has the best prognosis. If it is diagnosed and treated early, the mortality rate is less than 10%, and most patients fully recover their kidney function. For postrenal acute kidney injury, prompt diagnosis and definitive treatment provide a high likelihood of full recovery of kidney function, but long-term prognosis depends on the cause of the obstruction.

By comparison, intrarenal acute kidney injury has a less favorable outcome, and even a 0.3 mg/dL rise in the serum creatinine level significantly increases risk, with mortality rates ranging from 30 to 80%. Mortality is higher in older patients who have hospital-acquired acute kidney injury and who are admitted to intensive care units. Acute kidney injury accelerates the progression of chronic kidney disease and is often the major reason why it progresses to end-stage kidney disease (Chapter 116). The outcomes of glomerulonephritis (Chapter 107) and vasculitis (Chapter 249) depend on the specific disease. More than 5% of patients who require hemodialysis recover enough renal function to discontinue it, but most patients (and especially patients who have prior underlying kidney disease) require chronic renal replacement therapy (Chapter 117).

107 GLOMERULAR DISORDERS AND NEPHROTIC SYNDROMES

JAI RADHAKRISHNAN AND M. BARRY STOKES

GLOMERULAR DISORDERS

DEFINITION

Each *glomerulus,* the basic filtering unit of the kidney, consists of a tuft of anastomosing capillaries formed by the branching of the afferent arteriole. On average, 1 million glomeruli comprise approximately 5% of the weight of each kidney and provide almost 2 m^2 of glomerular capillary filtering surface. The glomerular basement membrane provides both a size- and charge-selective barrier to the passage of circulating macromolecules. Renal pathologic processes involving all glomeruli are called *diffuse* or *generalized;* if only some glomeruli are involved, the process is called *focal*. When dealing with the individual glomerulus, a process is *global* if the whole glomerular tuft is involved and *segmental* if only part of the glomerulus is involved. The descriptive terms *proliferative, sclerosing,* and *necrotizing* are often used (e.g., focal and segmental glomerulosclerosis; diffuse global proliferative lupus nephritis). Extracapillary proliferation or crescent formation is caused by the accumulation of macrophages, fibroblasts, proliferating epithelial cells, and fibrin within Bowman space. Such findings signify aggressive disease and consequently an adverse prognosis. Scarring of the tissue between the tubules and glomeruli, interstitial fibrosis, is also a poor prognostic sign.

EPIDEMIOLOGY

Glomerular disease is an important cause of end-stage kidney disease (Chapter 117), and diabetic kidney damage (Chapter 109) alone affects many millions of persons worldwide. Glomerular diseases associated with infectious agents such as malaria (Chapter 316), schistosomiasis (Chapter 326), human immunodeficiency virus (HIV; Chapter 355), and the hepatitis B and C viruses (Chapter 135) are major worldwide health problems. Manifestations of glomerular injury range from asymptomatic microhematuria and albuminuria to rapidly progressive oliguric kidney failure. Some patients develop massive fluid retention and edema at the onset of their glomerular disease, whereas others present with only the slow insidious signs and symptoms of chronic kidney failure (Chapter 117).

PATHOBIOLOGY

In a normal person, the urine contains no red blood cells (RBCs), the urinary excretion of albumin is less than 30 mg/day, and the total urinary excretion of protein is less than 140 mg/day. Glomerular diseases are characterized by breaks in the glomerular capillary wall, thereby leading to hematuria with proteinuria because of loss of the selective barrier to particles based on size and charge. Although increases in urinary protein excretion may come from the filtration of abnormal circulating proteins (e.g., light chains in multiple myeloma) or from the deficient proximal tubular reabsorption of normal, filtered low-molecular-weight proteins (e.g., β_2-microglobulin), the most common cause of proteinuria, and specifically albuminuria, is glomerular injury.

The nature of the initiating processes varies among different glomerular diseases. The nephrotic syndrome and glomerulonephritis (Table 107-1) are the key forms of glomerular disease. In the nephrotic syndrome (nephrosis), leakage of plasma proteins without inflammation is the primary pathogenic mechanism, whereas glomerulonephritis (nephritis) is characterized by glomerular inflammation that results in the passage of RBCs, white blood cells (WBCs), and plasma proteins into the urine. In some inflammatory diseases (e.g., lupus nephritis), nephrotic levels of proteinuria may be accompanied by cellular elements in a nephrotic-nephritic picture, whereas patients with milder involvement may have only isolated proteinuria or isolated hematuria.

In some conditions, such as diabetes and amyloidosis, structural and biochemical alterations are clearly present in the glomerular capillary wall. In others, immune-mediated kidney injury is caused by deposition of circulating immune complexes, in situ formation of immune complexes, or the localized effects of anti–glomerular basement membrane antibodies. Acquired defects in the glomerular podocytes in an increasingly recognized number of genetic glomerulopathies are also associated with proteinuria and progressive kidney dysfunction.

TABLE 107-1 TYPICAL FINDINGS IN NEPHROTIC SYNDROME VERSUS NEPHRITIS

NEPHROTIC SYNDROME	NEPHRITIS
KIDNEY INSUFFICIENCY ("AZOTEMIA")	
Uncommon at presentation	Common at presentation
PROTEINURIA	
Typically, high grade (>3 g/day)	Variable
Urine RBCs	
Few	Numerous (sometimes with RBC casts)
Urine RBC casts	
Unlikely	Likely

RBCs = red blood cells.

CLINICAL MANIFESTATIONS

Findings indicative of a glomerular origin of kidney disease include erythrocyte casts (Fig. 100-8) and dysmorphic RBCs in the urinary sediment, and abnormal amounts of albuminuria. Persistent urinary excretion of more than 500 to 1000 erythrocytes per milliliter (or more than 5 RBCs per high-power field on microscopy) is abnormal. Dysmorphic RBCs, which are deformed because of their passage through the glomerular capillary wall, as well as RBC casts, which are formed when these erythrocytes become enmeshed in a proteinaceous matrix in the lumen of the tubules, are also indicative of glomerular disease.

Proteinuria associated with glomerular disease may range from several hundred milligrams to more than 30 g daily. In some diseases, such as minimal change nephrotic syndrome, albumin is the predominant protein in the urine. In others, such as focal sclerosing glomerulonephritis and diabetes, the proteinuria, although still largely composed of albumin, is nonselective and contains many higher-molecular-weight proteins.

DIAGNOSIS

Some patients have asymptomatic microhematuria or proteinuria discovered by routine evaluations. Microscopic hematuria associated with deformed (dysmorphic) RBCs or RBC casts is likely to be glomerular in origin. Subnephrotic levels of proteinuria may arise from orthostatic proteinuria, exercise, hypertension, tubular disease, or glomerular damage.

In patients with asymptomatic urinary abnormalities of glomerular origin, the underlying kidney lesion may represent the early phase of a progressive glomerular disease or may be due to a benign, nonprogressive glomerular lesion. In general, if patients have less than 0.5 to 1.0 g of proteinuria daily or only glomerular microhematuria with a normal glomerular filtration rate (GFR) and no evidence of systemic disease, it is not necessary to proceed to a diagnostic kidney biopsy. Most of these patients need no immunosuppressive therapy. The patient can be followed closely, and biopsy need be performed only in patients with progressively increasing proteinuria or evidence of a decreasing GFR.[1]

THE NEPHROTIC SYNDROME

DEFINITION

The nephrotic syndrome (see Table 107-1) is defined by albuminuria of more than 3 to 3.5 g/day (or a ratio of 3.0 to 3.5 mg of protein per mg of creatinine in a random urine specimen) accompanied by hypoalbuminemia, edema, and hyperlipidemia. In practice, many clinicians refer to nephrotic range proteinuria regardless of whether patients have the other manifestations of the full syndrome.

EPIDEMIOLOGY

The annual incidence rate of the nephrotic syndrome in the U.S. is about 2 to 7 per 100,000 in children under age 16 years and about 3 per 100,000 among adults. The nephrotic syndrome may be primary and idiopathic (Table 107-2), or it may be caused by a known underlying condition, such as diabetes, amyloidosis, or systemic lupus erythematosus (Table 107-3). Although minimal change disease is the most common cause of nephrotic syndrome in children, idiopathic membranous nephropathy and focal segmental glomerular sclerosis

ABSTRACT

Glomerular diseases, which are characterized by pathologic alterations in normal glomerular structure and function, may result from systemic disease or from pathologic processes limited to the kidney (primary glomerular disease). The typical clinical signs of patients with glomerular disorders include edema, proteinuria, hematuria, hypertension, decline in kidney function, and abnormal urine sediments. A kidney biopsy is usually needed to make a specific diagnosis. Treatment of glomerular disease is based on the underlying pathogenic mechanism and may include conservative therapy (e.g., renin-angiotensin blockers and control of blood pressure), immunosuppressive therapy (e.g., in many primary glomerular diseases as well as autoimmune diseases such as lupus nephritis), or therapy directed against plasma cells (e.g., amyloidosis).

KEYWORDS

glomerular disease
nephrotic
nephritic
hematuria
proteinuria
glomerulonephritis

TABLE 107-2 SUBTYPES OF IDIOPATHIC NEPHROTIC SYNDROME IN ADULTS

SUBTYPE	INCIDENCE (%)
Minimal change disease	5-10
Focal segmental glomerulosclerosis	20-25
Membranous nephropathy	25-30
Membranoproliferative glomerulonephritis	5
Other proliferative and sclerosing glomerulonephritides	15-30

TABLE 107-3 NEPHROTIC SYNDROME ASSOCIATED WITH SPECIFIC CAUSES (SECONDARY NEPHROTIC SYNDROME)

SYSTEMIC DISEASES
Diabetes mellitus
Systemic lupus erythematosus and other collagen vascular diseases*
Amyloidosis (amyloid AL- or AA-associated)
INFECTIONS
Bacterial (congenital and secondary syphilis)*
Viral (hepatitis B, hepatitis C, HIV infection, infectious mononucleosis, cytomegalovirus infection)*
Parasitic (malaria, toxoplasmosis, schistosomiasis, filariasis)*
MEDICATION RELATED
Gold, mercury, and the heavy metals
Penicillamine
Nonsteroidal anti-inflammatory drugs, including COX2 inhibitors
Lithium
Captopril
"Street" heroin
Others: probenecid, chlorpropamide, rifampin, tolbutamide, phenindione, pamidronate
ALLERGENS, VENOMS, AND IMMUNIZATIONS
NEOPLASMS
Hodgkin lymphoma and leukemias/lymphomas (with minimal change lesion)
Solid tumors (with membranous nephropathy)
HEREDITARY AND METABOLIC DISEASES
Alport syndrome*
Fabry disease
Sickle cell disease
Diseases of the alternative complement pathway (C3 glomerulopathy and dense deposit disease)*
Genetic subtypes resulting from mutations in genes encoding podocyte proteins or mitochondrial proteins (isolated or syndromic)
OTHER
Pregnancy related (includes preeclampsia)
Chronic renal allograft nephropathy
Serum sickness
Accelerated hypertensive nephrosclerosis
Renal artery stenosis
Obesity
Reflux nephropathy

*Indicates disorders that could also present as a nephritic-nephrotic syndrome (RBC, RBC casts with nephrotic-range proteinuria).
COX = cyclooxygenase; HIV = human immunodeficiency virus; RBC = red blood cells.

are the most common causes in adults, with the former being most common in Whites and the latter in Blacks.

PATHOBIOLOGY

Hypoalbuminemia, which is largely a consequence of urinary protein loss, also may be due to proximal tubular catabolism of filtered albumin, the redistribution of albumin within the body, and reduced hepatic synthesis of albumin. As a result, the relationship among urinary protein loss, the level of the serum albumin, and other secondary consequences of heavy albuminuria is inexact.

Salt and volume retention in the nephrotic syndrome may occur via at least two different major mechanisms. In a minority of patients, hypoalbuminemia reduces the oncotic pressure of plasma, the resulting intravascular volume depletion leads to activation of the renin–angiotensin–aldosterone axis, and this activation increases the retention of kidney sodium and fluid. However, primary salt retention in the distal nephron, which occurs independently of the renin–angiotensin–aldosterone axis, is likely the main reason for salt and water retention in nephrosis.

Thromboembolism (Chapters 67 and 68) often occurs in patients with the nephrotic syndrome. Explanations include urinary loss of antithrombin III, protein C, and protein S, which prevent thrombosis, as well as increased synthesis of acute phase reactants that promote thrombosis.

Hyperlipidemia (Chapter 190), sometimes extreme, is common in the nephrotic syndrome, likely because low oncotic pressures upregulate hepatic synthesis of apolipoproteins. Alterations in key regulatory enzymes of lipid synthesis also contribute to the lipid abnormalities. Hyperlipidemia may be absent with some causes of the nephrotic syndrome (e.g., systemic lupus erythematosus, HIV-associated nephropathy, and amyloidosis), either because of hepatic involvement or because of a systemic inflammatory state.

CLINICAL MANIFESTATIONS

Patients may present with weight gain, peripheral edema when sitting or standing, and with periorbital edema on awakening. Hypertension is common, and varying degrees of hematuria may be present. A 24-hour urine sample (or urine protein/creatinine ratio) usually shows more than 3 to 3.5 g of proteinuria. Nephrotic patients often have a hypercoagulable state (Chapter 67) and are predisposed to deep vein thrombosis (Chapter 68), pulmonary emboli (Chapter 68), and renal vein thrombosis (Chapter 110). Patients with nephrotic syndrome have increased risk for atherosclerotic complications because of the hypercoagulability and also because most nephrotic patients have elevated levels of total and low-density lipoprotein (LDL) cholesterol and lipoprotein(a), with low or normal high-density lipoprotein (HDL) cholesterol.

DIAGNOSIS

Initial evaluation of the nephrotic patient includes laboratory tests to define whether the patient has primary or idiopathic nephrotic syndrome (see Table 107-2), or a secondary cause related to a systemic disease, toxin, or medication (see Table 107-3). Common screening tests include fasting blood sugar and glycosylated hemoglobin tests for diabetes, and antinuclear antibody test for collagen vascular disease. In patients with the nephritic or nephrotic-nephritic syndrome, a low serum complement level, suggests an immune complex–mediated disease (Table 107-4). In selected patients, cryoglobulins, hepatitis B and C serologies, HIV testing, antineutrophil cytoplasmic antibodies (ANCAs), anti-GMB antibodies, serum protein and immunofixation, and other tests may be useful.

A kidney biopsy is often required in the adult nephrotic patient. Biopsy results in patients with heavy proteinuria and the nephrotic syndrome are likely to provide a specific diagnosis, determine prognosis, and guide therapy.

TREATMENT

Treatment varies by the specific cause.[2] Elevated lipid levels should be treated (Chapter 190). Chronic oral anticoagulation (Chapter 70) with warfarin is needed if thrombotic complications occur and is commonly recommended in patients with additional risk factors for thrombosis (e.g., a prior idiopathic thromboembolic event, immobilization, severe heart failure, or morbid obesity). Warfarin also may be considered in patients who have membranous nephropathy with hypoalbuminemia (<2.8 g/L) and who are at low risk for bleeding. Data are insufficient regarding the use of the direct-acting oral anticoagulants.

Edema is treated with a low-salt diet and loop diuretics (Table 102-4). Use of maximally tolerated doses of angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (Table 64-7) often reduces proteinuria, increases the serum albumin level, and ameliorates the edema and hyperlipidemia. The combination of loop diuretics with intravenous albumin may be effective in patients with severe edema and signs of volume depletion.

IDIOPATHIC NEPHROTIC SYNDROME

MINIMAL CHANGE DISEASE

Minimal change disease, which is the most common pattern of nephrotic syndrome in children, accounts for only approximately 5 to 10% of cases of idiopathic nephrotic syndrome in adults. A similar histologic pattern may be seen as an adverse reaction to certain medications (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs], lithium) or in association with certain malignancies (e.g., Hodgkin disease). The presence of autoantibodies to the podocyte protein nephrin indicates an autoimmune pathogenesis in at least some cases.[3]

TABLE 107-4 SERUM COMPLEMENT LEVELS IN NEPHRITIC SYNDROME

REDUCED COMPLEMENT LEVEL (TYPICALLY WITH NEPHRITIS)
Infection-related glomerulonephritis (e.g., streptococcal infections, endocarditis, shunt infections)
Systemic lupus erythematosus
Cryoglobulinemia
C3 glomerulopathies
NORMAL SERUM COMPLEMENT LEVEL
Immunoglobulin A nephropathy and Henoch-Schönlein purpura
Anti–glomerular basement membrane disease
Pauci-immune rapidly progressive glomerulonephritis (e.g., granulomatous polyangiitis and microscopic polyangiitis)

CLINICAL MANIFESTATIONS

Patients typically present with weight gain and periorbital and peripheral edema. Proteinuria in adult patients can average as much as 10 g/day, and subnephrotic levels are rare. Approximately 30% of adults are hypertensive and 30% have microscopic hematuria. However, an active urinary sediment with RBC casts is not seen. Many adult patients have mild-to-moderate azotemia, which may be related to hypoalbuminemia and intravascular volume depletion or to a reduction in glomerular permeability and filtration. Complement levels and serologic test results are normal.

DIAGNOSIS

In minimal change disease, histopathology typically reveals no glomerular abnormalities on light microscopy (Fig. 107-1). The tubules may show lipid droplet accumulation from absorbed lipoproteins (hence the older term *lipoid nephrosis*). Immunofluorescence staining and electron microscopy (Fig. 107-2) show no immune-type deposits. By electron microscopy, the glomerular basement membrane is normal and effacement of the visceral epithelial foot processes is noted along virtually the entire distribution of every capillary loop (Fig. 107-2).

TREATMENT

The course of minimal change disease is often one of remissions followed by relapses. About 75 to 85% of adults respond to a regimen of either daily prednisone (1 mg/kg, maximum 80 mg) or alternate-day therapy (2 mg/kg, maximum 120 mg), tapered after 2 months of treatment for a total of 5 to 6 months of therapy.[A1] Adults are not considered steroid-resistant until they have failed to respond to 16 weeks of treatment. Tapering of the steroid dose after remission should be gradual over 1 to 2 months.

Approximately 40% of adults relapse by 1 year. Infrequent relapses can be treated similarly to the initial episode.

However, in adults who have contraindications to corticosteroids, who relapse frequently, or who become corticosteroid-dependent (defined as being unable to decrease the prednisone dose without recurrent proteinuria), equivalently efficacious options include rituximab (1000 mg IV repeated in 2 weeks), cyclosporine (3 to 5 mg/kg/day for 4 months), tacrolimus (0.05 to 0.1 mg/kg/day),[A2] or mycophenolate mofetil (750 to 1000 mg twice daily). Because cyclosporine and tacrolimus are potentially nephrotoxic, trough blood levels must be monitored, and the lowest level that is associated with remission should be maintained. Cyclophosphamide (up to 2 mg/kg/day for 8 weeks) also may be used but is less desirable because of its potential for gonadal toxicity and bone marrow suppression.

PROGNOSIS

The prognosis of minimal change disease is excellent. More than 50% of patients with minimal change disease have relapses, and 10 to 20% may become steroid-dependent. Most patients who have a progressive decline in kidney function exhibit focal segmental glomerulosclerosis rather than minimal change disease on a subsequent kidney biopsy.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Approximately 20% of adults with idiopathic nephrotic syndrome are found on biopsy to have focal segmental glomerulosclerosis. The incidence of focal segmental glomerulosclerosis is increasing in all races, but it is especially common in Black Americans.

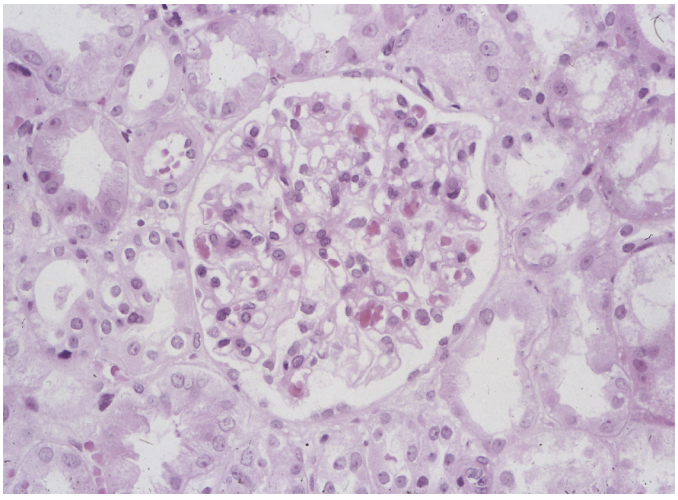

FIGURE 107-1. Unremarkable light microscopic appearance of minimal change disease glomerulopathy. Glomerular capillaries are patent and there is no glomerular hypercellularity.

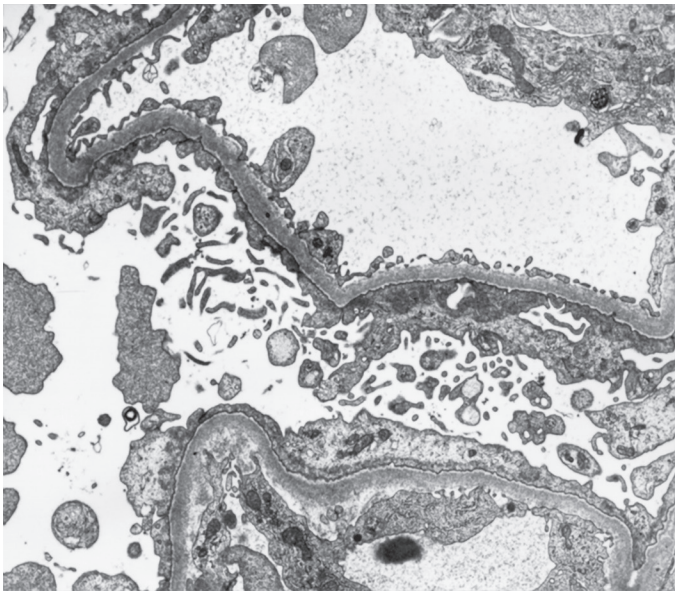

FIGURE 107-2. Minimal change disease. Electron micrograph shows widespread effacement of foot processes with microvillus transformation of the visceral epithelium. No electron-dense deposits are present (uranyl acetate, lead citrate stain; 6000×).

PATHOBIOLOGY

Several mechanisms are thought to underlie focal segmental glomerulosclerosis. In primary focal segmental glomerulosclerosis, glomerular permeability factors may cause direct injury to podocytes. In secondary focal segmental glomerulosclerosis, medications, viral infections,[4] or adaptive changes associated with glomerular hyperfiltration apparently cause the injury (Table 107-5).

Focal segmental glomerulosclerosis also can be associated with genetic variants in podocyte proteins. Pathogenic variants in collagen 4 appear to be emerging as the most common genetic form of focal segmental glomerulosclerosis. Other common defects include an autosomal recessive pattern caused by mutations in the structural protein podocin *(NPHS2)* and autosomal dominant forms caused by mutations in the structural protein α-actinin 4, the *TRPC6* glomerular slit diaphragm–associated channel, or *INF2*, which encodes a formin (actin-regulating protein). The predisposition of Black Americans to focal segmental glomerulosclerosis is partly related to two risk alleles of the apolipoprotein L1 *(APOL1)* gene, which apparently arose in high frequency because heterozygosity confers protection against African trypanosomiasis (Chapter 317), but for which biallelic inheritance increases the risk of focal segmental glomerulosclerosis by 10- to 20-fold. In the setting of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection, the collapsing variant of focal segmental glomerulosclerosis has been associated with high-risk apolipoprotein L1 alleles in Black American patients.[5]

TABLE 107-5 CAUSES OF SECONDARY FOCAL SEGMENTAL GLOMERULOSCLEROSIS

SECONDARY TO ALTERATIONS OF GLOMERULAR EPITHELIAL CELLS	
Viral infections	Human immunodeficiency virus (established) Cytomegalovirus (probably) Parvovirus B19, Epstein-Barr virus, hepatitis C virus (possibly) Hemophagocytic syndrome (possibly) Severe acute respiratory syndrome coronavirus-2 (with *APOL1* risk genotype)
Drug-induced	Direct-acting antiviral therapy mTOR inhibitors Calcineurin inhibitors Anthracyclines Heroin (adulterants) Lithium Interferon Anabolic steroids Nonsteroidal anti-inflammatory drugs
SECONDARY TO ADAPTIVE CHANGES WITH GLOMERULAR HYPERTENSION	
Reduced number of nephrons	Reflux nephropathy Renal dysplasia Oligomeganephronia Sickle cell disease Age-related focal segmental glomerulosclerosis
Normal number of nephrons	Obesity-related glomerulopathy Primary glomerular diseases Systemic diseases (e.g., diabetic nephropathy, hypertensive nephrosclerosis)

APOL1 = apolipoprotein L1; mTOR = mammalian target of rapamycin.

CLINICAL MANIFESTATIONS

Patients with primary focal segmental glomerulosclerosis typically present with proteinuria, hypoalbuminemia, and edema. Absence of hypoalbuminemia is associated with focal segmental glomerulosclerosis secondary to adaptive changes to glomerular hyperfiltration as opposed to primary focal segmental glomerulosclerosis where patients show low serum albumin. Hypertension is found in 30 to 50% of patients, and microscopic hematuria occurs in approximately half of patients. The GFR is decreased at presentation in 20 to 30% of patients. Complement levels and other serologic test results are normal.

DIAGNOSIS

The diagnosis requires kidney biopsy. By light microscopy, only some glomeruli (focal) initially have areas of scarring involving only portions of a glomerulus (segmental) (Fig. 107-3).[6] As kidney function declines, repeat biopsy specimens show more widespread glomerular involvement with segmental sclerosing lesions and increased numbers of globally sclerotic glomeruli. By immunofluorescence staining, immunoglobulin M (IgM) and C3 commonly are trapped in the areas of glomerular sclerosis. Electron microscopy shows no immune-type deposits and only visceral epithelial cell foot process effacement. Typically, primary focal segmental glomerulosclerosis is associated with extensive, diffuse foot process effacement, whereas these findings are segmental in the adaptive type of focal segmental glomerulosclerosis.

TREATMENT

For primary focal segmental glomerulosclerosis, corticosteroids (e.g., prednisone, 1 mg/kg/day, maximum 80 mg, or 2 mg/kg every other day, maximum 120 mg, as tolerated) are used as initial therapy for a minimum of 3 to 4 months and slowly tapered for a total of 6 months of therapy if remission is noted. A complete or partial remission may be seen in up to 40 to 60% of patients, with preservation of long-term kidney function. Patients who do not show any improvement in 4 to 8 weeks are less likely to respond and may be switched to second-line therapy, rather than being continued on high doses of corticosteroids. Patients who do not achieve remission within 4 months are termed steroid-resistant.

In patients who are steroid-resistant, cyclosporine (5 to 6 mg/kg/day) or tacrolimus (0.05 to 0.1mg/kg/day) is recommended.[A3] A minimum duration of 6 months is recommended before declaring resistance to calcineurin inhibitors. If remission occurs, a minimum of 12 months of therapy followed by a slow taper is suggested. Careful monitoring of kidney function and serum drug levels are necessary to avoid nephrotoxicity. Rituximab (e.g., two 1-g doses 1 week apart) has been used successfully in steroid-dependent or frequently relapsing patients,[7] but it is less effective in steroid-resistant patients.

Genetic forms of focal segmental glomerulosclerosis typically do not respond to immunosuppressive therapy. Treatment is conservative using ACE-inhibitors and angiotensin receptor blockers for blood pressure control (Table 64-7).

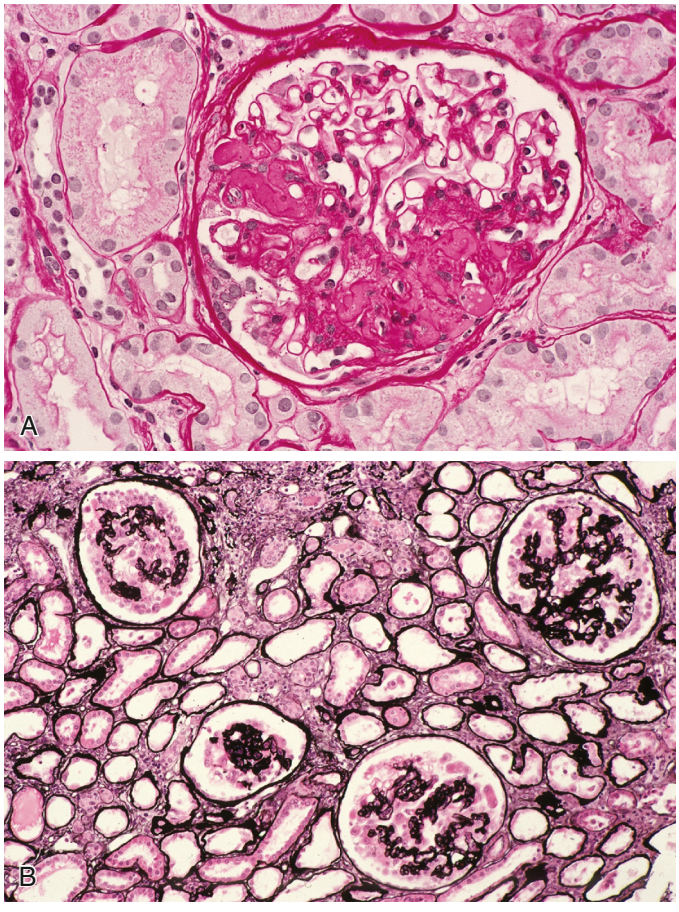

FIGURE 107-3. Focal segmental glomerulosclerosis. A, Segmental obliteration of glomerular capillaries by acellular matrix (sclerosis), which stains red with periodic acid–Schiff (PAS). **B,** Collapsing variant focal segmental glomerulosclerosis showing implosive collapse of the glomerular capillaries and hyperplasia of overlying epithelial cells (silver stain).

PROGNOSIS

The course of untreated focal segmental glomerulosclerosis is usually one of progressive proteinuria and declining GFR. The histopathologic variants of focal segmental glomerulosclerosis are associated with epidemiologic, clinical, and prognostic differences. For example, the "tip" variant has a relatively benign course, whereas the "collapsing" variant progresses more rapidly to kidney failure.

Only a minority of patients experience a spontaneous remission of proteinuria, and most untreated patients who do not remit eventually develop end-stage renal disease within 5 to 20 years. Patients with a sustained remission of their nephrotic syndrome are unlikely to progress to end-stage renal disease.

Most patients with genetic forms of focal segmental glomerulosclerosis are treatment-resistant, have a progressive course, and do not experience recurrences of the focal segmental glomerulosclerosis if they receive a kidney transplant. Primary focal segmental glomerulosclerosis recurs in the transplanted kidney in up to 30% of cases. Younger patients, those with a rapid course to kidney failure, and those with a prior recurrence are more likely to recur in the allograft.

MEMBRANOUS NEPHROPATHY

Membranous nephropathy is the most common pattern of idiopathic nephrotic syndrome in White patients. It also may be associated with infections (syphilis [Chapter 295], hepatitis B and C [Chapter 134]), systemic lupus erythematosus (Chapter 245), medications (gold salts, NSAIDs), and certain tumors (solid tumors and lymphomas). In most patients with primary membranous nephropathy, the antigen in the immune deposits is the M-type phospholipase receptor (PLA2R), which is present in podocytes.[8] Circulating PLA2R antibodies,

which are highly specific for the diagnosis of primary membranous nephropathy, combine with this antigen to form in situ immune complexes on the epithelial side of the basement membrane, thereby leading to proteinuria. Other recently implicated antigens associated with primary membranous nephropathy include exostosin, NCAM-1 (neural cell adhesion molecule 1), NELL-1 (neural epidermal growth factor–like 1 protein), PCDH7 (protocadherin 7), and SEMA3B (semaphoring 3B).[9] About 10% of patients have circulating autoantibodies to the thrombospondin type-1 domain-containing 7 A (THSD7A), which has been associated with malignancy-related membranous nephropathy.

CLINICAL MANIFESTATIONS

Membranous nephropathy typically manifests with proteinuria and edema. Hypertension and microhematuria are not infrequent, but kidney function and GFR are usually preserved at presentation. Despite the finding of complement in the glomerular immune deposits, serum complement levels are normal. Membranous nephropathy is the most common pattern of the nephrotic syndrome to be associated with a hypercoagulable state and renal vein thrombosis (Chapter 110). The presence of sudden flank pain, deterioration of kidney function, or acute pulmonary symptoms in a patient with membranous nephropathy should prompt an investigation for renal vein thrombosis and pulmonary emboli. Conversely, the presence of otherwise unexplained thromboembolism should lead to a search for nephrotic syndrome.

DIAGNOSIS

A kidney biopsy is not required to confirm the diagnosis of membranous nephropathy in patients who have nephrotic syndrome, intact kidney function, absence of systemic disease, and a positive anti-PLA2R antibody test.[10] Otherwise, a kidney biopsy is required to make the diagnosis and to exclude other glomerulopathies.

On light microscopy, the glomerular capillary loops often appear rigid or thickened (Fig. 107-4), but cellular proliferation is not seen. Immunofluorescence staining and electron microscopy show immune deposits along the glomerular capillary loops beneath the visceral epithelial cell layer (Fig. 107-5). The presence of circulating antibodies to the M-type phospholipase A_2 receptor are highly sensitive and specific for idiopathic membranous nephropathy, as is the finding of PLA2R antigen in the immune deposits in the kidney.

In patients who do not have PLA2R or other recently described antibodies, membranous nephropathy may be the result of an underlying condition. In such patients, a search for systemic disease (e.g., systemic lupus erythematosus; Chapter 245), infection (e.g., syphilis [Chapter 295] and hepatitis B and C [Chapter 134]), and occult malignancy should be undertaken.

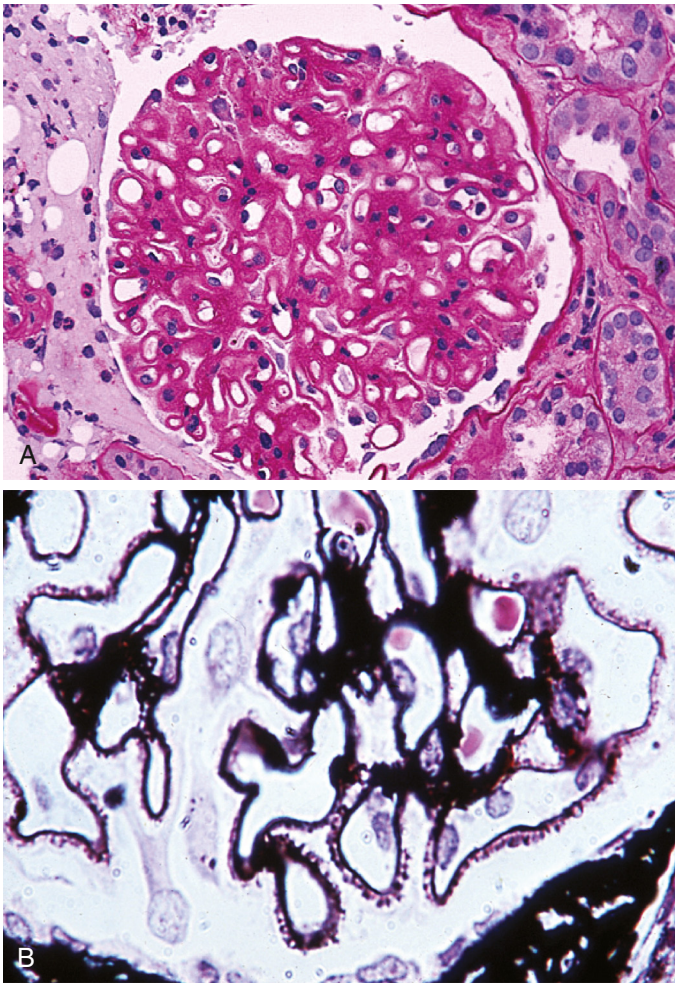

FIGURE 107-4. Membranous nephropathy. A, Light micrograph of membranous nephropathy demonstrating thickening of the glomerular capillary wall but no hypercellularity. **B**, Silver stain of idiopathic membranous nephropathy showing spike formation along the outer aspect of the glomerular basement membrane corresponding to projections of the basement membrane between the epimembranous deposits.

TREATMENT

All patients should receive optimal supportive care including blood pressure control and maximally tolerated doses of renin–angiotensin blockers (Table 64-7). Immunosuppressive therapy should be restricted to patients who are considered at risk for progressive kidney damage (Fig. 107-6).[A4,A5]

Cyclosporine (3.5 mg/kg/day adjusted to serum levels of 125 to 225 µg/L) plus prednisone (0.15 mg/kg/day up to a maximum of 15 mg/day) is the recommended initial therapy. Success with tacrolimus (0.05 to 0.10 mg/kg/day to target trough levels 3 to 8 ng/mL) has been similar to that with cyclosporine. Cyclosporine or tacrolimus should be used for a minimum of 4 months and withdrawn if there is no response. In the event of remission, treatment should be for a minimum of 12 months, usually with slow taper thereafter. Use of the anti-CD20 antibody rituximab (1000 mg IV × 2, 2 weeks apart then repeated at 6 months, if needed) has shown benefit in inducing remission.[A6] In patients at a high risk of progression, addition of rituximab after 6 months of treatment with cyclosporine is one alternative. However, the combination of corticosteroids (e.g., methylprednisolone, 1 g/day intravenously for 3 days, then prednisone, 0.5 mg/kg/day orally for 27 days, in months 1, 3, and 5) plus oral cytotoxic therapy (cyclophosphamide, 2 to 2.5 mg/kg/day, for 30 days in months 2, 4, and 6) is an alternative to rituximab[A7] for high-risk patients and is the suggested therapy for very high-risk patients.

Longitudinal monitoring of anti-PLA2R antibody levels at 6 months after the start of therapy may be useful for evaluating the response to treatment in patients, and can be used to guide adjustments to therapy.[11] Immunologic remission typical precedes proteinuric remission, and disappearance of the PLA2R antibody in patients who were positive allows discontinuation of immunosuppression despite persistent proteinuria.

In patients who do not respond to initial therapy, medications such as mycophenolate mofetil and adrenocorticotropic hormone may be attempted. However, nonresponsive patients should be referred to a specialized center with expertise in managing membranous nephropathy.

PROGNOSIS

In most large series, kidney survival in membranous nephropathy is more than 75% at 10 years, with a spontaneous remission rate of 20 to 30%. Patients with membranous nephropathy are at increased risk for developing renal vein thrombosis (Chapter 110), especially when their serum albumin levels decline.

In general, older patients, males, and those with heavy persistent proteinuria are most likely to progress to kidney failure and hence to benefit from therapy. Patients with primary membranous nephropathy and low levels of anti-*PLA2R* are more likely to have a spontaneous remission than are patients with high levels. Reductions of the circulating level of antibody to *PLA2R* precedes remission in most persons and may be a predictor of remission.

GLOMERULONEPHRITIS AND THE NEPHRITIC SYNDROME

EPIDEMIOLOGY AND PATHOBIOLOGY

The annual incidence of primary glomerulonephritis in U.S. adults is estimated to be between 0.2 to 2.5/100,000/year, with lower rates in children. The pathogenesis of glomerulonephritis includes infectious agents that activate the complement pathway. Glomerulonephritis also can be caused by the deposition of immune complexes in autoimmune diseases such as systemic lupus erythematosus (Chapter 245), IgA nephropathy, and from the effect of circulating antibodies directed against the glomerular basement membrane. Direct damage from activated white blood cells in the presence of antineutrophil cytoplasmic antibodies can also lead to the nephritic syndrome.

Invading neutrophils and monocytes, as well as resident glomerular cells, can damage the glomerulus through a number of mediators, including oxidants, chemoattractant agents, proteases, cytokines, and growth factors. Some

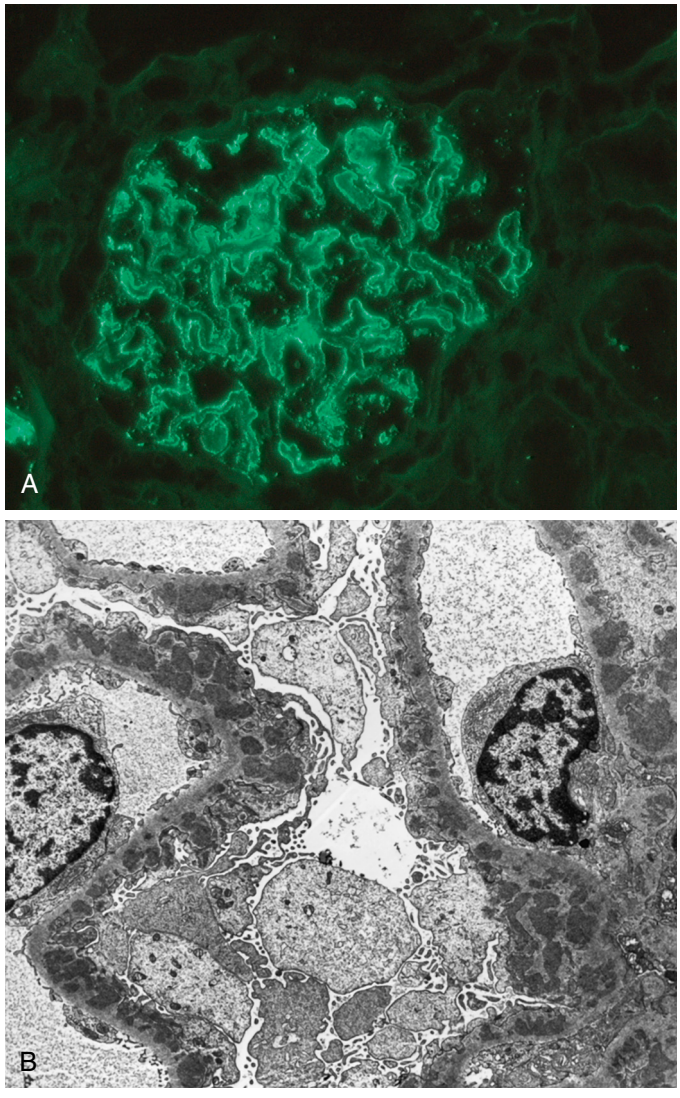

FIGURE 107-5. Membranous glomerulopathy. A. Granular capillary wall deposits of IgG on immunofluorescence microscopy. **B.** On ultrastructural examination, numerous, closely apposed epimembranous electron-dense deposits are separated by basement membrane spikes (uranyl acetate, lead citrate stain; 2500×).

factors, such as transforming growth factor-β, have been related to eventual glomerulosclerosis and chronic glomerular damage.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with glomerulonephritis present with a nephritic picture characterized by a azotemia, oliguria, hypertension, and an active urinary sediment with hematuria and red blood cell casts (see Fig. 100-8 and Table 107-1).[12] Hypertension is common and is caused by intravascular volume expansion. Patients may note dark, smoky, or cola-colored urine or hematuria, and the urine sediment is typically composed of erythrocytes, leukocytes, and a variety of casts, including red blood cell casts. The degree of proteinuria is variable from subnephrotic to the nephrotic range. An impairment of the GFR is common. Serum complement levels may be low in the immune complex–related cause (Table 107-4). Regardless of the inciting cause, glomerulonephritis is characterized on light microscopy by hypercellularity of the glomerulus, which may be composed of infiltrating inflammatory cells, proliferation of resident glomerular cells, or both. The mechanisms associated with the various forms of glomerulonephritis are based on staining patterns on immunofluorescence microscopy (Fig. 107-7).

IMMUNOGLOBULIN A NEPHROPATHY

EPIDEMIOLOGY AND PATHOBIOLOGY

IgA nephropathy is the most frequent form of idiopathic glomerulonephritis worldwide; it represents 15 to 40% of primary glomerulonephritis in parts of Europe and Asia but is uncommon in people of African ancestry. In the United States, some centers report this diagnosis in up to 20% of all primary glomerulopathies. Males outnumber females, with peak occurrence in the second to third decades of life.

In IgA nephropathy, most patients and many of their direct blood relatives have elevated circulating levels of IgA molecules that are galactose deficient at the hinge region. The predominant form of IgA is composed of polymeric IgA1. Patients, but not relatives, have circulating IgG and IgA autoantibodies against this galactose-deficient IgA. It is thought that a second "hit" phenomenon (e.g., infection, oxidative stress, etc.) stimulates production of these antibodies, and then the resulting immune complexes deposit in the glomeruli, thereby leading to an inflammatory reaction and consequent glomerulosclerosis and interstitial fibrosis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

IgA nephropathy often presents either as asymptomatic microscopic hematuria with or without proteinuria (the most common presentation in adults) or as episodic gross hematuria after an upper respiratory tract infection or exercise (the most common presentation in children and young adults).[13,14] Approximately 20 to 50% of all patients have hypertension.

IgA nephropathy has no validated diagnostic serum or urine biomarkers. Serum complement levels are typically normal. The diagnosis of IgA nephropathy is established on kidney biopsy by finding dominant or codominant IgA deposits on immunofluorescence microscopy (Fig. 107-8). Deposits of C3 and IgG also are often found. Light microscopy varies from the most common pattern of mild mesangial proliferation to severe crescentic glomerulonephritis. By electron microscopy, immune-type dense deposits are typically found in the mesangial and paramesangial areas.

Secondary causes of IgA nephropathy include viral (HIV [Chapter 359], viral hepatitis [Chapter 135]), inflammatory bowel disease (Chapter 127), autoimmune diseases (Chapter 236), liver cirrhosis (Chapter 139), and IgA-dominant infection-related glomerulonephritis. Variant forms of IgA nephropathy that require specific intervention include IgA deposition with minimal change disease, IgA nephropathy with acute kidney injury, and IgA nephropathy with rapidly progressive glomerulonephritis.

TREATMENT

The main focus of treatment of primary IgA nephropathy is optimized supportive care,[A8] including optimizing blood pressure, with dietary sodium restriction and the use of renin angiotensin blockers at maximally tolerated doses (Table 64-7) for patients whose urine protein is greater than 0.5 g/day, regardless of whether hypertension exists. Patients who present with gross hematuria and acute kidney injury should be treated conservatively because the majority will recover without intervention. No specific dietary intervention has shown to affect progression.

In patients who are at high risk of progression (defined as proteinuria >0.75 to 1g/day despite ≥90 days of optimized supportive care), immunosuppressive treatment should be considered, although its renal benefits are at least partly countered by its side effects.[A9] Corticosteroids are the preferred agents, typically with prednisone (1mg/kg/day for 2 months followed by a tapering schedule over a total of 6 months).[A10] Targeted-release oral budesonide (16 mg/day) to the distal ileum, where mucosal immune dysfunction may be the precipitating cause of the IgA complexes, reduces proteinuria.[A11] Dapagliflozin (10 mg/day) is associated with a reduction in albuminuria and a slower rate of progression of kidney disease.[A12] Omega-3 fish oils are not of proven benefit and are not recommended. Mycophenolate analogs and hydroxychloroquine have shown efficacy in small trials in China.

Nephrotic syndrome with minimal IgA deposits resembles minimal change disease and should be treated as such (see earlier). Rapidly progressive glomerulonephritis with crescents (defined as ≥50% decline in eGFR over <3 months) may rarely occur with IgA nephropathy. Such patients should be treated with corticosteroids and cyclophosphamide, similar to the treatment of antineutrophil cytoplasmic antibody–associated vasculitis (see later).

PROGNOSIS

The course is variable, with some patients showing no decline in GFR over decades and others developing the nephrotic syndrome, hypertension, and kidney failure. The International IgAN Prediction Tool (https://qxmd.com/calculate/calculator_499/international-igan-prediction-tool-at-biopsy-adults?_branch_match_id=656546875419766679) is a valuable resource to quantify the risk of progression and to inform shared decision-making.[15]

Kidney survival rates are estimated at 80 to 85% at 10 years and 65% at 20 years. A significant percentage of transplant recipients have a morphologic recurrence in the allograft, but graft loss is uncommon.

Low risk	Moderate risk	High risk	Very high risk
• Normal eGFR, proteinuria <3.5 g/day, and serum albumin level >3.0 g/dL OR • Normal eGFR and proteinuria <3.5 g/day (or a decrease >50% after 6 months of conservative therapy with an angiotensin converting enzyme inhibitor or an angiotensin receptor blocker)	• Normal eGFR, proteinuria >3.5 g/day (and a failure decrease >50% after 6 months of conservative therapy with an angiotensin converting enzyme inhibitor or an angiotensin receptor blocker) AND • Not fulfilling high-risk criteria	• eGFR <60 mL/min/1.73 m^2 and/or proteinuria >8 g/day for >6 months OR • Normal eGFR, proteinuria >3.5 g/day, and no decrease >50% after 6 months of conservative therapy with an angiotensin converting enzyme inhibitor or an angiotensin receptor blocker AND at least one of the following: • Serum albumin level <2.5 g/dL • PLA2Rab >50 RU/mL • Urinary α_1-microglobulin >40 µg/min • Urinary IgG >1 µg/min • Urinary β_2-microglobulin >250 mg/day • Selectivity index >0.20	• Life-threatening nephrotic syndrome OR • Rapid deterioration of kidney function not otherwise explained

IgA VASCULITIS (HENOCH-SCHÖNLEIN PURPURA)

IgA vasculitis, also called Henoch-Schönlein purpura (Chapter 249), is characterized by a small-vessel vasculitis with arthralgias, skin purpura, and abdominal symptoms, as well as a proliferative acute glomerulonephritis. IgA vasculitis is predominantly a disease of childhood, although cases occur at all ages.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical manifestations of IgA vasculitis (Chapter 249) include dermatologic, gastrointestinal, rheumatologic, and renal findings.[16] Skin involvement typically starts with a macular rash that coalesces into purpuric lesions (see Fig. 249-2) on the ankles, legs, and occasionally arms and buttocks. Gastrointestinal symptoms include cramps, diarrhea, nausea, and vomiting, with melena and bloody diarrhea in the most severely involved cases. Although arthralgias of the knees, wrists, and ankles are common, true arthritis is uncommon. Symptoms of different organ system involvement may occur concurrently or separately, and recurrent episodes during the first year are not uncommon.

The clinical presentation resembles small vessel vasculitis and cryoglobulinemic vasculitis. As with IgA nephropathy, patients and their relatives have elevated levels of circulating IgA molecules that are galactose deficient. Kidney biopsies are identical to those seen in IgA nephropathy. Skin biopsies typically show a small-vessel leukocytoclastic angiitis with immune deposition of IgA. The presence of hypertension and degree of proteinuria influences the kidney prognosis especially if persistent over time. Treatment approaches are similar to IgA nephropathy.

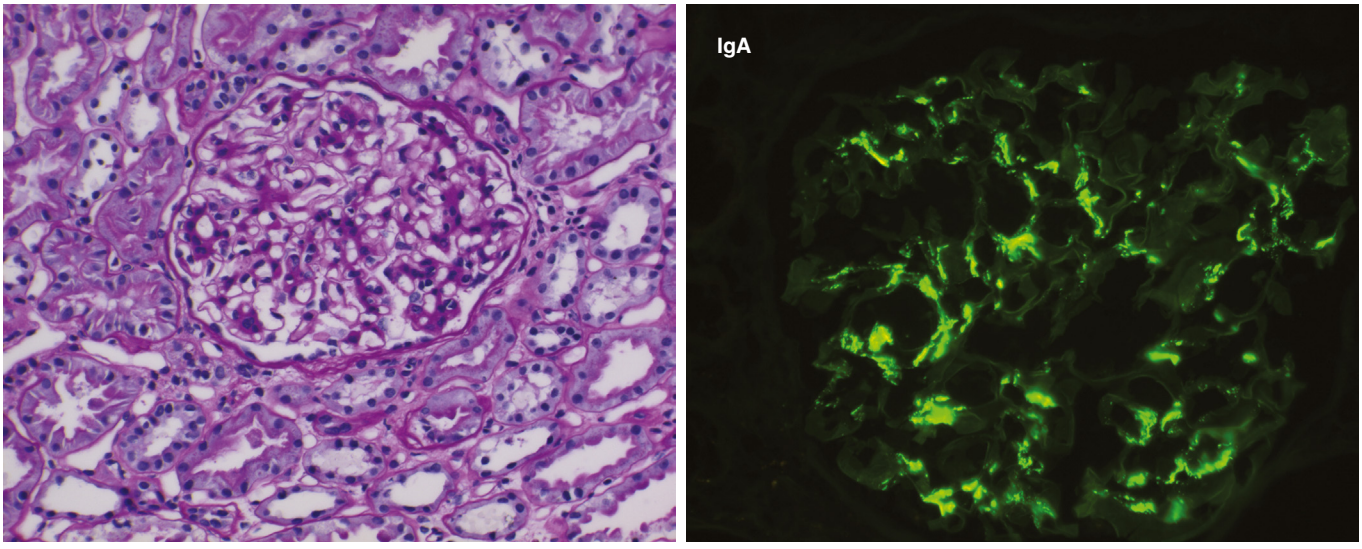

FIGURE 107-8. **Immunoglobulin A (IgA) nephropathy with mesangial cell proliferation by light microscopy and IgA deposition on immunofluorescence.**

POST-STREPTOCOCCAL GLOMERULONEPHRITIS

Acute post-streptococcal glomerulonephritis may occur in either an epidemic form or as sporadic cases after infection with nephritogenic strains of group A β-hemolytic streptococci (Chapter 269). Post-streptococcal glomerulonephritis is largely a disease of childhood, but severe disease in adults is well documented. The disease is most common after episodes of pharyngitis, but it can follow streptococcal infections at any site and subclinical cases greatly outnumber clinical cases. Post-streptococcal glomerulonephritis is an acute immune complex disease characterized by the formation of antibodies against streptococci with the localization of immune complexes and complement in the kidney. With improved socioeconomic conditions, the incidence of post-streptococcal glomerulonephritis has declined in developed nations. In adults, non-streptococcal bacterial infections are more common causes of infection-related glomerulonephritis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most cases manifest with hematuria, proteinuria, hypertension, and the nephritic syndrome (see Table 107-1) 10 days to several weeks after a streptococcal infection. Throat cultures and skin cultures of suspected sites of streptococcal involvement may no longer show group A β-hemolytic streptococci. A variety of antibodies (e.g., antistreptolysin O [ASLO], antihyaluronidase [AHT]) and a panel of antibodies against streptococcal antigens (which includes ASLO, AHT, antistreptokinase, and anti-DNase) often show high titers, but a change in titer over time is more indicative of a recent streptococcal infection. More than 95% of patients with post-streptococcal glomerulonephritis secondary to pharyngitis and 85% of patients with streptococcal skin infections have positive antibody titers. Complement C3 levels are decreased in more than 90% of patients during the episode of acute glomerulonephritis.

In a patient with a classic acute nephritic episode after a documented streptococcal infection, with a change in streptococcal antibody titer and a depressed serum complement level, a kidney biopsy adds little to the diagnosis. In other cases, a biopsy may be necessary to confirm the diagnosis. On light microscopy (Fig. 107-9), glomeruli are markedly enlarged and often fill the Bowman space. Glomeruli exhibit hypercellularity with infiltration of monocytes and polymorphonuclear cells and a proliferation of the glomerular cellular elements. The capillary lumens often are compressed. Some cases demonstrate extracapillary proliferation with crescents. On immunofluorescence microscopy, there is coarse granular deposition of IgG, IgM, and complement, especially C3, along the capillary wall. Electron microscopy shows large dome-shaped, electron-dense subepithelial deposits along the glomerular basement membrane.

TREATMENT AND PROGNOSIS

Therapy is symptomatic and directed at controlling the hypertension (see Table 64-7) and fluid retention with diuretic agents (Table 102-4) as needed. In most patients, this disease is self-limited, with recovery of kidney function and disappearance of hypertension in several weeks.[17] However, the presence of underlying kidney disease, especially diabetic nephropathy, is associated with a worse prognosis. Proteinuria and hematuria may resolve more slowly over months.

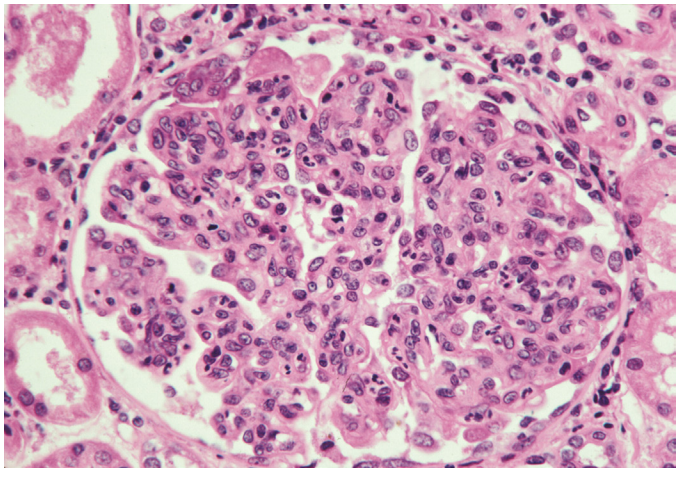

FIGURE 107-9. **Post-streptococcal glomerulonephritis.** A hypercellular glomerulus infiltrated by numerous polymorphonuclear leukocytes.

GLOMERULONEPHRITIS WITH ENDOCARDITIS, VISCERAL ABSCESSES, AND OTHER INFECTIONS

Various glomerular lesions are found in patients with acute and chronic bacterial endocarditis (Chapter 61). Although embolic phenomena can lead to glomerular ischemia and infarcts, a common finding is an immune complex glomerulonephritis. With *Streptococcus viridans* endocarditis, both focal or diffuse proliferative glomerulonephritis may be seen. With the increased incidence of *Staphylococcus aureus* endocarditis, 40 to 80% of patients have clinical evidence of an immune complex proliferative glomerulonephritis. Glomerulonephritis is now more common with acute than subacute bacterial endocarditis.[18]

Patients often have hematuria and urinary RBC casts, proteinuria ranging from less than 1 g/day to nephrotic levels, and progressive kidney failure. Serum complement C3 levels are usually reduced. Antineutrophil cytoplasmic antibodies (ANCA) occasionally may be positive, thereby leading to diagnostic confusion. Kidney insufficiency may be mild and reversible with appropriate antibiotic therapy, or it may be progressive and lead to dialysis and irreversible kidney failure.

A proliferative immune complex glomerulonephritis also can occur in patients with deep visceral bacterial abscesses and infections, such as empyema of the lung (Chapter 86) and osteomyelitis (Chapter 251). Immune complex forms of acute glomerulonephritis also have been noted in patients with bacterial pneumonias, including *Mycoplasma* (Chapter 293), and patients with chronically infected cerebral ventriculoatrial shunts for hydrocephalus. Many of these patients have nephrotic-range proteinuria and only mild kidney dysfunction. With appropriate antibiotic therapy, most glomerular lesions heal and kidney function recovers.

TABLE 107-6 CLASSIFICATION OF RAPIDLY PROGRESSIVE (CRESCENTIC) GLOMERULONEPHRITIS

PRIMARY
Anti–glomerular basement membrane antibody disease, Goodpasture syndrome (with pulmonary disease)
Immune complex–mediated
Pauci-immune (usually antineutrophil cytoplasmic antibody-positive)
SECONDARY
Membranoproliferative glomerulonephritis
IgA nephropathy, Henoch-Schönlein purpura
Post-streptococcal glomerulonephritis
Systemic lupus erythematosus

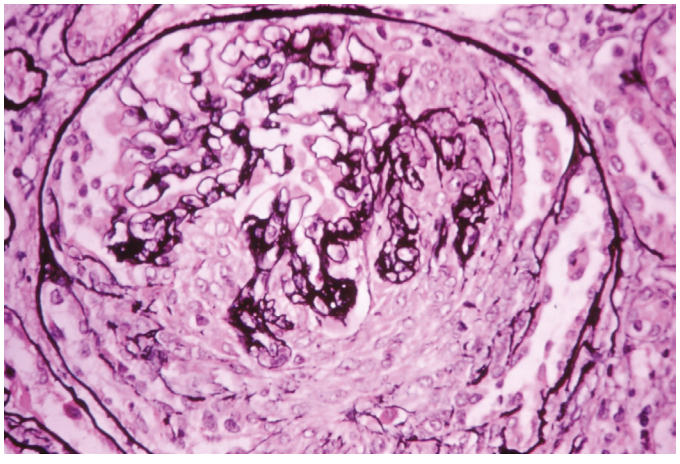

FIGURE 107-10. Rapidly progressive glomerulonephritis. A proliferation of cells in the Bowman space forming a crescent, with compression of the glomerular tuft.

An increased frequency of proliferative glomerulonephritis is also associated with staphylococcal infections in patients with diabetes. This glomerulonephritis is associated with IgA immune deposits (IgA-dominant infection related glomerulonephritis) in the glomeruli and has a poor prognosis.

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Rapidly progressive glomerulonephritis includes glomerular diseases that progress to kidney failure in a matter of weeks to months (Table 107-6).[19] The kidney biopsy shows extensive extracapillary proliferation manifested as crescent formation in the Bowman space (Fig. 107-10). The pathogenic mechanisms include linear anti–glomerular basement membrane antibodies, granular immune complex deposition (e.g., systemic lupus erythematosus, IgA vasculitis, infection-related glomerulonephritis), and pauci-immune, usually ANCA-positive, small vessel vasculitis.

ANTI–GLOMERULAR BASEMENT MEMBRANE DISEASE

Anti–glomerular basement membrane disease has two peaks of occurrence: in the third decade of life, predominantly in men, and after 60 years of age, predominantly in women. Anti–glomerular basement membrane disease (Fig. 107-11) is caused by circulating antibodies that are directed against the noncollagenous domain of the α_3 chain of type IV collagen. These antibodies damage the glomerular basement membrane, thereby resulting in an inflammatory response, breaks in the glomerular basement membrane, and the formation of a proliferative and often crescentic glomerulonephritis. If the anti–glomerular basement membrane antibodies cross-react with and damage the basement membrane of pulmonary capillaries, the patient develops pulmonary hemorrhage and hemoptysis, an association called Goodpasture syndrome and one of several diseases that can present with concomitant kidney and lung disease (Table 107-7).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients present with a nephritic picture (see Table 107-1). Kidney function may deteriorate from normal to dialysis-requiring levels in a matter of days to weeks.[20] Patients with pulmonary involvement may have life-threatening hemoptysis with dyspnea and with diffuse alveolar infiltrates on chest radiograph. The pathology of anti–glomerular basement membrane disease shows a proliferative glomerulonephritis, often with severe crescentic proliferation in the Bowman space (see Fig. 107-10). There is linear deposition of immunoglobulin (usually IgG) along the glomerular basement membrane by immunofluorescence (see Fig. 107-11), but electron microscopy does not show electron-dense deposits.

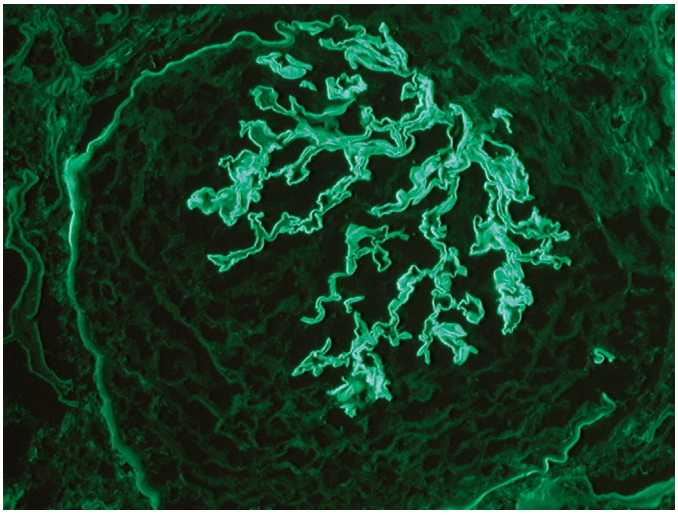

FIGURE 107-11. Anti–glomerular basement membrane glomerulonephritis. An immunofluorescence micrograph of a portion of a glomerulus with anti–glomerular basement membrane glomerulonephritis shows linear staining of glomerular basement membrane for immunoglobulin G (IgG) (fluorescein isothiocyanate anti-IgG stain, ×400).

TABLE 107-7 CLINICAL SYNDROMES OF KIDNEY DISEASES WITH CONCOMITANT PULMONARY DISEASES

DISEASE	MARKER
Goodpasture syndrome	+Anti–glomerular basement membrane antibodies
Small vessel vasculitis (granulomatous polyangiitis and microscopic polyangiitis)	+Antineutrophil cytoplasmic antibodies
Cryoglobulinemic vasculitis	Low C4 complement, +serum cryoglobulins
Systemic lupus erythematosus	+Anti-DNA antibodies, low complement
Nephrotic syndrome, renal vein thrombosis, pulmonary embolus	+Lung scan or +CT angiography
Pneumonia with immune complex glomerulonephritis	Low complement, circulating immune complexes
Uremic lung	Elevated creatinine level

CT = computed tomography.

TREATMENT

Although the treatment of this anti–glomerular basement membrane disease has not been studied in large controlled trials, intensive immunosuppressive therapy is recommended with corticosteroids, cyclophosphamide, and plasmapheresis. Rapid treatment is necessary to prevent irreversible kidney damage and is also needed in patients with pulmonary hemorrhage. The possible exceptions to immunosuppression are patients who have 100% crescents or more than 50% global glomerulosclerosis in an adequate biopsy sample without pulmonary hemorrhage and who are treated with dialysis at presentation, because the prognosis for renal recovery is poor.

Corticosteroids are given as daily pulse methylprednisolone (15 to 30 mg/kg to a maximum dose of 1000 mg/day IV for three doses), followed by prednisone (1 mg/kg/day orally to a maximum of 60 to 80 mg/day), and slowly tapered over 6 months. Cyclophosphamide (2 to 3 mg/kg/day orally, dose adjusted to kidney function, age, and the granulocyte count) for 3 months is also given. Daily plasmapheresis (40 to 50 mL/kg) against albumin is also recommended until anti–glomerular basement membrane antibodies are negative, typically

within 14 days. This combination therapy is effective in 90% of patients with lung hemorrhage. In patients who present with a serum creatinine less than 5.6 mg/dL, kidney survival is about 95% at 5 years. When the creatinine at presentation is greater than 5.6 mg/dL but the patient does not require immediate dialysis, renal survival is about 80% at 1 year and 50% at 5 years. In patients who present with an initial requirement for dialysis, however, renal recovery occurs only in about 8% of patients at 1 year. Relapses and recurrences are very rare after kidney transplantation.

IMMUNE COMPLEX RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Rapidly progressive glomerulonephritis-associated immune complex–mediated glomerular damage can be seen with idiopathic glomerulopathies, such as IgA nephropathy, IgA vasculitis, and idiopathic membranoproliferative glomerulonephritis, or with systemic diseases, such as infection-related glomerulonephritis, cryoglobulinemic vasculitis, and systemic lupus erythematosus. Many cases of crescentic postinfectious glomerulonephritis resolve with successful treatment of the underlying infection. The treatments of others are as described elsewhere in this chapter.

PAUCI-IMMUNE AND VASCULITIS-ASSOCIATED RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Pauci-immune rapidly progressive glomerulonephritis includes patients with and without evidence of systemic vasculitis. Most patients have circulating antineutrophil cytoplasmic antibodies (ANCAs) that are directed against components of neutrophil primary granules.[21] Clinical syndromes of ANCA-associated vasculitis include granulomatous polyangiitis (Chapter 249), microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis (Chapter 249).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with ANCA-associated vasculitis often present with progressive kidney failure and a nephritic picture (see Table 107-1). Patients with microscopic polyangiitis often have circulating perinuclear ANCA (antibodies directed against granulocyte myeloperoxidase) and a systemic clinical picture (Chapter 249) with arthritis, dermal leukocytoclastic vasculitis, pulmonary disease, and constitutional and systemic signs. Patients with granulomatous polyangiitis often have circulating cytoplasmic ANCA (antibodies directed against a granulocyte serine proteinase, anti-PR3), upper and lower respiratory tract involvement by granulomatous angiitis, as well as pauci-immune glomerulonephritis (Chapter 249). However, there is considerable overlap among these groups, and some patients have both ANCA and anti–glomerular basement membrane antibodies. Patients with eosinophilic granulomatosis with polyangiitis usually have a history of asthma, pulmonary infiltrates, and circulating eosinophilia. If they are ANCA positive, they often have associated glomerular disease. Although there is no direct correlation between ANCA titers and disease activity, patients with high titers (especially high anti-PR3 titers) and patients with a major recent increase in titers are more likely to have flares of their disease.

TREATMENT

For induction therapy (Fig. 107-12), corticosteroids in combination with cyclophosphamide or rituximab should be used as initial treatment. Corticosteroids are typically administered as pulse methylprednisolone (10 to 15 mg/kg/day up to a maximum of 500 to 1000 mg/day IV for 3 days, followed by prednisone or equivalent, 1 mg/kg/day orally for the first week). By 6 months, prednisone should be tapered to 5 mg/day in cyclophosphamide-treated patients and withdrawn in rituximab-treated patients. Adjunctive therapy with avacopan (30 mg twice daily for 52 weeks in combination with standard therapy), which is an inhibitor of the C5a complement receptor and which may allow for lower cumulative corticosteroid exposure, is recommended for severe disease.[A13] Cyclophosphamide may be administered intravenously (15 mg/kg IV every 2 to 3 weeks for 6 to 10 doses) or orally (1.5 to 2 mg/kg/day for 3 to 6 months). Rituximab, a monoclonal antibody against CD20-positive B cells (375 mg/m^2 weekly for 4 weeks, or 1 g at 0 and 2 weeks), is effective and as safe as cyclophosphamide at 6 months or more. The role of plasmapheresis is controversial, but it may be considered for patients who have a serum creatinine level greater than 5.7 mg/dL (500 mmol/L), who require dialysis, or who have rapidly worsening renal function, as well as for patients who have diffuse alveolar hemorrhage with hypoxemia. Plasmapheresis is also commonly prescribed in the overlap syndrome of ANCA vasculitis and anti–glomerular basement membrane disease. In patients who have severe ANCA-associated vasculitis, cyclophosphamide may be added to rituximab.

The risk of relapse is significant when ANCA-associated vasculitis is treated with cyclophosphamide induction, so azathioprine (1.5 mg/kg/day) with or without low-dose corticosteroids (e.g., prednisone 5 mg/day) or rituximab (500 mg at months 6, 12, and 18) without corticosteroids should be used to prevent relapse (see Fig. 107-12). Mycophenolate mofetil or methotrexate also have been used in patients intolerant or unable to take rituximab or azathioprine. The optimal duration of maintenance therapy after achieving remission is not known but should be between 18 months and 4 years with azathioprine and 18 months after rituximab. Patients with relapsing disease should preferably be treated with rituximab in addition to corticosteroids.

PROGNOSIS

The prognosis of untreated ANCA-associated vasculitis is poor (Chapter 249), with a 90% mortality at 2 years. Despite treatment, the 5-year mortality is 25%, with infection and active vasculitis being the main causes of death. Fortunately, ANCA-associated vasculitis has a low chance of recurrence in a kidney allograft.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

Membranoproliferative glomerulonephritis is classified based on immunofluorescence findings into immunoglobulin-mediated, complement-mediated and neither immunoglobulin or complement-mediated categories (Table 107-8).[22]

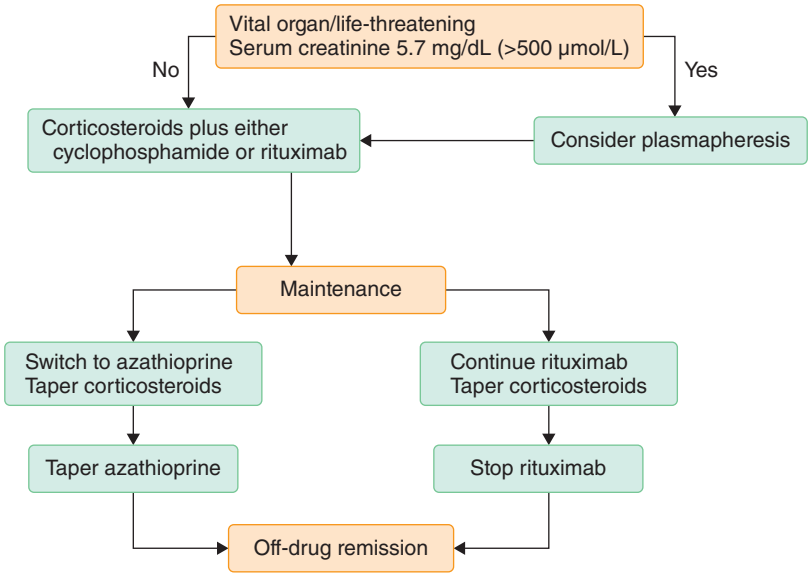

FIGURE 107-12. Treatment regimen for antineutrophil cytoplasmic antibodies–associated vasculitis. (Based on Kidney Disease: Improving Global Outcomes [KDIGO] Glomerular Diseases Work Group. KDIGO 2021 Clinical Practice Guideline for the Management of Glomerular Diseases. *Kidney Int*. 2021;100:S1-S276.)

TABLE 107-8 CAUSES OF A MEMBRANOPROLIFERATIVE PATTERN OF INJURY

Immunoglobulin-/immune complex–mediated	**Deposition of antigen–antibody immune complexes as a result of an infection:** • Viral: hepatitis C (including associated with mixed cryoglobulinemia), hepatitis B • Bacterial: endocarditis, infected ventriculo-atrial shunt, visceral abscesses, leprosy, meningococcal meningitis • Protozoa/other infections: malaria, schistosomiasis, mycoplasma, leishmaniasis, filariasis, histoplasmosis **Deposition of immune complexes as a result of an autoimmune disease:** • Systemic lupus erythematosus • Sjögren syndrome • Rheumatoid arthritis • Mixed connective tissue disease **Deposition of monoclonal Ig as a result of a monoclonal gammopathy due to a plasma cell or B cell disorder** **Fibrillary glomerulonephritis** **Idiopathic:** • None of the conditions above are present
Complement-mediated	**C3 glomerulonephritis and C3 dense deposit disease:** • Mutations in complement regulatory proteins: complement factor H, complement factor I, complement factor H–related protein 5 • Mutations in complement factors: C3 • Antibodies to complement factors: C3, C4, and C5 nephritic factors • Antibodies to complement regulatory proteins: complement factor H, complement factor I, complement factor B **C4 glomerulonephritis and C4 dense deposit disease**
Membranoproliferative pattern without immune complexes or complement	• Healing phase of hemolytic–uremic syndrome/thrombotic thrombocytopenic purpura • Antiphospholipid (anticardiolipin) antibody syndrome • POEMS syndrome • Radiation nephritis • Nephropathy associated with bone marrow transplantation • Drug-associated thrombotic microangiopathies • Sickle cell anemia and polycythemia • Dysfibrinogenemia and other prothrombotic states • Antitrypsin deficiency

POEMS = polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes.

Common causes of immunoglobulin-mediated membranoproliferative glomerulonephritis include systemic lupus erythematosus (Chapter 245), infections such as hepatitis C (Chapter 134), and monoclonal gammopathy (Chapter 173). Complement-mediated membranoproliferative glomerulonephritis includes dense deposit disease and C3 glomerulonephritis. The membranoproliferative glomerulonephritis pattern also can be seen without either complement or immunoglobulin deposition in chronic thrombotic microangiopathies that are associated with endothelial cell injury. All these stimuli have been proposed to incite the glomerular mesangial cells to grow out along the capillary wall and split the glomerular basement membrane.

C3 glomerulopathies, which include dense deposit disease and C3 glomerulonephritis, are rare glomerular diseases characterized by uncontrolled systemic activation of the alternative complement pathway. Many patients have C3 nephritic factor, an autoantibody that stabilizes the C3 convertase of the alternate complement pathway, whereas others have deficiencies of factor H, factor I, or other inhibitors of the alternative complement pathway. Dense deposit disease may be associated with partial lipodystrophy. Patients who have activation of the alternative complement pathway and who have a proliferative glomerulonephritis with C3 deposits that lack the electron microscopic features of dense deposit disease have C3 glomerulonephritis.

Most patients with membranoproliferative glomerulonephritis present with proteinuria or the nephrotic syndrome.[23] Low serum complement levels (C3 and C4) are found intermittently in immunoglobulin-associated membranoproliferative glomerulonephritis, whereas only the C3 level is usually reduced in dense deposit disease. The diagnosis of dense deposit disease requires a kidney biopsy that shows complement C3 in a characteristic ribbon-like pattern around the capillary loops (Fig. 107-13). All patients with membranoproliferative glomerulonephritis on a biopsy should be evaluated for underlying disease (see Table 107-8). If no cause is found, an evaluation for a complement-related disorder (Chapter 37) should be undertaken if possible.

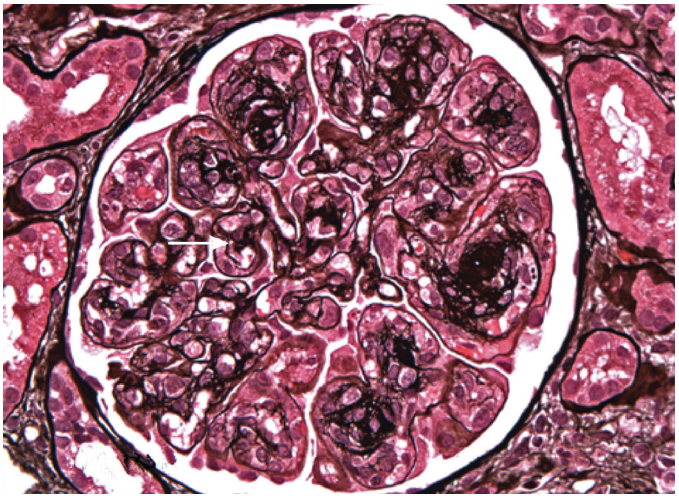

FIGURE 107-13. Membranoproliferative glomerulonephritis. Note lobulation of the glomerular tuft and duplication of the basement membrane as seen by silver stain.

TREATMENT

When the cause of immune complex membranoproliferative glomerulonephritis is determined, the initial approach to treatment should focus on the underlying pathologic process. For idiopathic immune complex membranoproliferative glomerulonephritis with proteinuria 3 g/day or less and normal kidney function, supportive care with blood pressure control, preferably with an ACE-inhibitor or angiotensin receptor blocker (Table 64-7), is adequate. For patients with abnormal kidney function but without crescentic involvements or an active urine sediment, with or without nephrotic-range proteinuria, corticosteroids and immunosuppressive therapy should be prescribed. Prednisone can be initiated at 1 mg/kg/day (maximum dose 60 to 80 mg/day) for 12 to 16 weeks. Mycophenolic acid analogs (e.g., mycophenolate mofetil 2 to 3 g/day) may be added for 6 to 12 months if a suboptimal response is seen after this time, with tapering of prednisone to 20 mg/day. In refractory patients, cyclophosphamide (2 mg/kg/day, maximum 200 mg/day) with prednisone (10 mg/day for 3 to 6 months) or rituximab (1 g × 2 doses 2 weeks apart, followed by a third dose in 6 months) may be given. For patients with rapidly progressive crescentic membranoproliferative glomerulonephritis, treatment with intravenous methylprednisolone (1 to 3 g) followed by oral corticosteroids and oral cyclophosphamide using a regimen similar to that used for patients with ANCA-associated vasculitis is suggested.

Patients who have C3 glomerulopathies (dense deposit disease and C3 glomerulonephritis) with moderate to severe disease (with proteinuria >1 g/day and hematuria or with declining kidney function) may be considered for immunosuppressive therapy with mycophenolic acid analogs plus corticosteroids, at doses similar to immune complex membranoproliferative glomerulonephritis. However, the evidence for efficacy for the latter is not established. The role of complement inhibitors is being actively investigated in both immune complex membranoproliferative glomerulonephritis and C3 glomerulopathies.

PROGNOSIS

The prognosis for membranoproliferative glomerulonephritis is dependent on whether patients achieve remission of proteinuria and stabilization of kidney function.[24] Up to 50 to 60% of untreated patients will progress to end-stage kidney disease within 10 to 15 years, but 25 to 40% of untreated patients will continue to have normal renal function. Spontaneous remission or improvement occurs in less than 10% of cases. With treatment, remission rates in observational studies have varied from 30 to 50%.

GLOMERULAR DISEASES ASSOCIATED WITH GENETIC DEFECTS

Some patients with focal segmental glomerulosclerosis have abnormalities in genes encoding for podocyte proteins, ion channels, or podocyte mitochondrial constituents. Other patients, often with a history of clinical kidney disease in siblings and other relatives, have other forms of hereditary nephritis.[25]

Alport Syndrome

Alport syndrome is a hereditary form of glomerulonephritis that often manifests with asymptomatic urinary findings. In approximately 85% of cases, it is an X-linked condition with hematuria and proteinuria, often in association with high-pitched hearing loss and abnormalities of the lens of the eye (lenticonus). X-linked form of disease are due to mutation in the α_5 chain of type IV collagen *(COL4A5)*. Mutations in the α_3 and α_4 chains of type IV collagen *(COL4A3, COL4A4)* cause dominant or recessive forms of disease.[26] Recessive forms of disease have severe, early-onset presentation, whereas dominant forms of disease have a very variable clinical course, ranging from normal, stable kidney function to progressive kidney failure. Patients with heterozygous pathogenic variants in *COL4A3/COL4A4* are often underdiagnosed and are frequently labeled as kidney disease of unknown cause. Although the light microscopy findings vary from mild mesangial proliferative to advanced sclerosing lesions depending on the stage of biopsy, electron microscopy typically shows areas of glomerular basement membrane thinning and other areas of glomerular basement membrane splitting with lamellations.

Use of ACE inhibitors (Table 64-7) at the onset of proteinuria delays progression of kidney failure, but males with X-linked Alport syndrome *(COL4A5)* often have progressive glomerulosclerosis and develop end-stage kidney disease. Owing to random X-inactivation, females with *COL4A5* mutations tend to have milder disease and may only progress to kidney failure late in life.

Fabry Disease

Fabry disease (Chapter 192), which is caused by an X-linked recessive genetic defect of α-galactosidase, leads to the deposition of ceramide trihexose in the kidneys and other organs. It may cause progressive proteinuria and kidney insufficiency in males and in some female carriers. It is associated with telangiectasias of the skin, typically in the bathing suit area, acroparesthesias, cardiac abnormalities, and eye changes. Replacement with intravenous recombinant enzyme agalsidase β is associated with clinical improvement.

Nail-Patella Syndrome

Nail-patella syndrome, associated with skeletal and nail deformities, is a rare cause of the nephrotic syndrome. It is due to an autosomal dominant mutation in the LMX1B transcription factor that regulates collagen, nephrin, and podocin gene expression. Progression to end-stage kidney disease is variable and estimated to be 1 to 15%. The use of maximally tolerated doses of ACE inhibitors or angiotensin receptor blockers (Table 64-7) may reduce proteinuria.

OTHER GLOMERULAR DISEASES

SYSTEMIC LUPUS ERYTHEMATOSUS

The pattern and degree of kidney involvement greatly influences the course and therapy of systemic lupus erythematosus (Chapter 245). Although the incidence of clinical kidney disease in systemic lupus erythematosus varies from 15 to 75%, histologic evidence of kidney involvement is found in most biopsy specimens.

The classification of lupus nephritis can provide a guide to therapy and prognosis (Table 107-9).[27] In general, patients with class I and II disease have mild lesions that require no therapy directed at the kidney, whereas all patients with class IV lesions (diffuse proliferative lupus nephritis) on biopsy (Fig. 107-14) require vigorous therapy. Many patients with class III (focal proliferative lupus nephritis) disease, especially patients who have active necrotizing lesions and large amounts of subendothelial deposits, also benefit from vigorous therapy. For patients with class V (membranous lupus nephritis) disease, the optimal therapy is less clear, and recommendations vary from uniform vigorous treatment to reserving such therapy for patients with serologic activity or more severe nephrotic syndrome.

TABLE 107-9 INTERNATIONAL SOCIETY OF NEPHROLOGY/RENAL PATHOLOGY SOCIETY CLASSIFICATION OF LUPUS NEPHRITIS

CLASS	CLINICAL FEATURES
I. Minimal mesangial lupus nephritis	Normal glomeruli by light microscopy but mesangial immune deposits by immunofluorescence
II. Mesangial proliferative lupus nephritis	Purely mesangial hypercellularity by light microscopy, with mesangial immune deposits
III. Focal lupus nephritis < 50% glomeruli involved A. Active A/C. Active and chronic C. Chronic	Active or inactive focal, segmental, or global endo- or extracapillary glomerulonephritis involving <50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations
IV. Diffuse lupus nephritis (>50% glomeruli involved); all may be with segmental or global involvement (S or G) A. Active A/C. Active and chronic C. Chronic	Active or inactive diffuse, segmental or global endo- or extracapillary glomerulonephritis involving ≥50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations
V. Membranous lupus nephritis glomerulonephritis	Global or segmental subepithelial immune deposits or their morphologic sequelae by light microscopy and by immunofluorescence or electron microscopy, with or without mesangial alterations
VI. Advanced sclerotic lupus nephritis	≥90% of glomeruli globally sclerosed without residual activity

The classification of glomerulonephritis in systemic lupus erythematosus revisited. *J Am Soc Nephrol*. 2004;15:241-250; and Bajema IM, Wilhelmus S, Alpers CE, et al. Revision of the International Society of Nephrology/Renal Pathology Society classification for lupus nephritis: clarification of definitions, and modified National Institutes of Health activity and chronicity indices. *Kidney Int*. 2018;93:789-796.

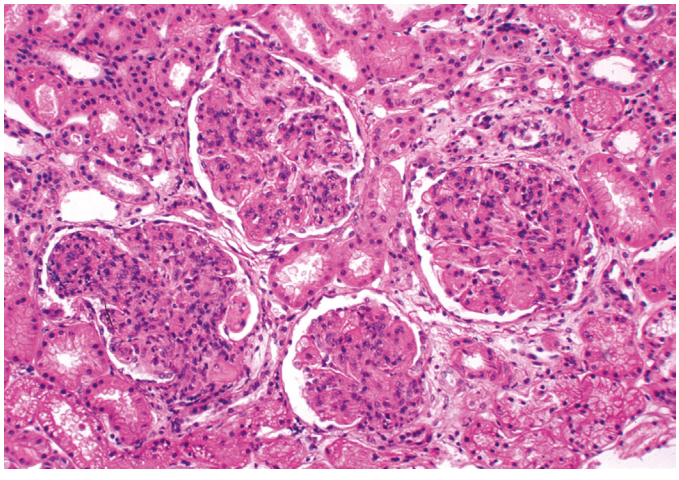

FIGURE 107-14. Diffuse proliferative lupus nephritis. Note involvement of all glomeruli.

TREATMENT

All patients with lupus nephritis should be treated with hydroxychloroquine (6.5 mg/kg ideal weight/day or 400 mg/day) or an equivalent antimalarial if there are no contraindications. For patients with class I or class II lupus nephritis with normal or low-grade proteinuria, no specific treatment is needed beyond what is given for extrarenal lupus. Patients who have class I/II lupus nephritis with nephrotic range proteinuria are considered to have lupus podocytopathy; treatment is as for minimal change disease (see earlier).

Initial therapy for patients with active class III or IV lupus nephritis, with or without a membranous component, is corticosteroids, with either low-dose intravenous cyclophosphamide or mycophenolic acid analogues (Fig. 107-15).[28]

A novel calcineurin inhibitor, voclosporin (23.7 mg twice daily), has been used with a mycophenolic acid analog and corticosteroids in patients with eGFR ≥45 mL/min/1.73 m^2 with improved response rates.[A14] Similarly, the addition of belimumab, a monoclonal antibody that inhibits B-cell activating factor (at 10 mg/kg intravenously), to standard therapy increases the response rate when added to initial therapy.[A15]

After the induction period, the prednisone dose should be tapered to below 5 to 7.5 mg/day and other medications should be discontinued. For maintenance therapy, mycophenolate mofetil (1000 mg twice daily) is preferred over azathioprine (2 mg/kg/day). If neither is tolerated, alternatives include tacrolimus (trough approximately 4 to 6 ng/mL or 5 to 7.4 nmol/L) or cyclosporine A (trough approximately 60 to 100 ng/mL or 50 to 83 nmol/L) or mizoribine (3 mg/kg/day).

Corticosteroids

Intravenous methylprednisolone
(0.25 to 0.50 g daily for 1 to 3 days)
then
oral prednisone
(0.6 to 1.0 mg/kg/day, maximum 80 mg)

plus

A. Cyclophosphamide

500 mg intravenously every 2 weeks for 6 doses,
0.5 to 1.0 g/m^2 intravenously monthly for 6 months,
or 1.0 to 1.5 mg/kg/day orally for up to 6 months

OR

B. Mycophenolic Acid Analogs

Mycophenolate mofetil (1.0 to 1.5 g orally twice daily)
or
mycophenolate acid sodium (0.72 to 1.08 g orally twice daily)

plus

A. Belimumab

(10 mg/kg intravenously every 2 weeks for 3 doses, then every 4 weeks)

OR

B. Calcineurin Inhibitors

Voclosporin (23.7 mg orally twice daily if eGFR >45 mL/min/1.73 m^2)

FIGURE 107-15. Initial therapy of active class III/IV with or without class V lupus nephritis. eGFR= estimated glomerular filtration rate. (Adapted from Kidney Disease: Improving Global Outcomes [KDIGO] Glomerular Diseases Work Group. KDIGO 2021 clinical practice guideline for the management of glomerular diseases. *Kidney Int*. 2021;100:S1-S276.)

Many patients with lupus nephritis (40 to 50%) produce autoantibodies against certain phospholipids, including anticardiolipin antibodies. Those patients who experience clotting in the glomeruli and arterioles require anticoagulation with either warfarin (Chapter 70) or antiplatelet agents (e.g., aspirin 81 to 325 mg/day) or with both, as well as immunosuppressive medications.

PROGNOSIS

Despite aggressive therapy, 10 to 30% of patients with lupus nephritis develop kidney failure. Moreover, patients with lupus nephritis have a higher risk for death compared with lupus patients without kidney involvement (Chapter 245). The risk of recurrence of lupus nephritis in kidney allografts is low.

DIABETES MELLITUS

Diabetic nephropathy, which is the most common form of glomerular disease in developed countries, is discussed in detail in Chapter 109.

MONOCLONAL GAMMOPATHY OF RENAL SIGNIFICANCE

Monoclonal gammopathy of renal significance refers to the association of B-cell or plasma-cell clonal disorders that per se do not fulfill criteria for cancer yet produce a nephrotoxic monoclonal immunoglobulin that leads to kidney disease. The toxicity of light chains results from multiple mechanisms, and kidney biopsy typically shows monotypic (single light and/or heavy chain) immunoglobulin deposition associated with a variety of morphologic patterns.[29]

AMYLOIDOSIS

Renal amyloid deposits, whether due to AL, AA, or hereditary-genetic forms of amyloid, are predominantly found within the glomeruli, where they often appear as amorphous eosinophilic extracellular nodules (Chapter 174). In all amyloidosis, proteins form β-pleated sheets, which are deposited in organs. All amyloid subtypes display apple-green birefringence under polarized light with the Congo red stain. By electron microscopy, amyloid appears as nonbranching rigid fibrils 8 to 10 nm in diameter. In AL amyloid, overproduction of an abnormal light chain (λ 80%, κ 20%) can be detected by immunofluorescence staining that shows monotypic λ or κ light chains. Most patients have a clonal proliferation of plasma cells and do not meet criteria for multiple myeloma. In AA amyloid, antisera to the AA protein stain the glomeruli. Some patients with kidney amyloidosis have genetic variants that lead to the production of amyloidogenic proteins such as transthyretin, LECT2, and apolipoproteins.

Almost 80% of patients with AL amyloid have kidney disease. Kidney manifestations include albuminuria and renal insufficiency. Extrarenal amyloid involvement may cause cardiac disease (Chapter 47) or neuropathy (Chapter 388). Diagnosis may be made from organ biopsy other than the kidney (e.g., myocardial, rectal, or fat pad biopsy). Treatment strategies for kidney AL amyloidosis are similar to those for multiple myeloma and other plasma cell dyscrasias: stem cell transplantation and the use of anti-plasma cell agents such as proteasome inhibitors (bortezomib, carfilzomib, daratumumab), dexamethasone, and lenalidomide (Chapter 173).

AA amyloid is associated with chronic inflammatory conditions such as rheumatoid arthritis (Chapter 243), familial Mediterranean fever (Chapter 240), inflammatory bowel disease (Chapter 127), osteomyelitis (Chapter 251), and other chronic infections. Treatment is directed at the underlying inflammatory process. Specific therapy against the primary inflammatory disease (e.g., anti–tumor necrosis factor therapy in rheumatoid arthritis and colchicine in familial Mediterranean fever) can reduce the production of serum AA protein in patients with AA amyloid.

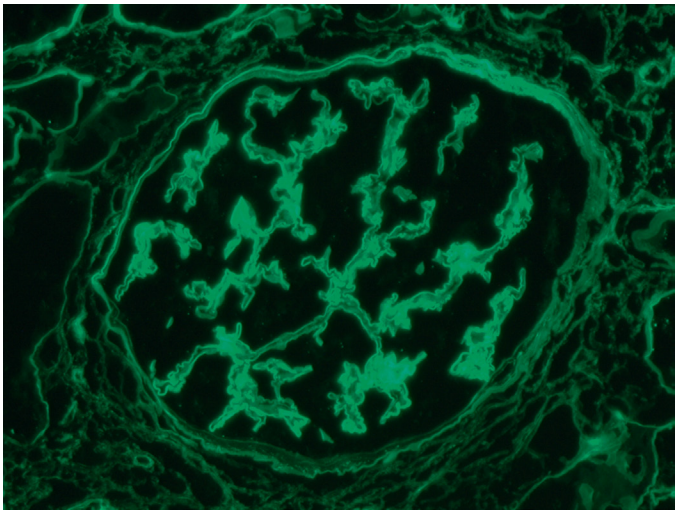

FIGURE 107-16. Light-chain deposition disease. Immunofluorescence shows linear staining of glomerular and tubular basement membranes for κ light chain.

LIGHT-CHAIN DEPOSITION DISEASE

Light-chain deposition disease, like AL amyloidosis, is a systemic disease caused by the overproduction and extracellular deposition of a monoclonal immunoglobulin light chain (Chapter 173). However, the deposits do not form β-pleated sheets, do not stain with Congo red, and are granular rather than fibrillar. Most patients with light chain deposition disease have a lymphoplasmacytic B-cell disease similar to multiple myeloma (Chapter 173).

Albuminuria is common, and the nephrotic syndrome is found in half of patients at presentation, often accompanied by hypertension and kidney insufficiency. On light microscopy, most glomeruli contain eosinophilic mesangial glomerular nodules. Some biopsy samples show associated light-chain cast nephropathy with eosinophilic laminated and fracturing casts obstructing the tubules, as seen in myeloma. By immunofluorescence, a single class of immunoglobulin light-chain (κ in 80% of cases) stains in a diffuse linear pattern along the glomerular basement membrane, in the nodules and along the tubular basement membranes (Fig. 107-16). The treatment for most patients with light-chain deposition disease is chemotherapy similar to that for myeloma (Chapter 173).

FIBRILLARY GLOMERULOPATHY–IMMUNOTACTOID GLOMERULOPATHY

Some patients with kidney disease have glomerular lesions with deposits of nonamyloid fibrillar proteins ranging in size from 12 to more than 50 nm.

Patients with these lesions have been divided into two groups. Patients with fibrillary glomerulonephritis have fibrils of 20 nm in diameter that are deposited in a random fashion in the glomerular basement membrane and are associated with deposits of the DNAJB9 protein in deposits. Immunotactoid glomerulonephritis is a much rarer disease often associated with lymphoproliferative disorders, in which the fibrils are much larger (30 to 50 nm) and have a tubular substructure. Proteinuria is found in almost all patients, and hematuria, the nephrotic syndrome, and kidney insufficiency eventually develop in most patients. No therapy is of proven benefit for the fibrillary glomerulopathy per se, and a search for a treatable underlying B cell disorder is important.[30]

HUMAN IMMUNODEFICIENCY VIRUS–ASSOCIATED NEPHROPATHY

Infection with HIV (Chapter 355) is associated with a number of patterns of kidney disease, including acute kidney injury (Chapter 106) and a unique form of glomerulopathy now called HIV-associated nephropathy. HIV-associated nephropathy is characterized by heavy proteinuria and rapid progression to kidney failure. On light microscopy, biopsies show global collapse of the glomerular tufts, severe tubulointerstitial changes with interstitial inflammation, edema, microcystic dilation of tubules, and severe tubular degenerative changes. On electron microscopy, tubuloreticular inclusions can be seen in the glomerular endothelium.[31] The use of ACE inhibitors or angiotensin receptor blockers (see Table 64-7 in Chapter 64) and antiretroviral therapy may decrease proteinuria and slow the progression to kidney failure. In addition, corticosteroids (e.g., prednisone, 1 mg/kg for 1 month followed by a taper over several months) may be beneficial in selected patients with HIV-associated nephropathy.

COVID-19–ASSOCIATED NEPHROPATHY

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and the coronavirus disease 2019 (COVID-19) that it causes can be associated with acute kidney injury. Postmortem examination in fatal cases shows diffuse acute tubular injury with a possible contribution of focal macrovascular and microvascular thrombi. Renal biopsies in patients with proteinuria and hematuria have demonstrated a glomerular-dominant pattern of injury, most notably a collapsing glomerulopathy similar to the findings seen in HIV-infected individuals with apolipoprotein L-1 *(APOL1)* risk allele variants. Other glomerular manifestations associated with COVID-19 include membranous nephropathy, ANCA-vasculitis, anti–glomerular basement membrane disease, and thrombotic microangiopathy.[32] Furthermore, acute flares of lupus nephritis, IgA nephropathy, and minimal change disease have been reported. SARS-CoV-2 vaccines have been rarely reported to be associated with relapsing or de novo glomerular disease, including IgA nephropathy, minimal change disease, ANCA-vasculitis, and others. The pathogenesis of glomerular disease associated with COVID-19 or vaccines is not understood, but is postulated to be related to immune activation.[33,34]

MIXED CRYOGLOBULINEMIA

Cryoglobulinemia (Chapter 173) is caused by the production of circulating immunoglobulins that precipitate on cooling and resolubilize on warming. Cryoglobulinemia may be found in association with infections, collagen vascular disease, and lymphoproliferative diseases such as multiple myeloma and Waldenström macroglobulinemia. Many patients with what was originally described as glomerulonephritis resulting from essential mixed cryoglobulinemia have been found to have hepatitis C–associated kidney disease. Some patients develop an acute nephritic picture with acute kidney insufficiency. Most patients have proteinuria, and approximately 20% present with the nephrotic syndrome. Hypocomplementemia, especially of the early components C1q to C4, is a characteristic finding in cryoglobulinemic glomerulonephritis, whether hepatitis C–related or idiopathic. Treatment of hepatitis C–associated cryoglobulinemia includes antiviral therapy (Chapter 135). When significant kidney disease is present, various combinations of corticosteroids with or without rituximab or cyclophosphamide or plasmapheresis have been used under expert guidance. Most patients with kidney disease have a slow, indolent course characterized by proteinuria, hypertension, hematuria, and renal insufficiency.

THROMBOTIC MICROANGIOPATHIES

A number of systemic diseases, including hemolytic-uremic syndrome (Chapters 110 and 158), thrombotic thrombocytopenic purpura (TTP; Chapter 158), and the antiphospholipid syndrome (Chapter 67), as well as microangiopathy associated with drugs such as mitomycin and cyclosporine, are characterized by microthromboses of the glomerular capillaries and small arterioles. The kidney findings may be dominant or only part of a more generalized picture of microangiopathy.

Kidney manifestations of the thrombotic microangiopathies may include gross or microscopic hematuria, proteinuria that is typically less than 2 g/day but may reach nephrotic levels, and renal insufficiency. Patients may have oliguric or nonoliguric acute kidney injury. In addition to glomerular chronic capillary thromboses, the histologic findings in all of the microangiopathies include a membranoproliferative glomerulonephritis pattern on light microscopy with no immune deposits or complement by immunofluorescence or electron microscopy, areas of ischemic damage, and intimal proliferation with luminal narrowing by thrombi of arterioles and small arteries.

In all thrombotic microangiopathies, treatment includes correcting hypovolemia, controlling hypertension, and the use of dialytic support for those with severe kidney failure. In TTP associated with an acquired or hereditary deficiency of the von Willebrand convertase ADAMTS-13 and in some other cases, plasmapheresis with fresh-frozen plasma is beneficial (Chapter 158).

In some patients whose hemolytic-uremic syndrome is not associated with Shiga toxin, defects in the alternate complement system are found. These patients with atypical hemolytic-uremic syndrome may benefit from eculizumab or ravulizumab, which inhibit complement C5 (Chapter 158). In the antiphospholipid syndrome, anticoagulation with heparin and then warfarin is useful (Chapter 67).

108 INTERSTITIAL NEPHRITIS

CYBELE GHOSSEIN AND ERIC G. NEILSON

DEFINITION

Interstitial nephritis is characterized by an inflammatory infiltrate in the interstitium of the kidney. It can be primary and begin in the tubulointerstitium or appear as a secondary event and spread from blood vessels, including the glomerular capillaries. Injury to the tubulointerstitial compartment can be the result of autoimmunity, toxic insult, infection, or exposure to drugs. In all cases, however, the inflammatory process has an immunologic component that leads to the release of tissue cytokines, which attract T lymphocytes and other monocytes, which eventually convert tubular epithelia into fibroblasts to produce fibrosis.[1]

Interstitial nephritis can be arbitrarily divided into acute and chronic types. The acute form often begins abruptly. When inciting events subside, so does the nephritis. If this occurs in a matter of days/weeks, the glomerular filtration rate tends to normalize, with little residual damage except in patients with preexisting disease. Any cause of acute interstitial nephritis can transform into chronic interstitial nephritis.

Chronic interstitial nephritis is persistent and over time reduces the number of functioning nephrons by encasing and dismantling them with irreversible fibrosis. Sometimes acute and chronic injury is difficult to distinguish because global destruction of the tubulointerstitium can occur within a matter of weeks.

EPIDEMIOLOGY

Acute interstitial nephritis appears unexpectedly in otherwise healthy individuals from a variety of causes. Approximately 1% of patients with hematuria and proteinuria have acute interstitial nephritis, and it is seen in 1 to 15% of autopsy series. In recent decades its prevalence has increased in individuals over age 65 years, perhaps owing to their more frequent exposure to prescription drugs.

Although the most common cause of acute interstitial nephritis is the use of pharmaceuticals,[2,3] other important causes include infection and autoimmune diseases (Table 108-1). Almost any class of drugs can cause acute interstitial nephritis, but antibiotics, diuretics, proton pump inhibitors, immune checkpoint inhibitors, and nonsteroidal anti-inflammatory drugs (NSAIDs) top the list. NSAIDs cause both acute interstitial nephritis and chronic analgesic nephropathy. Diphtheria in children (Chapter 272), legionellosis (Chapter 290), leptospirosis (Chapter 298), histoplasmosis (Chapter 308), tuberculosis (Chapter 299), and DNA viruses, such as cytomegalovirus (Chapter 347), Epstein-Barr virus (Chapter 348), and severe acute respiratory syndrome coronavirus-2[4] (Chapter 336), are well-recognized causes of acute interstitial nephritis. Anti–tubular basement membrane disease is a rare cause of autoimmune interstitial nephritis.

Although sarcoidosis or the tubulointerstitial nephritis and uveitis syndrome can manifest as acute interstitial nephritis, they often quickly evolve into chronic disease. Initially described in the MesoAmerican region, a new entity named chronic interstitial nephritis in agricultural communities (CINAC) has become an epidemic in many parts of the world. Initially thought to be due to episodic heat-related volume depletion, evidence now suggests that pesticide exposure may be causative factor.[5]

All forms of injury to the kidney, regardless of origin, progress to end-stage renal disease through a terminal phase of chronic interstitial nephritis. A wide variety of kidney diseases, such as the glomerulonephritides (Chapter 107), cystic diseases (Chapter 112), and diabetes (Chapter 210), will start slowly in the tubulointerstitium and often go unrecognized until late in the course, when biopsy shows chronic interstitial nephritis.

Primary chronic interstitial nephritis can be caused by a variety of toxic, metabolic, hematologic, obstructive, and infectious processes (Table 108-2). Chronic ingestion of six or more tablets per day of acetaminophen, aspirin, and NSAIDs, in combination for at least 3 years, can also put patients at risk for analgesic nephropathy. Light chains can cause tubular injury in patients with multiple myeloma (Chapter 173). More recently, immune checkpoint inhibitors frequently have been associated with acute interstitial nephritis that may progress to severe acute kidney injury.[6,7]

DRUGS

Antibiotics
- Penicillins
- Rifampin, ethambutol
- Sulfa
- Vancomycin
- Cephalosporins
- Erythromycin
- Fluroquinolones
- Trimethoprim-sulfamethoxazole
- Acyclovir

Nonsteroidal Anti-Inflammatory Drugs
- Selective and nonselective
- Cyclooxygenase-2 inhibitors

Diuretics
- Thiazides
- Furosemide
- Triamterene

Miscellaneous
- Captopril
- Ranitidine
- Proton pump inhibitors
- Phenobarbital
- Phenytoin
- Sodium valproate
- Carbamazepine
- Allopurinol
- Interferon
- Interleukin-2
- All-*trans*-retinoic acid
- Immune checkpoint inhibitors
- Nucleotide polymerase inhibitors
- Tyrosine kinase inhibitors

INFECTIONS

Bacteria
- *Legionella*
- *Brucella*
- *Diphtheria*
- *Streptococcus*
- *Staphylococcus*
- *Yersinia*
- *Salmonella*
- *Escherichia coli*
- *Campylobacter*

Viruses
- Epstein-Barr virus
- Cytomegalovirus
- Hantavirus
- Herpes simplex virus
- Hepatitis B virus
- Severe acute respiratory syndrome coronavirus-2

Other
- *Mycoplasma*
- *Rickettsia*
- *Leptospira*
- *Mycobacterium tuberculosis*
- *Schistosoma mekongi*
- *Toxoplasma*
- *Chlamydia*

AUTOIMMUNE DISEASES

Anti–tubular basement membrane disease
Tubulointerstitial nephritis and uveitis (TINU) syndrome
Kawasaki disease

PATHOBIOLOGY

Pathophysiology

Regardless of the origin of renal inflammation, the kidneys do not irreversibly fail until fibrosis and tubular atrophy develop. Chronic interstitial nephritis is the pathologic equivalent of clinical progression because it is the final common pathway to permanent tissue damage. The degree of reduction in the glomerular filtration rate correlates with the degree of interstitial injury. Urinary flow is impeded by

ABSTRACT

Interstitial nephritis is the final common pathway to chronic renal failure. Interstitial lesions may be a primary kidney lesion or secondary to many forms of glomerulonephritis, hypertension, or diabetes. Acute interstitial nephritis is seen following use of pharmaceutical drugs, infections, or idiopathic autoimmune diseases. Kidney biopsy may be useful in assessing cause and extent of damage. Treatment of early disease depends on removal of inciting factors, and in the absence of improvement, use of short courses of immunosuppressive drugs.

KEYWORDS

interstitial nephritis
renal tubular acidosis
kidney biopsy

tubular obstruction. Increased vascular resistance causes progressive tubular injury and fibrosis. A net reduction in the cross-sectional area of peritubular vessels increases postglomerular resistance to the extent that the compensatory increase in glomerular hydrostatic pressure cannot fully restore filtration to normal levels. Tubuloglomerular feedback assumes increasing importance in the transition from acute to chronic glomerulonephritis when autoregulation of renal blood flow is disrupted by tubulointerstitial fibrosis. Loss of autoregulation by tubuloglomerular feedback results from the absence or insensitivity of the afferent arteriole. Perhaps more significant is the effect of interstitial pressure on the sensitivity of the feedback mechanism. Tubular atrophy may disrupt the normal renal osmotic gradient by decreasing sodium chloride transport along the proximal tubule or thick ascending loop of Henle. The result is poor abstraction of water from the filtrate, with hyposthenuria and polyuria. Such an increase in solute and water within the tubular fluid results in adaptive downregulation of the glomerular filtration process.

Patients with Fanconi syndrome exhibit proximal tubular epithelium alterations that variably impair transporter function in the area of injury. These tubular defects are classically and occasionally seen in light-chain myeloma, cystinosis, Lowe syndrome, and the tubulointerstitial nephritis and uveitis syndrome, as well as after exposure to selected drugs, such as tenofovir or ifosfamide.

The antigen targets engaging the inflammasome and the immune system in interstitial nephritis are slowly unfolding. Drugs act as haptens, mimic endogenous structures in the interstitium, alter regulation of the immune system, or function in some combination of the foregoing. Bacteria, fungi, and viruses can infect the kidney and cause mononuclear cell infiltration or activate toll-like receptors on tubular epithelia, which subsequently educate the adaptive immune response to events in the interstitium. Renal-specific autoimmune diseases such as anti–tubular basement membrane disease or spontaneous interstitial nephritis remain confined to the kidney, whereas systemic diseases spread to the kidney, where they cause persistent chronic interstitial nephritis.

Although the adaptive immune response is similar to that of other tissues, T-cell activation figures prominently in interstitial nephritis. Antibodies (e.g., anti–tubular basement membrane disease) and/or immune complex deposition along the tubular basement membrane (e.g., systemic lupus erythematosus) are rarely seen. Antigens presented by class II major histocompatibility complex molecules on macrophages, dendritic cells, and adjacent tubular epithelia, in conjunction with associative recognition molecules, engage the CD4/CD8 T-cell repertoires. The resultant cytokine and protease activity injures tubular nephrons and basement membranes and causes fibroblasts to form locally by epithelial-mesenchymal transition and to proliferate. Transforming growth factor-β (TGF-β), fibroblast growth factor 2, and platelet-derived growth factor are particularly active in this transition. If the nephritis persists, fibrogenesis dismantles nephrons and causes tubular atrophy; in late stages, the inflammatory reaction outgrows its survival factors and lymphocytes, and fibroblasts disappear by apoptosis and leave an acellular fibrotic scar.

Rarely, patients may have autosomal dominant tubulointerstitial kidney disease (Chapter 112)[8,9] caused by mutations in various genes, including uromodulin (*UMOD*), hepatocyte nuclear factor-1β (*HNF1B*), renin (*REN*), and mucin-1 (*MUC1*). Viruses, including Epstein-Barr virus, have been long suspected of contributing to idiopathic chronic interstitial nephritis. Malakoplakia and xanthogranulomatous pyelonephritis are probably not defects in nephrogenesis but rather are destructive responses to bacterial inflammation in the interstitium. Focal abnormalities in kidney structure can be a nidus for infections associated with perinephric, psoas, or peritoneal abscesses. Children with vesicoureteral reflux (Chapter 113) can have chronic or repeating episodes of pyelonephritis, but whether the reflux or the infection is more important to progression to renal failure is unclear. There is also no agreement on whether recurrent pyelonephritis by itself produces chronic interstitial nephritis in adults.

Pathology

Both kidneys are typically involved, except in cases of unilateral infection, obstruction, or trauma. The inflammatory reaction in acute interstitial nephritis consists mainly of T lymphocytes and monocytes, but neutrophils, plasma cells, and eosinophils can be present. The T cells are of a mixed phenotype with a distinct preference for $CD4^+$ lymphocytes. The infiltrative process is associated with interstitial edema, which displaces tubules away from one another and causes the kidneys to swell. The tubular basement membrane may be disrupted in more severe cases, but immune deposits are rarely found by immunofluorescence. In patients on anti-programmed cell death protein-1 (PD-1) and anti-programmed death ligand-1 (PD-L1) therapy, immunohistochemistry may show positive PD-1 or PD-L1 staining in patients with acute interstitial nephritis from these therapies.[10]

On gross inspection, the kidney in chronic interstitial nephritis has an irregular contour or contracted appearance. Pathologically, the tubular epithelia sit on thickened or disrupted tubular basement membranes and are often effaced against dilated lumens; the tubules eventually dismantle and atrophy. *Chronic* is a relative term, because fibrotic changes can be seen within 7 to 10 days of continuing inflammation. In primary interstitial nephritis, the glomerular compartment eventually succumbs to the ongoing fibrotic process; normal glomeruli are surrounded by periglomerular fibrosis and subsequently undergo segmental or global sclerosis. Chronic vascular thickening and glomerular changes are present in advanced stages of disease, so pathologic determination of the primary cause may be difficult in some biopsy samples. Progressive glomerular

TABLE 108-3 TYPICAL CLINICAL MANIFESTATIONS OF ACUTE INTERSTITIAL NEPHRITIS

History of drug hypersensitivity or recent infection and taking antibiotics
Sudden onset of fever lasting several days to weeks
Variable degrees of hypertension
Rise in creatinine with FE_{Na} > 1.0; no expected acute tubular necrosis or glomerulonephritis
Kidney size normal or increased
Hematuria with mild proteinuria (<1.0 g)
Presence of WBC casts and WBCs on urinalysis; rarely eosinophils

FE_{Na} = fractional excretion of sodium; WBC = white blood cell.

sclerosis also occurs with aging and must be factored in when interpreting the biopsy findings.

A third pathologic category, granuloma formation, can be seen in either acute or chronic interstitial nephritis. In acute granulomatous interstitial nephritis, granulomas are sparse and non-necrotic and giant cells are rare. In chronic interstitial nephritis, granulomas contain an abundance of giant cells, and those caused by tuberculosis may become necrotic. Drugs are a common cause of this lesion in the acute setting, and most of the drugs associated with acute interstitial nephritis have been reported to cause granuloma formation. When numerous granulomas are present in the absence of drug exposure, sarcoidosis (Chapter 83), granulomatosis with polyangiitis (Chapter 249), histoplasmosis (Chapter 308), or tuberculosis (Chapter 299) should be considered, depending on the context. The kidney granulomas seen in granulomatosis with polyangiitis are almost always accompanied by glomerular and vascular pathology.

ACUTE INTERSTITIAL NEPHRITIS

CLINICAL MANIFESTATIONS

Most patients present with an asymptomatic rise in the serum creatinine level or an abnormal urinalysis, and it is important to consider acute interstitial nephritis in any patient with an unexplained precipitous diminution in kidney function.[11] Because kidney injury is often asymptomatic, patients already may have substantial kidney dysfunction on initial presentation. Patients also may present with nonspecific symptoms such as lethargy or weakness, and some patients may have fever. Oliguria may be present in patients who have severe acute kidney injury (Chapter 106).

Several features can distinguish acute interstitial nephritis from acute tubular necrosis (Chapter 106) or glomerulonephritis (Chapter 107; Table 108-3).[12] Fever and occasional flank pain, owing to acute distention of the kidney capsule, may occur in infection or with drug-induced acute interstitial nephritis. Allergic reactions can be associated with maculopapular rash, fever, and eosinophilia, but this triad is seen in less than 33% of all patients with acute interstitial nephritis; this triad is more common in antibiotic-related acute interstitial nephritis and is rarely seen when NSAIDs are the cause. These signs and symptoms of drug reaction have been codified and referred to as the DRESS syndrome (*d*rug *r*ash, *e*osinophilia, and *s*ystemic *s*ymptoms; Chapter 407), which is associated with interstitial nephritis in up to 40% of patients with persistent exposure to selected drugs.

The course of kidney failure in acute interstitial nephritis progresses over several days to weeks and follows the kinetics of the primary immune response. However, kidney failure can be precipitous, especially in patients re-exposed to a previous agent. Rarely, the course can be protracted, with the glomerular filtration rate declining over a period of months if the diagnosis is not recognized.

The onset of drug-induced nephritis ranges from days to weeks after the initiation of therapy, depending on previous drug exposure history. The classic setting for a drug reaction is a febrile patient with an infectious process and who defervesces while taking antibiotics but then develops recurrent fever several days later.

DIAGNOSIS

A careful history often points to the diagnosis (see Table 108-1). Urinalysis is particularly helpful. Mild-to-moderate proteinuria and hematuria are seen in most cases. The sediment typically shows red and white blood cells, as well as white blood cell casts. However, a bland urine sediment does not exclude the diagnosis of acute interstitial nephritis. A red blood cell cast (see Fig. 100-8) suggests a glomerular diagnosis. The finding of eosinophils in the urine supports the diagnosis of allergic interstitial nephritis, but the positive predictive value is low, even with more than 5% eosinophils in the urine, and the absence of eosinophiluria does not exclude the diagnosis of acute interstitial nephritis.

TABLE 108-4 WHEN TO CONSIDER A RENAL BIOPSY TO DIAGNOSE ACUTE INTERSTITIAL NEPHRITIS

The setting, history, or clinical findings do not support a diagnosis of acute tubular necrosis or volume depletion
The clinical setting warrants a tissue diagnosis to determine the type of lesion, the extent of involvement, or the degree of fibrosis
The patient is stable enough to undergo biopsy and receive immunosuppressive drugs
The physician believes that the choice of therapy or the length of treatment is partially determined by the type of tissue injury

An elevated serum creatinine level is usually the first abnormal laboratory result in interstitial nephritis. The normal serum creatinine of 0.6 to 1.3 mg/dL varies with muscle mass, age, and gender. Early recognition of acute interstitial nephritis requires a high degree of clinical suspicion because the serum creatinine level may be only mildly elevated even after the kidneys lose half their function.

Given the lack of glomerular involvement in acute interstitial nephritis, the degree of proteinuria is nearly always less than 3 g per 24 hours and is more typically less than 1 g per 24 hours. Nephrotic-range proteinuria is not seen except in the presence of a coexisting glomerular lesion, such as a concurrent minimal-change lesion, which can be seen in NSAID-induced interstitial nephritis. Many patients with acute interstitial nephritis also have a fractional excretion of sodium (FE_{Na}) greater than 1 and occasionally are oliguric.

Imaging is of little diagnostic value. The kidney in acute interstitial nephritis is usually normal or slightly increased in size on echographic or tomographic images. Increased cortical echogenicity may correlate with diffuse interstitial infiltrates on renal biopsy.

Differential Diagnosis

It is sometimes difficult to distinguish among nonoliguric acute tubular necrosis, acute interstitial nephritis, and glomerulonephritis without a biopsy.[13] Exposure to pharmaceuticals is responsible for most cases of acute interstitial nephritis, followed by infections and autoimmune disease. Selective tubular defects and tubular syndromes, such as proximal acquired Fanconi syndrome or distal renal tubular acidosis, can be seen in subacute or chronic interstitial nephritis but are unusual in acute interstitial nephritis.

Biopsy

Ultimately, the diagnosis can be established with certainty only by renal biopsy, which confirms and assesses the extent of acute interstitial inflammation. A biopsy should be performed in patients who have acute kidney failure, who have suggestive signs or symptoms of an interstitial process, and in whom prerenal azotemia and obvious acute tubular necrosis cannot be excluded on clinical grounds (Table 108-4). In primary acute interstitial nephritis, the biopsy demonstrates inflammatory cells that typically spare the glomeruli until late in the course (Fig. 108-1A). Lesions that reduce kidney function are usually diffuse, but drug-induced interstitial injury is often patchy and commonly begins deep in the cortex, closer to the corticomedullary junction, before spreading.

TREATMENT

The principal intervention for acute interstitial nephritis is to remove the inciting drug or treat the underlying cause, whether it be infectious or autoimmune.[14] In observational series, patients treated with steroids seem to do somewhat better, so a trial of prednisone (starting at 0.75 to 1.0 mg/kg/day orally) can be given daily for approximately 1 week, and the response can be assessed clinically. In patients whose autoimmune disease does not respond to steroids or who develop steroid toxicity, another immunosuppressive agent such as mycophenolate mofetil, azathioprine, or cyclophosphamide can be tried under expert guidance. These agents also can be used as steroid-sparing agents if long-term therapy is needed. High-dose immunosuppression should not be continued without some evidence of benefit because immunosuppressive drugs in patients with azotemia can lead to serious infection and even death. In such cases, these drugs can be reserved to use with kidney transplantation (Chapter 117) if the primary disease does not respond.

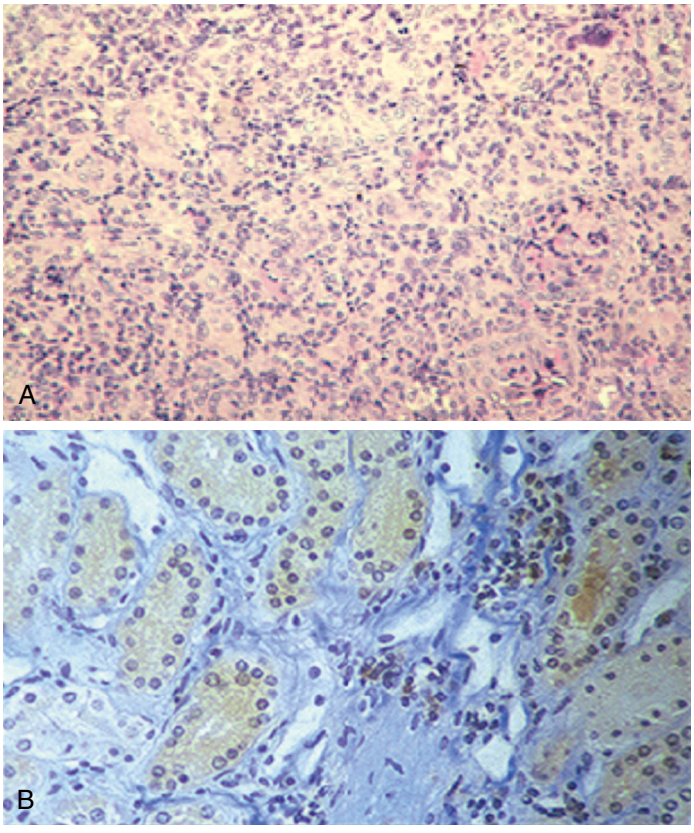

FIGURE 108-1. Interstitial nephritis on biopsy. A, Acute interstitial nephritis can be most aggressive when the interstitium is crowded with mononuclear cells and giant cells that destroy nearly all tubular nephrons (hematoxylin and eosin). **B,** Chronic interstitial nephritis is a slower process, with substantial collagen deposition (*blue color;* trichrome), tubular dropout, and fibroblasts in the interstitial spaces widened by fibrosis.

PROGNOSIS

The prognosis for acute interstitial nephritis is good if it is recognized early in the setting of minimal fibrosis.[15] Early removal of offending agents or prompt treatment of the underlying disorder when appropriate is essential. However, acute kidney tubular injury can be a catalyst for the development of chronic kidney disease.[16]

CHRONIC INTERSTITIAL NEPHRITIS

CLINICAL MANIFESTATIONS

Patients with primary chronic interstitial nephritis typically have elevated serum creatinine levels and signs and symptoms of kidney failure, including hematuria, isosthenuria or hyposthenuria, nocturia, fatigue, and nausea. Before the glomerular filtration rate falls below 25 to 30 mL/min, tubular acidosis is common. Anemia is often out of proportion to the degree of renal failure, and many patients have hypertension but only minimal edema until they develop advanced stages of kidney failure. Acquired Fanconi syndrome can be seen in patients with a serum creatinine level less than 2.5 mg/dL in the setting of drug exposure, myeloma, human immunodeficiency virus (HIV) infection, lead exposure, and herbal nephropathy.

DIAGNOSIS

A careful history including drug or toxin exposure, kidney imaging, and laboratory findings can often point to a probable diagnosis (see Table 108-2). As for any patient with evidence of kidney failure, the evaluation includes laboratory tests to determine possible causes and severity. These tests include measures of renal function (serum creatinine level and blood urea nitrogen level), as well as levels of serum electrolytes, calcium, phosphate, uric acid, and albumin. Urinalysis typically shows a fixed specific gravity of approximately 1.010, occasional glycosuria, and proteinuria (often <1 g/L); and red cells, white cells, and granular casts may be seen. Depending on the clinical situation, the search for specific causes may include serum and urine protein electrophoresis, blood and urine cultures, serologic tests for autoimmune diseases (e.g., cryoglobulin level, antinuclear antibodies, anti–neutrophil cytoplasmic antibody, and anti–glomerular basement membrane antibody levels [see Table 236-3]), or viral infection, particularly after renal transplantation (Chapter 117).

Selective tubular defects and tubular syndromes, such as proximal acquired Fanconi syndrome (bicarbonaturia with a plasma carbon dioxide [CO_2] content <20 mEq/L, aminoaciduria, phosphate wasting, uricosuria, and glycosuria) or distal renal tubular acidosis type 1 (urine pH >5.6, plasma CO_2 content <20 mEq/L, with low or high potassium) can be seen occasionally in subacute or chronic interstitial nephritis. Patients with Fanconi syndrome quickly develop an alkaline urine (pH >7.5) and increased fractional excretion of urine bicarbonate when the serum bicarbonate is elevated above 20 mEq/L by intravenous infusion.

Ultrasound images may show increased echogenicity and/or atrophic kidneys. Classic images of analgesic nephropathy on tomography are quite specific (Fig. 108-2) and show a decrease in overall kidney size, with atrophic scars and an irregular cortical contour, sometimes accompanied by papillary necrosis.

On biopsy (see Table 108-4), chronic interstitial nephritis is manifest by a cellular infiltrate that is eventually replaced by tubulointerstitial fibrosis (see Fig. 108-1B). Infiltrates of lymphocytes and rare neutrophils are scattered and less abundant than in acute interstitial nephritis. Genetic testing may detect a genetic tubulopathy (Chapters 108 and 113) in a substantial minority of patients.[17]

Specific Causes

Analgesics

Aspirin, acetaminophen, and NSAIDs in combination are a source of toxic metabolites and can induce medullary ischemia and papillary necrosis, sometimes with papillary calcification.[18] Uroepithelial malignancies also occur with increased frequency in this group of patients.

Aristolochic Acid Nephropathy

Aristolochic acid has been implicated as a cause of Balkan nephropathy and so-called Chinese herbal nephropathy. A growing number of people are taking vitamins and herbal preparations purchased from health food stores (Chapter 30), and some of these remedies contain botanicals that produce chronic interstitial nephritis. Patients who are dieting often use these remedies and are first seen when they already have late-stage disease, which increases the risk for uroepithelial malignancies (Chapter 182).

Human Immunodeficiency Virus Tubulointerstitial Nephropathy

Predominate tubulointerstitial nephropathy accounts for about 25% of the renal lesions seen on biopsy in HIV-infected patients (Chapter 359).[19] Biopsies show two general forms: a tubulopathy or an interstitial nephritis. In the tubulopathy, damage is to the proximal tubule. About 80% of cases are associated with drug exposure, particularly tenofovir (Chapter 357), but poorly controlled HIV is an even more important risk factor. Approximately 30% of patients improve with time. Patients in the tubulointerstitial nephritis group have a mononuclear infiltration and more persistent viral loads, but 50 to 60% recover.

Tubulointerstitial Nephritis with Uveitis Syndrome

Seen at any age but more commonly in young women and children, this syndrome may be idiopathic, genetic, or in response to pharmaceutical exposure.[20] Unilateral or bilateral anterior panuveitis (Chapter 391) may precede or follow evidence of interstitial nephritis that starts acutely but may persist as chronic kidney injury. If the renal function is not greatly impaired, concomitant Fanconi syndrome may suggest proximal tubular involvement.

Vascular Disease

Chronic renal ischemia from vascular injury can lead to interstitial nephritis, nephrosclerosis, and fibrosis, which are the classic renal lesions of untreated essential hypertension (Chapter 64). Similar injury is seen with aging, diabetes (Chapter 109), sickle cell disease (Chapter 149), and radiation nephritis (Chapter 18). This interstitial injury from vascular diseases is quite different from the aggressive necrosis seen with acute vasculitis. In patients who are taking calcineurin inhibitors such as cyclosporine or tacrolimus, renal ischemia from vasoconstriction can cause interstitial fibrosis that is sometimes difficult to distinguish from chronic allograft rejection (Chapter 117).

Immunoglobulin G4–Related Interstitial Nephritis

Immunoglobulin G4 (IgG4)-related interstitial nephritis is a systemic syndrome that presents in the kidney as inflammatory masses associated with

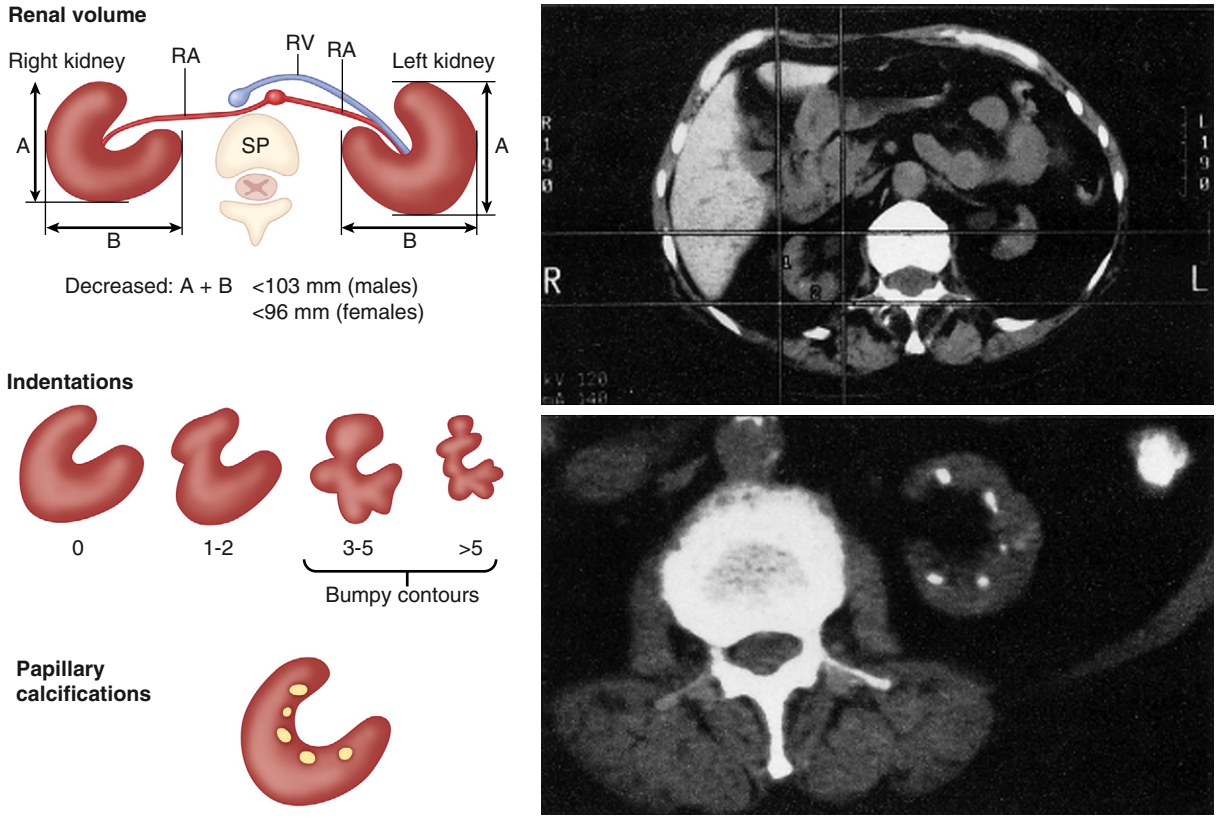

FIGURE 108-2. Renal changes in analgesic nephropathy seen by tomographic imaging. Structural changes, including reduced volume, nodularity, and calcifications, are seen on computed tomography. RA = right artery; RV = right vein; SP = spinal vertebra. (From Elseviers MM, De Schepper A, Corthouts R, et al. High diagnostic performance of CT scan for analgesic nephropathy in patients with incipient to severe renal failure. *Kidney Int*. 1995;48:1316.)

plasma cells, interstitial mononuclear cell infiltrates, and storiform fibrosis. Patients may have lesions in other organs, such as the liver, pancreas, parotids, thyroid, and myocardium.[21] Eosinophilia and low complement levels can be seen. Serum IgG4 levels and tissue plasma cells are increased, but it is not clear whether the IgG4 antibodies are a biomarker or causative. IgG4 is also separately associated with membranous nephropathy (Chapter 107) and nephrotic-range proteinuria.

Obstruction

Significant urinary obstruction, regardless of its etiology, is an important cause of chronic interstitial nephritis. Complete or partial urinary tract obstruction is accompanied by a decline in glomerular filtration and classic tubular abnormalities, including diminished reabsorption of solutes, impaired excretion of H^+ and K^+, and a vasopressin-resistant concentrating defect in the medulla. Obstruction is associated with a fall in the glomerular filtration rate because of reduced plasma flow and hydraulic pressure associated with the release of angiotensin II, leukotrienes, and nitric oxide, a process leading to mononuclear cell infiltration. Growth factors such as TGF-β, which is released by infiltrating cells, may contribute to the interstitial and glomerular fibrosis. Obstruction is more common in men than in women and is part of the routine assessment of kidney failure by kidney ultrasound (Chapters 106 and 114). Almost all obstructed kidneys eventually become infected if the obstruction is not relieved.

Hypercalcemia

Hypercalcemia can decrease glomerular filtration via renal vasoconstriction, a decrease in the glomerular ultrafiltration coefficient, and volume depletion as a result of a vasopressin-resistant concentrating defect associated with nephrocalcinosis and calcium deposition around the basement membranes of the distal tubules and collecting ducts. Such deposition secondarily leads to mononuclear cell infiltration and tubular death. Nephrocalcinosis also occurs in normocalcemic disorders of augmented calcium absorption through the gut (e.g., sarcoidosis [Chapter 83], vitamin D intoxication [Chapter 227]), skeletal breakdown (neoplasms or multiple myeloma [Chapter 173]), or classic distal renal tubular acidosis (Chapter 104).

Myeloma

The chronic kidney disease of multiple myeloma (Chapter 173) is caused by several mechanisms, including cast nephropathy ("myeloma kidney"), coexistent volume depletion, hypercalcemia (Chapter 227), nephrocalcinosis (Chapter 227), and uric acid nephropathy.[22] Proteinaceous casts form in dilated, atrophic distal nephron segments that are surrounded by multinucleated giant cells in interstitial infiltrates. The casts typically contain both Tamm-Horsfall protein and a pathologic light chain. Interstitial plasma cells and mononuclear infiltrates, calcifications in the interstitium, and amyloid deposits in the vessels and glomeruli are often present. Light chains are nephrotoxic by directly damaging tubular cells or by intrarenal obstruction because of the formation of casts. In the setting of excess production of light chains, the reabsorptive capacity of proximal tubule is overwhelmed, thereby leading to their urinary excretion as Bence Jones proteins. Proximal tubular damage may also lead to Fanconi syndrome.

Lead Toxicity

Epidemiologic analyses support the association between an excess burden of lead (Chapter 20) and chronic kidney disease. Blood lead levels reflect only recent, not chronic, exposure and can be normal in patients who have a significant burden of lead. Lead preferentially deposits in the proximal tubule, and nuclear inclusions within proximal tubular cells are characteristic of lead nephropathy. Ingestion of moonshine liquor, with its high lead content, as well as certain occupations, such as lead smeltering, can be an important historical clue to the diagnosis.

In adults, lead nephropathy produces chronic interstitial nephritis, fibrosis, and nephrosclerosis. Proximal tubular dysfunction may produce isolated tubule defects or a full Fanconi syndrome. Patients often have recurrent gout with gouty tophi, hyperuricemia, hypertension, and anemia. Some laboratories can measure δ-aminolevulinic acid dehydratase, which is inhibited by lead. Although chelation studies may document body lead burden, this test is difficult to perform in patients who have renal failure. X-ray fluorescent measurements of in vivo skeletal lead stores correlate well with ethylenediaminetetraacetic acid (EDTA) chelation tests and have the advantage of being rapid and noninvasive.

Cadmium Toxicity

Cadmium nephropathy (Chapter 20) is seen in regions where contamination from smelters results in prolonged low-level exposure. Cadmium is bound to metallothionein, and proximal tubular cells take up these complexes. The

liver and kidney are the two major organs in which cadmium accumulates. Cadmium's half-life in the body is longer than 10 years. As with blood levels of lead, blood levels of cadmium fall after acute exposure because of extensive tissue deposition. Once a threshold of kidney deposition is exceeded, excess cadmium is excreted in urine. Cadmium intoxication produces irreversible proximal tubular dysfunction, hypercalciuria, nephrolithiasis, and metabolic bone disease with pain (called "ouch-ouch" disease in Japan).

Oxalate Nephropathy

Oxalate nephropathy results from the deposition of calcium oxalate in the tubular interstitium, thereby leading to mild secondary inflammation and tubular atrophy and fibrosis. Although oxalate nephropathy can occur in patients who have primary inborn errors of glycolate metabolism that lead to overproduction of oxalate (Chapter 189), more commonly it occurs in patients who have secondary causes of increased oxalate excretion (e.g., patients with roux-en-y gastric bypass, inflammatory bowel disease, or short bowel syndrome) because of increased intestinal availability and permeability of oxalate or decreased degradation of oxalate. Diagnosis requires a high index of suspicion. A 24-hour urine collection to measure oxalate excretion can help, but ultimately a kidney biopsy is needed to make the diagnosis.[2,3]

Autosomal Dominant Tubular Interstitial Diseases

Autosomal dominant tubular interstitial diseases are a rare group of inherited syndromes that lead to progressive chronic kidney disease and eventually lead to kidney failure (Chapter 112). The several subtypes of autosomal dominant tubular interstitial disease have an autosomal dominant inheritance pattern, present in late childhood or early adulthood, and are slowly progressive. Some patients may have early-onset gout. Kidney imaging may show small medullary cysts. Kidney biopsy will usually show nonspecific findings. A provisional diagnosis can made by obtaining a thorough family history in the appropriate clinical context. Genetic testing for mutations in uromodulin (*UMOD*) will confirm the clinical diagnosis in the majority of patients, whereas other patients will have mutations in renin (*REN*), hepatocyte nuclear factor-1β (*HNF1B*), or Mucin-1 (*MUC1*).

TREATMENT

Inciting factors such as obstruction, infection, drugs, or toxins should be removed whenever possible. Chronic interstitial fibrosis rarely responds to aggressive treatment. However, in immunoglobulin G4–related interstitial nephritis, the renal lesions in many patients respond briskly to corticosteroid treatment. In addition, treatment of tubulointerstitial nephritis with uveitis syndrome is with varying doses of methylprednisolone followed by oral prednisone under expert guidance may be beneficial in some patients. Varying durations of supplemental or steroid-sparing immunosuppression with mycophenolate mofetil or cyclophosphamide also have been used. Immunosuppression may also be helpful in sarcoidosis (Chapter 83).

Otherwise, the treatment is like that of other causes of chronic kidney disease. Angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers (Table 64-7) are used early to slow disease progression, with a systolic blood pressure goal of 120/80 mm Hg (Chapters 64 and 117). Sodium glucose cotransporter-2 inhibitors (see Table 210-6) may be indicated in patients who have a glomerular filtration rate <75 mL/min (but not <45 mL/min for empagliflozin or <25 mL/min for dapagliflozin except in special circumstances under expert supervision) and an albumin to creatinine ratio >200 mg/g to slow the progression of kidney disease. Early treatment of acidosis with sodium bicarbonate (starting at 650 mg twice daily) is important to reach a goal bicarbonate level of 23 mEq/L. Other treatment goals include treatment of symptomatic anemia with erythropoiesis-stimulating agents to maintain a hemoglobin concentration between 10 and 11 g/L, treatment of hyperphosphatemia with oral phosphate binders, and hyperparathyroidism with activated vitamin D analogues (Chapters 116 and 117).

For certain specific causes of chronic interstitial nephritis, specific therapeutic approaches are warranted. For analgesic nephropathy, stopping analgesic use can help reduce progression. For hypercalcemia (Chapter 227), therapy is directed toward the primary disease—reduction of the serum calcium concentration, when appropriate, and correction of acid-base disturbances.

Appropriate therapy for presumed cast nephropathy in multiple myeloma includes chemotherapy to ameliorate excess production of light chains (Chapter 173), treatment of hypercalcemia (Chapter 227), alkalinization of the urine with the addition of bicarbonate to hypotonic fluids, and avoidance of radiocontrast agents, which may enhance the nephrotoxicity of light chains. Loop diuretics should be used with caution, particularly in the setting of volume depletion.

EDTA is advocated as chelation therapy for lead toxicity (Chapter 20). The goal of chelation is to normalize the EDTA mobilization test. In occasional patients, this treatment may arrest or reverse the progression of the kidney failure.

PROGNOSIS

Chronic interstitial nephritis tends to progress slowly. However, the prognosis is highly variable and depends on the underlying condition, the degree of fibrosis, the presence of glomerulosclerosis on kidney biopsy, and the patients' comorbid conditions, including cardiovascular disease and diabetes mellitus.

109 DIABETES AND THE KIDNEY

RAYMOND C. HARRIS

EPIDEMIOLOGY

In the industrialized world, diabetes mellitus is the single leading cause of end-stage renal disease (ESRD). Despite the improved care of patients with diabetes, both the incidence and prevalence of ESRD secondary to diabetes continue to rise. In the United States, almost 50% of patients undergoing either dialytic therapy or renal transplantation have ESRD as a result of diabetic nephropathy, and more than 40% of the new (incident) cases of ESRD are attributable to diabetes. Currently, more than 200,000 U.S. patients receive ESRD care as a result of diabetic nephropathy.

In the United States, Europe, and Japan, more than 90% of patients with diabetes have type 2 rather than insulinopenic type 1 diabetes (Chapter 210). In patients with type 1 and type 2 diabetes, the incidence rate of renal disease is equivalent when patients are monitored for an extended period of time, and more than 80% of the ESRD secondary to diabetes in the United States is seen in patients with type 2 diabetes. The demographics of ESRD secondary to type 2 diabetes mirror the prevalence of type 2 diabetes in the U.S. population, with a higher incidence in females and in Black Americans, Hispanic Americans, Native Americans, and Asian Americans, with a peak incidence in the fifth to seventh decades. Much of the increased mortality in both type 1 and type 2 diabetes is associated with the prevalence of nephropathy.

Given the global epidemic of obesity, the incidence of diabetic nephropathy is increasing worldwide.[1,2] Smoking, hypertension, and elevated blood cholesterol levels may be predisposing factors for the development of diabetic nephropathy in patients with type 2 diabetes.

PATHOBIOLOGY

Hyperglycemia

The metabolic sequelae of hyperglycemia appear to be the most important causative factor in the development of diabetic nephropathy.[3] Hyperglycemia leads to increased generation of reactive oxygen species; depletion of the reduced form of nicotinamide dinucleotide (phosphate); activation of the polyol pathway, which can lead to de novo synthesis of diacylglycerol and increased protein kinase C activity; alterations in the hexosamine pathway; and nonenzymatic protein glycation (advanced glycosylation end products). All of these pathways have been implicated in the development of diabetic nephropathy, and better glucose control generally reduces the risk of nephropathy and other microvascular diabetic complications.[4] For example, patients who have glucokinase mutations, which are associated with milder hyperglycemia (average hemoglobin A_{1c} [HbA_{1c}] levels 6.9%), have far less proteinuria, microalbuminuria, or nephropathy than patients who have long-standing type 2 diabetes with HbA_{1c} levels averaging 7.8%. Furthermore, randomized interventional studies clearly demonstrate that relatively better control of blood sugar decreases the development of nephropathy in type 1 diabetes, and observational studies with repeat renal biopsies show that the renal lesions of diabetic nephropathy may reverse after long-term functioning pancreas transplantation.

Hemodynamics

Patients with type 1 and, to a lesser extent, type 2 diabetes exhibit an increased glomerular filtration rate (GFR), so-called hyperfiltration, that is mediated by proportionately greater relaxation of the afferent arteriole than the efferent

liver and kidney are the two major organs in which cadmium accumulates. Cadmium's half-life in the body is longer than 10 years. As with blood levels of lead, blood levels of cadmium fall after acute exposure because of extensive tissue deposition. Once a threshold of kidney deposition is exceeded, excess cadmium is excreted in urine. Cadmium intoxication produces irreversible proximal tubular dysfunction, hypercalciuria, nephrolithiasis, and metabolic bone disease with pain (called "ouch-ouch" disease in Japan).

Oxalate Nephropathy

Oxalate nephropathy results from the deposition of calcium oxalate in the tubular interstitium, thereby leading to mild secondary inflammation and tubular atrophy and fibrosis. Although oxalate nephropathy can occur in patients who have primary inborn errors of glycolate metabolism that lead to overproduction of oxalate (Chapter 189), more commonly it occurs in patients who have secondary causes of increased oxalate excretion (e.g., patients with roux-en-y gastric bypass, inflammatory bowel disease, or short bowel syndrome) because of increased intestinal availability and permeability of oxalate or decreased degradation of oxalate. Diagnosis requires a high index of suspicion. A 24-hour urine collection to measure oxalate excretion can help, but ultimately a kidney biopsy is needed to make the diagnosis.[2,3]

Autosomal Dominant Tubular Interstitial Diseases

Autosomal dominant tubular interstitial diseases are a rare group of inherited syndromes that lead to progressive chronic kidney disease and eventually lead to kidney failure (Chapter 112). The several subtypes of autosomal dominant tubular interstitial disease have an autosomal dominant inheritance pattern, present in late childhood or early adulthood, and are slowly progressive. Some patients may have early-onset gout. Kidney imaging may show small medullary cysts. Kidney biopsy will usually show nonspecific findings. A provisional diagnosis can made by obtaining a thorough family history in the appropriate clinical context. Genetic testing for mutations in uromodulin (*UMOD*) will confirm the clinical diagnosis in the majority of patients, whereas other patients will have mutations in renin (*REN*), hepatocyte nuclear factor-1β (*HNF1B*), or Mucin-1 (*MUC1*).

TREATMENT

Inciting factors such as obstruction, infection, drugs, or toxins should be removed whenever possible. Chronic interstitial fibrosis rarely responds to aggressive treatment. However, in immunoglobulin G4–related interstitial nephritis, the renal lesions in many patients respond briskly to corticosteroid treatment. In addition, treatment of tubulointerstitial nephritis with uveitis syndrome is with varying doses of methylprednisolone followed by oral prednisone under expert guidance may be beneficial in some patients. Varying durations of supplemental or steroid-sparing immunosuppression with mycophenolate mofetil or cyclophosphamide also have been used. Immunosuppression may also be helpful in sarcoidosis (Chapter 83).

Otherwise, the treatment is like that of other causes of chronic kidney disease. Angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers (Table 64-7) are used early to slow disease progression, with a systolic blood pressure goal of 120/80 mm Hg (Chapters 64 and 117). Sodium glucose cotransporter-2 inhibitors (see Table 210-6) may be indicated in patients who have a glomerular filtration rate <75 mL/min (but not <45 mL/min for empagliflozin or <25 mL/min for dapagliflozin except in special circumstances under expert supervision) and an albumin to creatinine ratio >200 mg/g to slow the progression of kidney disease. Early treatment of acidosis with sodium bicarbonate (starting at 650 mg twice daily) is important to reach a goal bicarbonate level of 23 mEq/L. Other treatment goals include treatment of symptomatic anemia with erythropoiesis-stimulating agents to maintain a hemoglobin concentration between 10 and 11 g/L, treatment of hyperphosphatemia with oral phosphate binders, and hyperparathyroidism with activated vitamin D analogues (Chapters 116 and 117).

For certain specific causes of chronic interstitial nephritis, specific therapeutic approaches are warranted. For analgesic nephropathy, stopping analgesic use can help reduce progression. For hypercalcemia (Chapter 227), therapy is directed toward the primary disease—reduction of the serum calcium concentration, when appropriate, and correction of acid-base disturbances.

Appropriate therapy for presumed cast nephropathy in multiple myeloma includes chemotherapy to ameliorate excess production of light chains (Chapter 173), treatment of hypercalcemia (Chapter 227), alkalinization of the urine with the addition of bicarbonate to hypotonic fluids, and avoidance of radiocontrast agents, which may enhance the nephrotoxicity of light chains. Loop diuretics should be used with caution, particularly in the setting of volume depletion.

EDTA is advocated as chelation therapy for lead toxicity (Chapter 20). The goal of chelation is to normalize the EDTA mobilization test. In occasional patients, this treatment may arrest or reverse the progression of the kidney failure.

PROGNOSIS

Chronic interstitial nephritis tends to progress slowly. However, the prognosis is highly variable and depends on the underlying condition, the degree of fibrosis, the presence of glomerulosclerosis on kidney biopsy, and the patients' comorbid conditions, including cardiovascular disease and diabetes mellitus.

109 DIABETES AND THE KIDNEY

RAYMOND C. HARRIS

EPIDEMIOLOGY

In the industrialized world, diabetes mellitus is the single leading cause of end-stage renal disease (ESRD). Despite the improved care of patients with diabetes, both the incidence and prevalence of ESRD secondary to diabetes continue to rise. In the United States, almost 50% of patients undergoing either dialytic therapy or renal transplantation have ESRD as a result of diabetic nephropathy, and more than 40% of the new (incident) cases of ESRD are attributable to diabetes. Currently, more than 200,000 U.S. patients receive ESRD care as a result of diabetic nephropathy.

In the United States, Europe, and Japan, more than 90% of patients with diabetes have type 2 rather than insulinopenic type 1 diabetes (Chapter 210). In patients with type 1 and type 2 diabetes, the incidence rate of renal disease is equivalent when patients are monitored for an extended period of time, and more than 80% of the ESRD secondary to diabetes in the United States is seen in patients with type 2 diabetes. The demographics of ESRD secondary to type 2 diabetes mirror the prevalence of type 2 diabetes in the U.S. population, with a higher incidence in females and in Black Americans, Hispanic Americans, Native Americans, and Asian Americans, with a peak incidence in the fifth to seventh decades. Much of the increased mortality in both type 1 and type 2 diabetes is associated with the prevalence of nephropathy.

Given the global epidemic of obesity, the incidence of diabetic nephropathy is increasing worldwide.[1,2] Smoking, hypertension, and elevated blood cholesterol levels may be predisposing factors for the development of diabetic nephropathy in patients with type 2 diabetes.

PATHOBIOLOGY

Hyperglycemia

The metabolic sequelae of hyperglycemia appear to be the most important causative factor in the development of diabetic nephropathy.[3] Hyperglycemia leads to increased generation of reactive oxygen species; depletion of the reduced form of nicotinamide dinucleotide (phosphate); activation of the polyol pathway, which can lead to de novo synthesis of diacylglycerol and increased protein kinase C activity; alterations in the hexosamine pathway; and nonenzymatic protein glycation (advanced glycosylation end products). All of these pathways have been implicated in the development of diabetic nephropathy, and better glucose control generally reduces the risk of nephropathy and other microvascular diabetic complications.[4] For example, patients who have glucokinase mutations, which are associated with milder hyperglycemia (average hemoglobin A_{1c} [HbA_{1c}] levels 6.9%), have far less proteinuria, microalbuminuria, or nephropathy than patients who have long-standing type 2 diabetes with HbA_{1c} levels averaging 7.8%. Furthermore, randomized interventional studies clearly demonstrate that relatively better control of blood sugar decreases the development of nephropathy in type 1 diabetes, and observational studies with repeat renal biopsies show that the renal lesions of diabetic nephropathy may reverse after long-term functioning pancreas transplantation.

Hemodynamics

Patients with type 1 and, to a lesser extent, type 2 diabetes exhibit an increased glomerular filtration rate (GFR), so-called hyperfiltration, that is mediated by proportionately greater relaxation of the afferent arteriole than the efferent

ABSTRACT

Diabetic nephropathy, which is also known as diabetic kidney disease, is one of the most prominent "microvascular" complications of diabetes and is a major source of morbidity and mortality. Both the incidence and the prevalence of diabetic nephropathy continue to rise. The vast majority of incident and prevalent cases of diabetic nephropathy are secondary to type 2, obesity-prone diabetes. With the global rise in obesity, an increasing incidence of diabetic nephropathy is being reported worldwide. Patients who develop diabetic nephropathy classically progress from initial presentation with microalbuminuria to development of nephrotic-range proteinuria and progressive decline in glomerular filtration rate until the development of end-stage kidney disease. Diabetic nephropathy is the underlying reason why almost 50% of all patients are currently receiving renal replacement therapy in the United States. Control of hyperglycemia and blood pressure can decrease the incidence of diabetic nephropathy but does not completely eliminate the risk. Therapeutic options include medications that interfere with the renin-angiotensin system (ACE inhibitors or angiotensin receptor blockers) as well as sodium-glucose cotransporter-2 (SGLT2) inhibitors, glucagon-like peptide-1 (GLP-1) analogues, and nonsteroidal mineralocorticoid receptor antagonists. Appropriate use of these agents can slow the progression of diabetic nephropathy, reduce cardiovascular complications, and increase longevity.

arteriole. This hyperfiltration leads to increased glomerular blood flow and elevated glomerular capillary pressure. With poorly controlled diabetes, patients also develop glomerular hypertrophy, with an increased glomerular capillary surface area. These intraglomerular hemodynamic and structural alterations may contribute to the development or progression (or both) of diabetic renal injury. Blockade of the renin-angiotensin system with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers and the use of sodium-glucose cotransporter-2 (SGLT2) inhibitors reduce this elevated intraglomerular capillary pressure in experimental animals, so this hyperfiltration hypothesis potentially explains how these medications slow the progression of diabetic nephropathy.

Hormones and Cytokines

A number of cytokines, hormones, and intracellular signaling pathways are implicated in the development and/or progression of diabetic nephropathy, notably transforming growth factor β, connective tissue growth factor, angiotensin II, vascular endothelial growth factor, endothelin, prostaglandins, and nitric oxide.[5] Because these factors have also been implicated in a variety of nondiabetic kidney diseases, they are not specific for diabetic nephropathy. However, agents that interrupt production and signaling of angiotensin II are very effective in slowing the progression of diabetic nephropathy.

Genetics

Although poor glycemic and blood pressure control undoubtedly contribute to the development of diabetic nephropathy, nephropathy may or may not occur in an individual patient even after many years of hypertension and hyperglycemia. Type 1 diabetic patients whose siblings have diabetic nephropathy have a greater than 70% lifetime risk of developing diabetic nephropathy themselves. Patients with type 2 diabetes also appear to have a hereditary predisposition for or against the development of diabetic nephropathy.

However, diabetic nephropathy is likely to be a polygenic disease, and its development and progression are likely related to the inheritance of multiple polymorphisms with variable effect sizes. For example, Black Americans with apolipoprotein-1 genetic risk genotypes do not have an increased predisposition to develop diabetic nephropathy, but nephropathy has an accelerated progression in such patients. In addition, the lack of nephropathy in patients with glucokinase mutations may be more pronounced than can be explained just by their relatively lower HbA_{1c} levels. Studies also suggest a long-term programming or memory effect in the development of diabetic kidney disease, such that patients whose type 1 diabetes was poorly controlled in the past will develop nephropathy at an increased rate despite subsequent excellent glycemic control. These findings suggest the possible role for epigenetic programming—such as for the glomerular expression of enzymes in glycolytic, sorbitol, methylglyoxal, and mitochondrial pathways—in type 1 diabetic patients who develop diabetic nephropathy.

CLINICAL MANIFESTATIONS

Diabetic kidney disease progresses through four stages at variable rates in different patients.[6,7]

Natural History

Diabetic nephropathy progresses through four relatively distinct stages (Fig. 109-1).

Stage I

In stage I, which commences soon after the overt manifestations of diabetes, renal blood flow and GFR increase by up to 50%, and the kidney's glomeruli and tubules hypertrophy compared with age- and weight-matched normal control subjects. Although patients with type 2 diabetes also tend to have an elevated GFR during the early course of their disease, the GFR increases are not usually as pronounced as seen with insulin-dependent diabetes mellitus. At this stage, macroalbuminuria (>300 mg per 24 hours) is not detectable, but transient microalbuminuria (30 to 300 mg per 24 hours) can occasionally be measured by radioimmunoassay, enzyme-linked immunosorbent assay, or special dipsticks, especially when induced by stress, physical exertion, concurrent illness, or poor glycemic control.[8] Hypertension is usually absent in the early stages in type 1 diabetic patients but is present in 10 to 25% of type 2 diabetic patients at initial evaluation.

Stage II

Approximately 30% of type 1 diabetic patients progress to stage 2, which is characterized by fixed microalbuminuria after a median of about 10 years of diabetes. Although the GFR either remains elevated or is within the normal range at this stage, renal histology becomes abnormal and is manifested as glomerular and tubular basement membrane thickening and the inception of mesangial matrix expansion. Microalbuminuria is more likely in patients who have evidence of other microvascular insults, especially proliferative retinopathy. Microalbuminuria is a more specific sign of diabetic nephropathy in type 1 diabetes than in type 2 diabetes because of the high incidence of hypertension, which itself may lead to microalbuminuria, in the latter.

Stage III

The majority of patients who are initially seen with fixed microalbuminuria progress to overt nephropathy (stage III) within 5 to 7 years. In this stage, patients have overt proteinuria (>500 mg of total protein per 24 hours) and macroalbuminuria, which are detectable with a routine urinary protein dipstick. With the onset of stage III, estimated glomerular filtration rate (eGFR) is usually below normal levels for age and continues to decrease as the disease progresses, but the serum creatinine level may remain in the normal range. Blood pressure begins to rise in type 1 diabetic patients with stage III nephropathy. In type 2 diabetic patients, who frequently have preexistent hypertension, blood pressure commonly becomes more difficult to control.

Stage IV

Stage IV, or advanced diabetic nephropathy, is characterized by a relentless decline in renal function and progression to ESRD. Patients typically have heavy or nephrotic-range proteinuria (>3.5 g/24 hr) and systemic hypertension but have no evidence of inflammatory glomerular (red blood cell casts) or tubulointerstitial (white blood cells, white blood cell casts) lesions. The kidneys may be inappropriately large for the observed degree of renal insufficiency. However, a subset of patients with type 2 diabetes develops chronic kidney disease without nephrotic-range proteinuria. Whether this difference represents a fundamental difference in the pathophysiology of the two conditions or represents the synergistic effects of other kidney injuries, such as hypertensive renal disease, is unclear.

Other Renal Complications

Patients with diabetes also have an increased rate of other kidney and genitourinary abnormalities. Type IV (hyporeninemic, hypoaldosteronemic) metabolic acidosis (Chapter 104) with hyperkalemia is commonly encountered in diabetic patients who have mild to moderate renal insufficiency. These patients should be carefully monitored for the development of severe hyperkalemia (Chapter 103) in response to volume depletion or after the initiation of drugs that interfere with the renin-angiotensin system, such as ACE inhibitors, angiotensin II receptor blockers, β-adrenergic blockers, nonsteroidal anti-inflammatory agents, and heparin, as well as potassium-sparing diuretics.

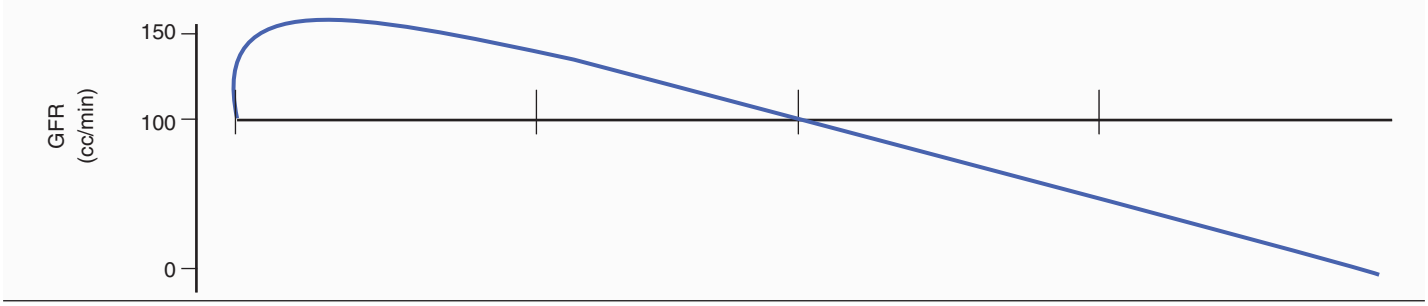
Patients with diabetes have an increased incidence of bacterial and fungal infections of the genitourinary tract (Chapter 263). In addition to lower urinary tract infections, they have an increased risk for pyelonephritis as well as for intrarenal and perinephric abscesses (Chapter 263).

Unilateral or bilateral renal artery stenosis (Chapter 110) occurs more frequently in the type 2 diabetic population than in age-matched nondiabetic individuals and should be considered if a diabetic patient has intractable hypertension or a rapidly rising serum creatinine level immediately after initiation of therapy with an ACE inhibitor or angiotensin receptor blocker. Other causes of acute deterioration in renal function include papillary necrosis with ureteral obstruction owing to sloughing of a papilla, obstructive uropathy caused by bladder dysfunction as a result of autonomic neuropathy, and contrast media–induced acute tubular necrosis (Chapter 106). In addition, prerenal azotemia or acute tubular necrosis may develop in diabetic patients as a result of heart failure or volume depletion owing to vomiting induced by gastroparesis (Chapter 210) or diarrhea from autonomic neuropathy.

DIAGNOSIS

The diagnosis of overt diabetic nephropathy[9] is made by three main criteria: the presence of proteinuria within an appropriate time frame, the presence of retinopathy (90 to 95% in type 1 and 60 to 65% in type 2), and the absence of other causes of nephrotic syndrome or renal insufficiency. For patients who have type 1 diabetes and who develop diabetic nephropathy, significant proteinuria is seen within 11 to 23 years of the onset of diabetes. Although microalbuminuria does not always progress to overt proteinuria in these patients, it always precedes overt proteinuria in the patients who do progress. All patients with type 1 diabetes should be screened for microalbuminuria 5 years after the diagnosis and yearly thereafter. Patients who have type 2 diabetes should be screened for microalbuminuria at the time of diagnosis and yearly thereafter.

	Stage I	Stage II	Stage III	Stage IV
Median year of onset	0	10	15-17	18-20
Patients with diabetes (%)	100	30-35	30	30



Urinary protein	Occasional and transient microalbuminuria	Fixed microalbuminuria	Proteinuria (>500 mg/24 hr) and microalbuminuria (200 mg/24 hr)	Nephrotic-range proteinuria (<3.5 g/24 hr)
Systemic manifestations	Hypertension: absent in type 1; often present in type 2	Hypertension: absent in type 1; typical in type 2	Hypertension: absent in type 1 and worsening in type 2	Manifestations of chronic renal insufficiency
Renal morphology and history	Kidney hypertrophy	Glomerular basement membrane thickening and mesangial matrix expansion	Focal glomerulosclerosis (± nodular or Kimmelstiel-Wilson lesions) Microvascular hyalinosis and tubulointerstitial fibrosis	Kidney may still be inappropriately large for level of renal insufficiency Global glomerulosclerosis and tubulointerstitial fibrosis

FIGURE 109-1. Stages of diabetic nephropathy. GFR = glomerular filtration rate.

Renal Biopsy

Renal biopsy is rarely required to make the diagnosis unless another cause of proteinuria and renal failure is suspected (Chapters 100, 107, and 108). If performed, the biopsy will reveal diffuse or nodular (Kimmelstiel-Wilson) glomerulosclerosis. Although the Kimmelstiel-Wilson lesion is considered pathognomonic of advanced diabetic nephropathy, only approximately 25% of patients manifest this lesion. A nodular pattern of glomerulopathy mimicking Kimmelstiel-Wilson lesions may also be seen in light chain nephropathy (Chapter 173). Nodular glomerular lesions can also be observed in amyloidosis (Chapter 174) and membranoproliferative glomerulonephritis type II (Chapter 107). An additional pathognomonic feature of diabetic nephropathy is the finding of both afferent and efferent arteriolar hyalinosis, which can be distinguished from the isolated afferent arteriolar lesion of essential hypertension. In overt diabetic nephropathy, tubular alterations owing to tubular hypoxia may mediate the progressive decline in renal function, and progressive tubulointerstitial fibrosis correlates most closely with the decline in renal function.

PREVENTION AND TREATMENT

Glycemic Control

Glycemic control significantly lessens the incidence of nephropathy in patients with type 1 diabetes for at least 20 or more years but does not completely eliminate the risk (Fig. 109-2).[10] In patients with type 2 diabetes, tight control reduces the progression of microvascular complications but appears to be less effective in reducing the risk of macrovascular complications. The goal of diabetic treatment is an HbA_{1c} of 7% or less unless patients have significant comorbid conditions or an increased risk for hypoglycemia.[A1,11]

In latent (stage II) and overt (stage III) diabetic nephropathy, renal function declines. With declining renal function, some oral hypoglycemic agents become contraindicated (Chapter 210). Because of the increased risk of prolonged hypoglycemia, use of sulfonylureas is contraindicated in patients with stage 3b chronic kidney disease or worse (e.g., a GFR <45). Because of the potentially increased risk of lactic acidosis with metformin therapy in patients who have renal insufficiency, treatment guidelines currently recommend not administering it to patients with serum creatinine of greater than 1.7. In addition, as GFR declines, insulin requirements may decrease owing to reduced insulin degradation and clearance by the failing kidney (Chapter 210).

The treatment of diabetic kidney disease has been revolutionized by the advent of SGLT2 inhibiting agents,[12,13] which reduce glucose levels without causing hypoglycemia.[A2] In multiple studies, treatment with canagliflozin (initial dose of 100 mg once daily, increasing to 300 mg starting from week 13),[A3] empagliflozin (10 or 25 mg once daily),[A4] or dapagliflozin (10 mg once daily)[A5] has reduced cardiovascular events, including the progression of renal disease, in patients with type 2 diabetes (Chapter 210).[A6] In addition to glycosuria, these inhibitors reduce intraglomerular pressure through tubuloglomerular feedback, promote an osmotic diuresis and natriuresis, and lower blood pressure. These agents increase the risk of urinary tract infections, and they are currently not approved for treatment of patients with type 1 diabetes because of the potential risk of developing ketoacidosis. Since the glucose-lowering effect of SGLT2

Stage I	Tight glucose control BP control—consider use of ACEI or ARB
Stage II	Tight glucose control BP control ACEI or ARB SGLT2 inhibitor* Finerenone Smoking cessation Weight reduction Exercise Annual eye examination
Stage III	BP control ACEI or ARB SGLT2 inhibitor or GLP-1 analogue* Finerenone Restriction of dietary protein (to 0.8 g/kg/day of ideal body weight) Antihyperlipidemic medications
Stage IV	BP control ACEI or ARB SGLT2 inhibitor or GLP-1 analogue† Finerenone Treat manifestations of nephrotic syndrome and chronic renal insufficiency Prepare for renal replacement therapy, including prevention of abnormalities in calcium and phosphorus metabolism and prevention of anemia by early use of erythropoietin

FIGURE 109-2. Treatment of diabetic nephropathy. ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin-receptor blocker; BP = blood pressure; GLP-1 = glucagon-like peptide; SGLT2 = sodium glucose cotransporter 2. *SGLT2 inhibitor preferred, but GLP-1 analogue is the alternative if they cannot be used or are not tolerated †See text for adjustments/discontinuation in stage IV.

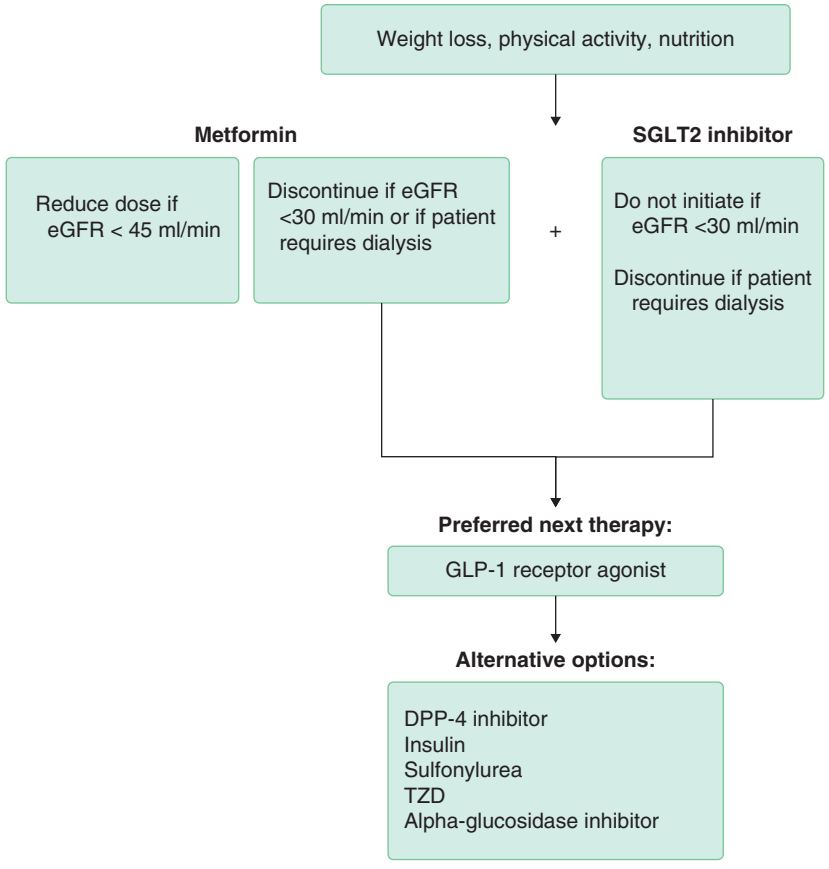


FIGURE 109-3. Approach to oral hypoglycemic agents in type 2 diabetic kidney disease. DPP-4 = dipeptidyl peptidase 4; eGFR = estimated glomerular filtration rate; GLP-1 = glucagon-like peptide 1; SGLT2 = sodium glucose cotransporter 2; TZD = thiazolidinedione.

inhibitors depends on glomerular filtration, the current recommendation is that they should be discontinued when the eGFR falls below 30 mL/min.

An alternative approach, especially when the GFR is too low to use SGLT2 inhibitors, is to use one of the subcutaneous glucagon-like receptor 1 (GLP-1) analogues (Fig. 109-3):[A7] liraglutide (1.2 or 1.8 mg once daily, added to basal insulin),[A8] semaglutide (starting dose of 0.25 mg for 4 weeks, then increasing to 0.5 mg for 4 weeks until a maintenance dose of 0.5 mg or 1.0 mg weekly is achieved),[A9] or dulaglutide (1.5 mg weekly).[A10] Efpeglenatide (4 to 6 mg subcutaneously weekly) is another experimental option.[A11] These agents also can slow the progression of diabetic nephropathy and reduce cardiovascular events in type 2 diabetes, and they can be continued until the GFR falls to 15 mL/min. These agents do not cause ketoacidosis but can induce hypoglycemia.

Blood Pressure Control

Elevated blood pressure is an important risk factor in the progression of diabetic nephropathy. To slow the progression of diabetic nephropathy, some guidelines recommend a blood pressure goal of <140/90 mm Hg whereas others recommend a target of <130/80 mm Hg.[14–16]

Medications that interfere with the renin-angiotensin system, either ACE inhibitors or angiotensin receptor blockers, are the preferred agents (see Tables 64-8 and 64-9), with calcium-channel antagonists as second-line therapy.[A12] SGLT2 inhibitors also lower blood pressure and can reduce the need for additional antihypertensive agents.[A13]

Because of the high prevalence of type IV renal tubular acidosis (Chapter 104) and renal artery stenosis (Chapter 110) associated with diabetic nephropathy, patients treated with ACE inhibitors or angiotensin receptor blockers should have their serum potassium and creatinine levels monitored closely in the first week after the initiation of therapy. If blood pressure control is not achieved with these agents, diuretics and other antihypertensive agents, including cardioselective β-blockers, α-blockers, and nondihydropyridine calcium-channel blockers, can be added (Chapter 64).[A14] Dihydropyridine calcium-channel blockers induce selective afferent arteriolar vasodilation and may increase intraglomerular capillary pressure, so they are usually reserved for patients who do not achieve blood pressure control with other agents.

Nonsteroidal Mineralocorticoid Antagonism

The addition of a nonsteroidal mineralocorticoid antagonist, finerenone (20 mg daily to standard of care with an ACE inhibitor or an angiotensin receptor blocker can significantly slow loss of kidney function[A15] and protect against cardiac complications in patients with type 2 diabetic nephropathy.[A16] Although hyperkalemia is a rare complication, careful monitoring and management of potassium levels are indicated when adding this agent.

General Measures

Because morbidity and mortality from cardiovascular disease are significantly increased in patients with diabetic nephropathy, physicians should encourage smoking cessation (Chapter 363) and should prescribe statins for patients with hyperlipidemia (Chapter 190). Judicial restriction of dietary protein to 0.8 g/kg of ideal body weight per day is also recommended. Although further dietary protein restriction may retard the progression of diabetic nephropathy, considerations of such restrictions must be balanced against the individual patient's nutritional requirements.

Renal Replacement Therapy

In general, the management of a diabetic patient nearing ESRD is similar to that of a nondiabetic patient (Chapter 116). Stage III patients should be under the care of a nephrologist, and planning should be initiated for the modality of dialysis. Although dialysis is generally initiated when the GFR declines to less than 10 mL/min, earlier initiation of dialysis is sometimes necessary in diabetic patients in whom issues such as volume-dependent hypertension or hyperkalemia may not otherwise be manageable without renal replacement therapy. Uremia and gastroparesis also can lead to malnutrition or uncontrollable recurrent emesis. More than 80% of patients with end-stage diabetic nephropathy receive dialysis as their modality of renal replacement therapy (Chapter 117), with about five times as many undergoing hemodialysis as compared with peritoneal dialysis (Chapter 117).

Approximately 25% of renal transplants performed in the United States are in diabetic patients. Pancreas and combined kidney-pancreas transplantation can significantly improve the quality of life of patients with diabetic nephropathy by improving autonomic neuropathy, by retarding or possibly correcting retinopathy, and by avoiding the potential complications of insulin administration. However, all transplantation options remain limited by organ availability.

PROGNOSIS

Diabetic nephropathy is relentlessly progressive, even though appropriate medical therapy may slow the progression. Epidemiologic data suggest that diabetic nephropathy is associated with about a 15-year reduction in life expectancy because of the microvascular and macrovascular complications of diabetes (Chapter 210) as well as the kidney disease itself.

Because of their associated cardiovascular, cerebrovascular, and peripheral vascular disease, as well as their increased risk for infection, the mortality of diabetic patients who receive dialysis (Chapter 117) is 1.5 to 2.0 times worse

than in nondiabetic patients, corresponding to a 5-year survival rate of less than 20% in diabetic patients undergoing maintenance dialysis. Outcomes are worse in patients whose HbA_{1c} levels are above 8.5%. Long-term survival and quality of life are generally superior after kidney transplantation compared with chronic dialysis. However, the other microvascular complications (retinopathy, neuropathy) are not improved by renal transplantation alone.

110 VASCULAR DISORDERS OF THE KIDNEY

THOMAS M. COFFMAN AND STEPHEN R. SMITH

Vascular disorders of the kidney include renal artery stenosis, atheromatous embolization, renal infarction, and renal vein thrombosis. Each of these abnormalities has characteristic clinical manifestations, but treatment options are limited, except for fibromuscular dysplasia. The kidneys also can be affected by systemic vasculitis, thrombotic thrombocytopenic purpura, malignant hypertension with fibrinoid necrosis, extrinsic compression of the renal vessels, trauma, dissection, and radiation-induced injury.

RENAL ARTERY STENOSIS

DEFINITION

Renal artery stenosis is defined as narrowing of one or both renal arteries, thereby resulting in reduction in blood flow to the kidney. The leading cause is atherosclerosis (about 90% of cases), followed by fibromuscular dysplasia. Although renal artery stenosis is often clinically silent, its major clinical sequelae are hypertension and reduced kidney function. A subset of patients with renal artery stenosis has renovascular hypertension, a diagnosis that can be confirmed when an intervention to correct renal artery stenosis results in a significant decline in blood pressure or a reduction in medications needed to control blood pressure.

EPIDEMIOLOGY

Some degree of renal artery stenosis is present in 10 to 20% of patients who have severe or therapy-resistant hypertension, recent-onset hypertension, hypertension developing at an early age, or hypertension with an abdominal bruit. A similar prevalence is observed in patients whose renal arteries are imaged during coronary arteriography for known or suspected coronary artery disease.

Atherosclerosis is the most common cause of renal artery stenosis, accounting for about 90% of clinically identified cases.[1,2] For atherosclerotic renal artery stenosis, epidemiologic risk factors mirror those of atherosclerotic vascular disease (Chapter 40), including risk factors such as hyperlipidemia (Chapter 190), diabetes (Chapter 210), hypertension (Chapter 64), smoking (Chapter 363), and increasing age. Most patients have evidence of widespread atherosclerosis involving the coronary, cerebral, and/or peripheral arteries.

Fibromuscular dysplasia (Chapter 66), which is a distinctly less frequent cause of renal artery stenosis compared with atherosclerosis, typically manifests between ages 20 to 60 years and is more common in women. Although its exact prevalence in the general population is not clear, mild, non-obstructive fibromuscular lesions are seen in about 4% of individuals undergoing renal arteriograms for evaluation as renal transplant donors. Although familial clusters of patients with fibromuscular dysplasia have been reported, most cases are sporadic, and no genetic associations have yet been identified.[3] Rare causes of renal artery stenosis include renal artery dissection, emboli, and extrinsic compression.[4]

PATHOBIOLOGY

The pathobiology of atherosclerotic renal artery stenosis is no different than for atherosclerosis in other arteries (Chapter 41). Fibromuscular dysplasia is an idiopathic, segmented, noninflammatory disease principally of medial layers of the artery (Chapter 63). Any artery can be involved, and about 90% of affected individuals have multifocal disease.

The pathobiologic sequelae of apparent renal artery stenosis depend on the extent and the acuity of the reduction of renal blood flow, as well as whether one or both renal arteries are affected. When the renal artery has a 70% or greater stenosis and a 20 to 25% peak systolic gradient across that stenosis, reduced perfusion pressure to the kidney triggers the release of renin by the juxtaglomerular apparatus, thereby activating the renin–angiotensin–aldosterone system and causing vasoconstriction, the retention of fluid and sodium, and hypertension, sometimes accompanied by flash pulmonary edema.

With bilateral renal artery stenosis or unilateral stenosis in a patient with a solitary functioning kidney, sustained reductions in the glomerular filtration rate can lead to chronic kidney disease, referred to as ischemic nephropathy. Although the kidneys are high-flow organs whose relatively low oxygen consumption provides some protection against the downstream consequences of reduced renal blood flow, critical stenosis sustained for prolonged periods can cause irreversible loss of kidney function. Non-hemodynamic mechanisms, such as activation of pro-inflammatory and pro-fibrotic pathways, also likely play a role. Impaired expression of angiogenic factors, such as vascular endothelial growth factor, results in pathologic remodeling of the renal microvasculature. These non-hemodynamic factors may explain, at least in part, why kidney function may not significantly improve after procedures that successfully restore a normal patency of the renal artery.

The nature of vascular disease in renal artery stenosis differs depending on the cause. With atherosclerosis, stenosis is caused by intrusion of atherosclerotic plaques, which may originate in the aorta, into the lumen of the main renal arteries. In atherosclerotic disease, the stenosis is commonly seen at the ostial segment at the origin of the renal artery, although stenoses can also occur along the entirety of one or both renal arteries. By contrast, fibromuscular dysplasia can be focal but more commonly is multifocal and characterized by areas of post-stenotic dilatation, thereby leading to the angiographic appearance of beads on a string. In fibromuscular dysplasia, lesions are typically located away from the origin of the renal artery, often in the midportion of the vessel or at the first arterial bifurcation.

than in nondiabetic patients, corresponding to a 5-year survival rate of less than 20% in diabetic patients undergoing maintenance dialysis. Outcomes are worse in patients whose HbA_{1c} levels are above 8.5%. Long-term survival and quality of life are generally superior after kidney transplantation compared with chronic dialysis. However, the other microvascular complications (retinopathy, neuropathy) are not improved by renal transplantation alone.

110 VASCULAR DISORDERS OF THE KIDNEY

THOMAS M. COFFMAN AND STEPHEN R. SMITH

Vascular disorders of the kidney include renal artery stenosis, atheromatous embolization, renal infarction, and renal vein thrombosis. Each of these abnormalities has characteristic clinical manifestations, but treatment options are limited, except for fibromuscular dysplasia. The kidneys also can be affected by systemic vasculitis, thrombotic thrombocytopenic purpura, malignant hypertension with fibrinoid necrosis, extrinsic compression of the renal vessels, trauma, dissection, and radiation-induced injury.

RENAL ARTERY STENOSIS

DEFINITION

Renal artery stenosis is defined as narrowing of one or both renal arteries, thereby resulting in reduction in blood flow to the kidney. The leading cause is atherosclerosis (about 90% of cases), followed by fibromuscular dysplasia. Although renal artery stenosis is often clinically silent, its major clinical sequelae are hypertension and reduced kidney function. A subset of patients with renal artery stenosis has renovascular hypertension, a diagnosis that can be confirmed when an intervention to correct renal artery stenosis results in a significant decline in blood pressure or a reduction in medications needed to control blood pressure.

EPIDEMIOLOGY

Some degree of renal artery stenosis is present in 10 to 20% of patients who have severe or therapy-resistant hypertension, recent-onset hypertension, hypertension developing at an early age, or hypertension with an abdominal bruit. A similar prevalence is observed in patients whose renal arteries are imaged during coronary arteriography for known or suspected coronary artery disease.

Atherosclerosis is the most common cause of renal artery stenosis, accounting for about 90% of clinically identified cases.[1,2] For atherosclerotic renal artery stenosis, epidemiologic risk factors mirror those of atherosclerotic vascular disease (Chapter 40), including risk factors such as hyperlipidemia (Chapter 190), diabetes (Chapter 210), hypertension (Chapter 64), smoking (Chapter 363), and increasing age. Most patients have evidence of widespread atherosclerosis involving the coronary, cerebral, and/or peripheral arteries.

Fibromuscular dysplasia (Chapter 66), which is a distinctly less frequent cause of renal artery stenosis compared with atherosclerosis, typically manifests between ages 20 to 60 years and is more common in women. Although its exact prevalence in the general population is not clear, mild, non-obstructive fibromuscular lesions are seen in about 4% of individuals undergoing renal arteriograms for evaluation as renal transplant donors. Although familial clusters of patients with fibromuscular dysplasia have been reported, most cases are sporadic, and no genetic associations have yet been identified.[3] Rare causes of renal artery stenosis include renal artery dissection, emboli, and extrinsic compression.[4]

PATHOBIOLOGY

The pathobiology of atherosclerotic renal artery stenosis is no different than for atherosclerosis in other arteries (Chapter 41). Fibromuscular dysplasia is an idiopathic, segmented, noninflammatory disease principally of medial layers of the artery (Chapter 63). Any artery can be involved, and about 90% of affected individuals have multifocal disease.

The pathobiologic sequelae of apparent renal artery stenosis depend on the extent and the acuity of the reduction of renal blood flow, as well as whether one or both renal arteries are affected. When the renal artery has a 70% or greater stenosis and a 20 to 25% peak systolic gradient across that stenosis, reduced perfusion pressure to the kidney triggers the release of renin by the juxtaglomerular apparatus, thereby activating the renin–angiotensin–aldosterone system and causing vasoconstriction, the retention of fluid and sodium, and hypertension, sometimes accompanied by flash pulmonary edema.

With bilateral renal artery stenosis or unilateral stenosis in a patient with a solitary functioning kidney, sustained reductions in the glomerular filtration rate can lead to chronic kidney disease, referred to as ischemic nephropathy. Although the kidneys are high-flow organs whose relatively low oxygen consumption provides some protection against the downstream consequences of reduced renal blood flow, critical stenosis sustained for prolonged periods can cause irreversible loss of kidney function. Non-hemodynamic mechanisms, such as activation of pro-inflammatory and pro-fibrotic pathways, also likely play a role. Impaired expression of angiogenic factors, such as vascular endothelial growth factor, results in pathologic remodeling of the renal microvasculature. These non-hemodynamic factors may explain, at least in part, why kidney function may not significantly improve after procedures that successfully restore a normal patency of the renal artery.

The nature of vascular disease in renal artery stenosis differs depending on the cause. With atherosclerosis, stenosis is caused by intrusion of atherosclerotic plaques, which may originate in the aorta, into the lumen of the main renal arteries. In atherosclerotic disease, the stenosis is commonly seen at the ostial segment at the origin of the renal artery, although stenoses can also occur along the entirety of one or both renal arteries. By contrast, fibromuscular dysplasia can be focal but more commonly is multifocal and characterized by areas of post-stenotic dilatation, thereby leading to the angiographic appearance of beads on a string. In fibromuscular dysplasia, lesions are typically located away from the origin of the renal artery, often in the midportion of the vessel or at the first arterial bifurcation.

ABSTRACT

Renal artery stenosis, atheromatous embolization to the kidneys, renal vein thrombosis, and renal infarction are the principal vascular disorders of the kidney. Renal artery stenosis is usually atherosclerotic in origin and treated with antihypertensive medications. By comparison, fibromuscular renal artery stenosis responds well to interventional therapies, which may even cure the hypertension. Atheromatous renal embolization is usually a sequela of an intra-arterial intervention and portends a poor prognosis. Renal vein thrombosis is often related to a hypercoagulable state, such as seen in the nephrotic syndrome, but can also be caused by trauma or tumor.

renal artery stenosis
fibromuscular dysplasia
atheromatous embolization
renal vein thrombosis
kidney infarction

CLINICAL MANIFESTATIONS

The clinical manifestations of renal artery stenosis may be minimal in many patients, and the diagnosis is often made incidentally during the course of unrelated vascular studies. The most common clinical manifestation of significant renal artery stenosis is arterial hypertension (Chapter 64). Flash pulmonary edema also can be observed and may be more common in patients who have had prior manifestations of heart failure.

Renovascular hypertension from fibromuscular dysplasia should be suspected in patients who have the onset of hypertension at an early age, especially in women, whereas atherosclerotic renal artery hypertension should be considered when an elderly patients or a patient with atherosclerosis in other organ systems develops new-onset hypertension or the sudden worsening of previously well-controlled existing hypertension. The presence of an abdominal bruit on physical examination should further increase the index of suspicion.

In renal artery stenosis caused by atherosclerosis, kidney damage (i.e., a reduction in the glomerular filtration rate) is generally slowly progressive without proteinuria or an active urinary sediment. By comparison, a progressive reduction in the glomerular filtration rate is uncommon with fibromuscular dysplasia. An acute precipitous decrease in the estimated glomerular filtration rate after initiating therapy with an inhibitor of the renin angiotensin system may indicate bilateral renal artery stenosis or unilateral stenosis in a patient with one functioning kidney.

TABLE 110-1 CLINICAL SITUATIONS IN WHICH STENTING OR SURGICAL REVASCULARIZATION IS LIKELY APPROPRIATE FOR ATHEROSCLEROTIC RENAL ARTERY STENOSIS

Flash pulmonary edema or recurrent acute coronary syndrome with hypertension and moderate or more renal artery stenosis with a resting translesional mean gradient ≥10 mm Hg
Stage IV chronic kidney disease with bilateral moderate renal artery stenosis and a resting translesional mean gradient ≥10 mm Hg and a kidney size >7 cm in pole-to-pole length
Stage IV chronic kidney disease and global renal ischemia with unilateral severe renal artery stenosis in a solitary kidney or bilateral severe renal artery stenosis without another explanation
Uncontrolled hypertension despite maximally tolerated doses of at least three antihypertensive agents, one of which is a diuretic agent, and bilateral or solitary severe renal artery stenosis

DIAGNOSIS

Since establishing the diagnosis of atherosclerotic renal artery principally influences the choice among medical therapies (Table 64-9) rather than guiding interventional therapies, specific diagnosis is helpful only in limited situations in which careful antihypertensive therapy is unsuccessful (Table 110-1).[5] By comparison, diagnosis and interventional treatment of fibromuscular muscle dysplasia can potentially cure hypertension and avoid its complications, so prompt diagnosis is important.

The diagnosis of renal artery stenosis requires an imaging study using Doppler ultrasound, computed tomographic angiography (CTA), magnetic resonance angiography (MRA), or conventional arteriography, with arteriography considered the gold standard for diagnosis. The choice among these options depends on the patient's characteristics, local imaging expertise, and whether the diagnosis would modify therapy. Doppler ultrasound requires a skilled operator and is typically less sensitive and specific than contrast-based approaches. CTA and MRA require exposure to iodinated or gadolinium-based contrast material, respectively, both of which can have toxicities, especially in individuals with reduced kidney function. Another option is MRA using ferumoxytol, which is an iron-containing contrast agent with no risk of nephrogenic sclerosis or nephrotoxicity but with somewhat lower resolution. However, noninvasive tests carry a significant likelihood of overestimating the degree of stenosis compared with conventional arteriography, so confirmatory catheter angiography is typically required for patients who are considered candidates for angioplasty or stenting.

Atherosclerotic stenoses are generally irregular and can be bilateral (Fig. 110-1), whereas stenoses of fibromuscular dysplasia typically show a "string of beads" appearance (Fig. 110-2). Isolated measurements of peripheral vein plasma renin activity are of limited utility in the diagnosis of renal artery stenosis, but measuring peripheral or renal vein plasma renin activity after a single dose of captopril may be of some value in determining whether an observed stenosis is hemodynamically significant.

TREATMENT

Atherosclerotic Renal Artery Stenosis

For atherosclerotic renal artery stenosis, neither percutaneous angioplasty nor stenting provide improved overall outcomes compared with best medical treatment.[A1,A2] Nevertheless, some individuals (i.e., patients whose severe hypertension requires three medications, who have had a recent acute decline in kidney function, or who have episodes of flash pulmonary edema) may have better subsequent blood pressure control or kidney function following stenting or surgical revascularization (see Table 110-1).[6–8]

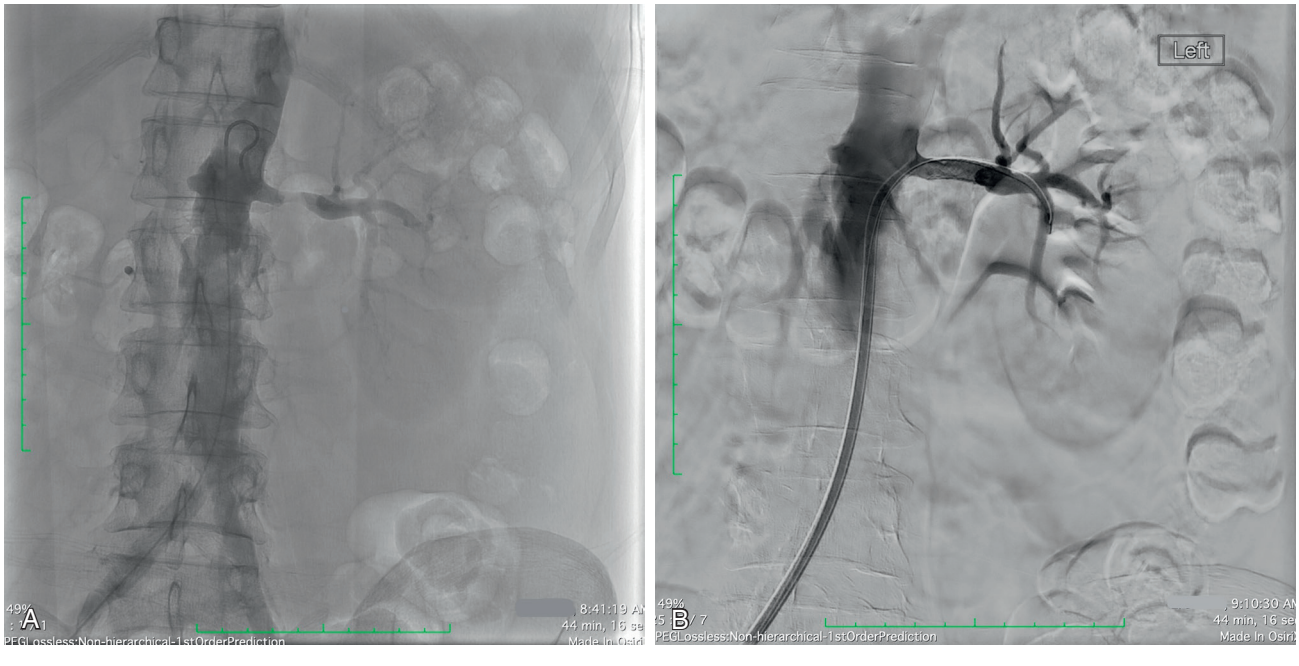

FIGURE 110-1. Renal artery atherosclerosis. A, Renal arteriogram showing moderate atherosclerotic stenosis of the left renal artery and total occlusion of the right renal artery in a patient with resistant hypertension and chronic kidney disease. **B,** Left renal artery with stent in place. The patient's blood pressure did not improve with stenting of the left renal artery but did improve dramatically with resection of the atrophic right kidney, not seen on the arteriogram.

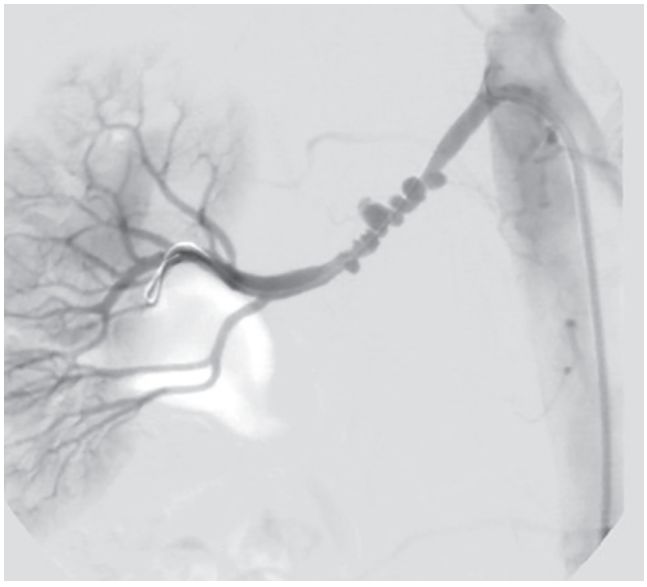

FIGURE 110-2. Right renal arteriogram showing "beads on a string" appearance of fibromuscular dysplasia.

As a result, medical management is the preferred therapeutic approach for the majority of individuals with atherosclerotic renal artery stenosis. The best medical therapy, based on expert opinion, includes smoking cessation (Chapter 363), management of hyperlipidemia (Chapter 190), aspirin (75 to 100 mg per day), and control of hypertension (Chapter 64) with inhibitors of the renin–angiotensin system (Tables 64-7 and 64-9) while carefully monitoring kidney function.

Fibromuscular Dysplasia

By comparison, nonrandomized data support a benefit from percutaneous angioplasty for patients who have fibromuscular dysplasia in terms of improved blood pressure control in 35 to 70% of patients.[9] Young women with severe hypertension may particularly benefit. Stenting is not generally required for lesions of fibromuscular dysplasia. Since fibromuscular dysplasia can be multifocal (Chapter 66), patients also may require angioplasty for lesions in other vascular beds or may need repeat renal angioplasty for recurrent disease in renal arteries years after successful angioplasty.

PROGNOSIS

Because atherosclerotic renal artery stenosis typically is a manifestation of severe systemic disease, it is a poor prognostic sign and patients are at markedly increased risk for ischemic events in other organs and the progression of renal insufficiency. For patients with fibromuscular dysplasia, prognosis depends on successful treatment of the hypertension as well as the severity and treatability of lesions in other vascular beds (Chapter 66).

ATHEROMATOUS EMBOLIZATION OF THE RENAL ARTERIAL SYSTEM

DEFINITION

Atheromatous cholesterol embolization (Chapter 66) is a multiorgan syndrome, which rarely can be caused by a spontaneous rupture of an atheromatous plaque but more commonly is a complication associated with interventional vascular procedures or the use of anticoagulants and thrombolytic agents. A shower of small particles, including cholesterol crystals from the larger central arteries to the distal circulation, can affect both native and transplanted kidneys. The clinical syndrome is distinct from arterial thromboembolism, in which larger thrombi lodge in downstream arteries and cause acute infarction.

EPIDEMIOLOGY

The precise incidence of renal atheromatous embolization is difficult to determine. Among patients known to have abdominal aortic aneurysms, the incidence is about 3% over 15 months, whereas the incidence is only 1% over 3 years in patients with thoracic aortic aneurysm.[10] Atheromatous embolization occurs in about 0.4% of patients undergoing left heart catheterization (Chapter 59),[11] and about two thirds of such cases affect the kidneys. Of patients who develop atheromatous embolization in the absence of a vascular procedure, about 7% have been taking anticoagulants or have received thrombolytic therapy. In patients over age 60 years who undergo a kidney biopsy for acute kidney injury (Chapter 106), about 5% have evidence of atheroembolic disease. Consistent with the epidemiology of atherosclerosis, atheroembolic disease is more commonly seen in older patients who have a high burden of systemic vascular disease.

PATHOBIOLOGY

Because of their small size, cholesterol emboli do not typically cause significant impairment of renal blood flow but instead tend to lodge and occlude smaller 100- to 200-μm arterioles such as arcuate and interlobular arteries and the glomerular capillaries. The presence of the crystals in vascular lumens leads to a complex inflammatory response with associated ischemia and necrosis. The glomerular lesion is presumably related to secondary effects of atheroembolization, including activation of immune and inflammatory mediators. The early phase of the inflammatory reaction includes neutrophils and eosinophils, but then a subsequent foreign body reaction is characterized by multinucleated giant cells and macrophages. The NLRP3 inflammasome has been implicated in the genesis of the inflammatory response. Complement is activated, as is the renin–angiotensin system, and some patients have reduced serum levels of complement. Emboli may be cleared over time by fibrinolysis and uptake by the endothelial cells, followed by their release into the perivascular space.

CLINICAL MANIFESTATIONS

Although a preceding invasive vascular procedure is an important precipitating event, the clinical manifestations can become apparent from days to months after the procedure. Involvement of other vascular beds is common and the presence of extrarenal atheroemboli such as livedo reticularis (Fig. 66-4), a petechial or purpuric rash (Chapter 66), ischemic toes, or amaurosis fugax with Hollenhorst plaques on fundoscopic examination strongly support the diagnosis.

The clinical presentation of atheromatous embolization to the kidneys is notoriously variable, but hypertension and slowly declining glomerular filtration rate are consistent features. Accordingly, the differential diagnosis is large and often includes acute tubular necrosis (Chapter 106), contrast nephrotoxicity (Chapter 59), allergic interstitial nephritis (Chapter 108), and vasculitis (Chapter 249).[12]

DIAGNOSIS

No pathognomonic laboratory tests are available, but peripheral blood eosinophilia may occur early in the course, and complement levels are low in a minority of cases. Inflammatory markers such as the erythrocyte sedimentation rate and the C-reactive protein level are typically elevated. Urinalysis is usually bland, but heavy proteinuria can occur. A urinary sediment with red cells is suggestive of acute glomerulonephritis and is rarely seen.

Tissue biopsy, typically of kidney, skin, or muscle, provides a definitive diagnosis but is not required in patients who have a history of a recent vascular procedure accompanied by physical findings suggestive of embolization. On kidney biopsy, the pathognomonic histologic feature on light microscopy is the presence of cholesterol crystal clefts (Fig. 110-3). The histopathologic process is patchy, and the sensitivity of kidney biopsy can be improved from about 75% with a single biopsy core to about 95% with the standard two cores. Focal segmental glomerulosclerosis is also seen in a substantial portion of biopsies.

TREATMENT

Although corticosteroids are often prescribed, no specific treatments are proven to be beneficial. Nevertheless, moderate- to high-dose statin therapy (Table 190-2) may be associated with better outcomes, whether at baseline or started after diagnosis. In the absence of effective medical therapy, prevention of further embolization emphasizes the avoidance, if possible, of anticoagulants and interventional vascular procedures. Blood pressure control, preferably with an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker (Table 64-9), is recommended.

PROGNOSIS

Prognosis of patients with renal atheroembolism is poor.[13] Approximately 30% of patients progress to end-stage kidney disease that requires dialysis, although a minority of patients who initiate dialysis may eventually recover sufficient kidney function to discontinue dialysis. Median survival from the time of diagnosis is about 5.5 years, and most patients die from cardiovascular complications as a reflection of the severity of their underlying atherosclerotic vascular disease.

RENAL INFARCTION

Occlusion of a main or segmental renal artery is an uncommon occurrence, accounting for 0.004 to 0.007% of emergency department visits. The cause can usually be traced to one of three processes: thromboembolism, a renal

vascular abnormality, or thrombosis in the setting of hypercoagulability (Chapter 67). Despite a rigorous evaluation,[14] up to 20 to 30% of cases have no identifiable cause.

The most common source of thromboembolism causing renal infarction is atrial fibrillation (Chapter 52), but thromboemboli to the kidney may also arise from endocarditis (Chapter 61), paradoxical embolus through a patent foramen ovale (Chapter 55), an atrial myxoma (Chapter 47), or aortic aneurysm (Chapter 63). Although renal infarction from thromboembolism usually affects only one kidney, bilateral disease also can be observed, and multiple segmental areas of infarction are typically seen.

The most common vascular abnormalities associated with renal infarction are spontaneous dissection of a renal artery aneurysm and fibromuscular dysplasia. However, infarction also can be seen after trauma and after endovascular procedures.

Hypercoagulable disorders associated with renal infarction, often bilateral, include thrombophilia (Chapter 67), the antiphospholipid syndrome (Chapter 160), the hypercoagulable state associated with nephrotic syndrome (Chapter 107), and in the setting of coronavirus-2019 (COVID-19)-associated hypercoagulability (Chapter 336).[15] Vasculitis (Chapter 249) is a very rare cause of renal infarction.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical presentation of renal infarction can be fairly nonspecific and may resemble other more common disorders such as pyelonephritis (Chapter 263) or nephrolithiasis (Chapter 111).[16] Flank pain is the most common presenting symptom, sometimes accompanied by nausea and fever and often accompanied by increased blood pressure, which may be dramatically elevated. If the cause is embolic, symptoms ascribable to emboli in other vascular beds may be present. Leukocytosis and elevations in the erythrocyte sedimentation rate, C-reactive protein level, and lactate dehydrogenase level are common.

Diagnosis is confirmed by cross-sectional imaging, usually by a CT angiogram, which is rapid and accurate, showing typical findings of a segmental lack of enhancement indicative of infarction. In individuals with a reduced glomerular filtration rate, MRA imaging using a non–gadolinium-based contrast such as ferumoxytol is a safe alternative. If a lesion in the main renal artery is suspected, catheter-based contrast arteriography may be warranted.

TREATMENT

Treatment is based on the suspected cause of the infarction. If a renal artery is totally occluded by thrombus, intra-arterial infusion of a thrombolytic agent may be of benefit. If embolism from the heart is suspected, immediate systemic anticoagulation is indicated with unfractionated or low-molecular-weight heparin (Table 70-3) followed by long-term anticoagulation therapy. Whether direct-acting anticoagulants (see Table 70-6) are superior to warfarin over the long term in this condition is unknown. The long-term benefit of systemic anticoagulation in patients with idiopathic renal infarction is uncertain. Surgical or percutaneous intervention is usually limited to patients who have bilateral occlusions, occlusions to a solitary kidney, traumatic renal artery thrombosis, or procedure-related thrombosis.

PROGNOSIS

The prognosis in renal infarction correlates with the extent of the kidney parenchyma that is affected and whether treatment can re-establish perfusion within 60 to 90 minutes. Because the lesions are typically segmental, are self-limited, and do not involve the entire kidney, prospects for maintaining adequate kidney function are better than for patients with atheroembolic disease, in which the injury tends to be diffuse. By 60 months, about 45% of patients have hypertension and two-thirds have stage 3 or higher chronic kidney disease (Chapter 116).[17] Follow-up imaging often shows that the affected kidney is smaller in size and has reduced function compared with the unaffected contralateral kidneys, but most patients do not require dialysis.

RENAL VEIN THROMBOSIS

Complete or partial thrombotic occlusion of one or both renal veins is a rare condition that occurs almost exclusively when at least two of three of the Virchow triad are present: low blood flow or stasis, trauma to the endothelium, and hypercoagulability. Males are affected more often than females, and the left renal vein is involved more often than the right, rarely because of extrinsic compression of the left renal vein by the superior mesenteric artery and aorta.[18] The most common setting for renal vein thrombosis is the nephrotic syndrome (Chapter 107), in which severe hypoalbuminemia is associated with the urinary loss of inhibitors of coagulation (e.g., protein S and antithrombin III), an increase in procoagulant factors (e.g., fibrinogen and β-thromboglobulin), and low oncotic pressure. Of the causes of nephrotic syndrome, membranous glomerulopathy is most commonly associated with renal vein thrombosis, although the incidence of 1% is not high enough to warrant routine screening. Primary causes of hyper-coagulability (Chapter 67), such as factor V Leiden and antiphospholipid antibody syndrome, are also associated with renal vein thrombosis.[19,20] Trauma can cause renal vein thrombosis, most often after kidney transplantation when mechanical stress or kinking of the renal vein in combination with low post-transplant blood flow may cause thrombosis. Renal cell carcinoma (Chapter 182) invading the renal vein and inferior vena cava can induce thrombosis. Profound volume depletion can lead to low blood flow in the renal veins and rarely cause thrombosis.

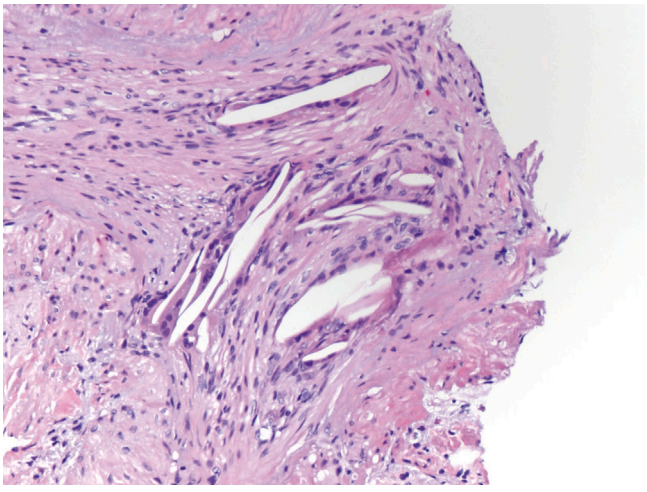

FIGURE 110-3. Hematoxylin and eosin–stained kidney biopsy showing cholesterol clefts in a renal arteriole.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Renal vein thrombosis may be asymptomatic, particularly if chronic. In the acute setting, however, flank pain, fever, nausea, and vomiting may occur along with gross hematuria. The differential diagnosis often includes pyelonephritis (Chapter 263) and nephrolithiasis (Chapter 111). If the left renal vein is involved, the gonadal vein may become distended, thereby causing the pelvic congestion syndrome in females and painful swelling of the left testicle in males.

Although Doppler ultrasound is a reasonable screening test and is often the study of choice for detecting renal vein thrombosis after kidney transplantation, the diagnosis is most readily made in native kidneys by CT angiography or MRI venography. Characteristic findings include enlargement of the kidney and renal vein, delayed excretion of contrast with a persistent nephrogram, and distortion of the renal pelvis and calyces. In more chronic cases, ureters may be notched by compressing venous varicosities.

TREATMENT

Patients who have asymptomatic unilateral renal vein thrombosis and good kidney function may not require anticoagulation. For patients with acute symptomatic renal vein thrombosis, anticoagulation with unfractionated or low-molecular-weight heparin (Table 70-3) should be followed by oral anticoagulation with warfarin to a target international normalized ratio of 2.0 to 3.0[21] to avoid further thromboembolic events and preserve kidney function, unless patients have contraindications to such treatment. Instillation of thrombolytic agents in the renal vein or, rarely, surgical thrombectomy is reserved for acute bilateral renal vein thrombosis or for unilateral renal vein thrombosis in a solitary functioning kidney. Long-term low-molecular-weight heparin may be preferred for renal vein thrombosis associated with a renal cell carcinoma. The optimal duration of systemic anticoagulation is unknown, but anticoagulation can be discontinued in patients whose membranous nephropathy goes into remission.

PROGNOSIS

Systemic anticoagulation is generally successful in preventing further thromboembolic events with an acceptable rate of bleeding complications, particularly if anti-platelet therapy is not used concurrently. Renal prognosis depends largely on the cause of the renal vein thrombosis and whether that cause resolves, persists, or recurs.[22]

111 NEPHROLITHIASIS

DAVID A. BUSHINSKY

Kidney stones are composed of crystals in a protein matrix. Most crystals contain calcium, which is generally complexed with oxalate, phosphate, or both, whereas other stones are composed of uric acid, magnesium ammonium phosphate (struvite), or cystine, alone or in combination. Kidney stones form when the saturation of their components exceeds the solubility of the solid phase in urine.

EPIDEMIOLOGY

The annual incidence of kidney stones in industrialized nations exceeds 1 per 1000 persons, with a lifetime risk of about 10% in women and about 15% in men. The incidence of stone formation peaks in the fourth and fifth decades, and prevalence increases with age until approximately 70 years in men and 60 years in women. In the United States, the prevalence of nephrolithiasis has increased from 3% in the late 1970s to more than 5%, an increase that is likely due to changes to diet and lifestyle, as well as more accurate diagnosis.[1] The estimated yearly economic cost of kidney stones exceeds $5 billion in the United States.

In the United States, Whites are more likely to develop renal stones than are other ethnic groups. Stones are more common in hot, dry climates, perhaps because greater fluid loss through the skin and respiratory epithelium leads to more concentrated urine. Many occupations make it inconvenient to utilize a restroom, and these individuals often avoid fluids in an effort to avoid urination, thereby leading to excretion of concentrated urine. Insufficient rehydration among people who engage in physical activity and have large insensible losses also leads to concentrated urine.

Obesity is correlated with the risk for kidney stone formation. Individuals weighing more than 220 pounds or having a body mass index greater than 30 are significantly more likely to form stones than are individuals who weigh less than 150 pounds or have a body mass index between 21 and 22.9.

The types of stones vary around the world,[2] but in the United States, the majority of stones are calcium oxalate and/or calcium phosphate (>80%), and less than 10% are pure uric acid stones. By comparison, about 70% of stones in the Mediterranean and Middle East are composed of uric acid. Magnesium ammonium phosphate (struvite) stones account for 1 to 25% of stones, whereas cystine stones comprise 1 to 2% of stones.[3]

PATHOBIOLOGY

Human bone is composed of calcium and phosphate, principally in the form of apatite. Once humans reach their adult height and their skeleton is fully mineralized, the net amount of calcium that is absorbed by nonpregnant individuals must be excreted in the urine. Similarly absorbed phosphate that is not needed for bone mineralization or cell growth must be excreted. Oxalate is an end product of metabolism, and it too must be excreted in the urine. The need for water conservation by terrestrial humans often leads to excretion of these ions in relatively scant amounts of urine, thereby promoting increased saturation with respect to the solid phases of calcium oxalate and/or calcium phosphate. Increasing saturation drives the formation of the solid crystal phase and is expressed as the ratio of calcium oxalate (or phosphate) ion activity to its solubility. At ratios of greater than 1, termed supersaturation, a solid phase can form, whereas the substances remain in solution at ratios less than 1. When urine is supersaturated, ions can bond to form the more stable, solid phase, which is termed *nucleation*. Homogeneous nucleation refers to the bonding of similar ions into crystals. The more common and thermodynamically favored heterogeneous nucleation occurs when crystals grow on dissimilar crystals or substances as cellular debris in the urine. Although humans produce inhibitors of stone formation, such as osteopontin and Tamm-Horsfall protein, supersaturation can overwhelm this inhibition, and a solid phase will form.

Calcium Stones

About 70 to 80% of kidney stones contain calcium, which is often complexed with oxalate or phosphate. Calcium-containing kidney stones are most often caused by excessive excretion of calcium (hypercalciuria), oxalate (hyperoxaluria), or urate (hyperuricosuria) or insufficient excretion of citrate (hypocitraturia).[4]

Calcium-containing stone formation has a strong genetic component.[5] Idiopathic hypercalciuria is thought to be a polygenic disorder in which a generalized dysregulation of calcium transport in the kidney, intestine, and bone leads to increased urinary calcium. A number of single-nucleotide polymorphisms, in genes coding for the calcium-sensing receptor, the vitamin D receptor, and osteopontin, and others, have been associated with calcium nephrolithiasis. Overall, 14 monogenic mutations account for 15% of nephrolithiasis/nephrocalcinosis, and genetic factors appear to explain about 20 to 35% of the interindividual variation in excretion of ions critical to stone formation.

Urinary oxalate is derived from endogenous metabolism of glyoxylate and ascorbic acid or from dietary sources, such as cocoa, nuts, tea, and certain leafy green vegetables such as spinach. The three main causes of hyperoxaluria are excessive oxalate ingestion *(dietary oxaluria)*, excessive intestinal absorption of oxalate *(enteric oxaluria)* that is paradoxically observed in malabsorptive gastrointestinal disorders, and excessive endogenous oxalate production seen in certain hepatic enzyme deficiencies (*primary hyperoxaluria*; Chapter 189). Additionally, ethylene glycol, a common automobile antifreeze, is metabolized to oxalate and can cause excessive urinary oxalate excretion in conjunction with severe metabolic acidosis and renal failure (Chapter 96).

Enteric oxaluria results in elevated urinary oxalate levels (60 to 100 mg/day).[6] In gastrointestinal malabsorptive conditions such as Crohn disease (Chapter 127), celiac sprue (Chapter 126), jejunoileal bypass (Chapter 201), and chronic pancreatitis (Chapter 130), malabsorbed fatty acids bind dietary calcium, thereby leaving oxalate free to pass into the colon, where it is more likely to be absorbed owing to the presence of bile acids; this excess oxalate is then subsequently filtered by the glomerulus and excreted in the urine. Intestinal bacteria also can influence oxalate levels by degrading it, preventing its absorption, or even stimulating its secretion from the circulation into the intestine.

Primary hyperoxaluria (Chapter 189) results from defects in hepatic enzymes in the liver glyoxylate pathway; the results are substantial endogenous oxalate production and a marked elevation of urinary oxalate (80 to 300 mg/day).[7] Oxalate deposits in numerous organs, including the heart, bone marrow, muscle, and renal parenchyma, where they lead to renal failure, cardiomyopathy, and bone marrow suppression at an early age. In type 1 primary hyperoxaluria, which accounts for about 80% of cases, the hepatic enzyme alanine glyoxylate aminotransferase, which converts glyoxylate to glycine, is deficient because of one of a large number of mutations in the *AGXT* gene. With deficient alanine glyoxylate aminotransferase, the glyoxylate is converted to oxalate. In the milder type 2 primary hyperoxaluria, which represents approximately 10% of cases, patients lack D-glycerate reductase and glyoxylate reductase owing to mutations in the *GRHPR* gene. Type 3 primary hyperoxaluria, which accounts for about 5% of cases, is a result of mutations in the *HOGA1* gene that catalyzes the cleavage of 4-hydroxy-2-oxoglutarate to pyruvate and glyoxylate.

Nephrolithiasis and nephrocalcinosis can also result from a variety of monogenic disorders, such as Dent disease (X-linked recessive nephrolithiasis; Chapter 113), McCune-Albright syndrome (Chapters 212 and 229), osteogenesis imperfecta type 1 (Chapter 239), and congenital lactase deficiency (Chapter 126).

Citrate inhibits stone formation by combining with calcium to form a soluble complex that reduces the availability of calcium to bind with oxalate or phosphate. The principal risk factor for hypocitraturia is a high protein intake. Men often have lower urinary citrate concentrations than women. Distal renal tubular acidosis (Chapter 104) promotes the formation of calcium phosphate stones owing to bone demineralization and an alkaline tubular pH.

Calcium oxalate kidney stones form on calcium phosphate deposits, termed Randall plaques, which are located in the renal papillae. Randall plaque formation is positively correlated with urine calcium excretion and negatively

PATHOBIOLOGY

Human bone is composed of calcium and phosphate, principally in the form of apatite. Once humans reach their adult height and their skeleton is fully mineralized, the net amount of calcium that is absorbed by nonpregnant individuals must be excreted in the urine. Similarly absorbed phosphate that is not needed for bone mineralization or cell growth must be excreted. Oxalate is an end product of metabolism, and it too must be excreted in the urine. The need for water conservation by terrestrial humans often leads to excretion of these ions in relatively scant amounts of urine, thereby promoting increased saturation with respect to the solid phases of calcium oxalate and/or calcium phosphate. Increasing saturation drives the formation of the solid crystal phase and is expressed as the ratio of calcium oxalate (or phosphate) ion activity to its solubility. At ratios of greater than 1, termed supersaturation, a solid phase can form, whereas the substances remain in solution at ratios less than 1. When urine is supersaturated, ions can bond to form the more stable, solid phase, which is termed *nucleation*. Homogeneous nucleation refers to the bonding of similar ions into crystals. The more common and thermodynamically favored heterogeneous nucleation occurs when crystals grow on dissimilar crystals or substances as cellular debris in the urine. Although humans produce inhibitors of stone formation, such as osteopontin and Tamm-Horsfall protein, supersaturation can overwhelm this inhibition, and a solid phase will form.

Calcium Stones

About 70 to 80% of kidney stones contain calcium, which is often complexed with oxalate or phosphate. Calcium-containing kidney stones are most often caused by excessive excretion of calcium (hypercalciuria), oxalate (hyperoxaluria), or urate (hyperuricosuria) or insufficient excretion of citrate (hypocitraturia).[4]

Calcium-containing stone formation has a strong genetic component.[5] Idiopathic hypercalciuria is thought to be a polygenic disorder in which a generalized dysregulation of calcium transport in the kidney, intestine, and bone leads to increased urinary calcium. A number of single-nucleotide polymorphisms, in genes coding for the calcium-sensing receptor, the vitamin D receptor, and osteopontin, and others, have been associated with calcium nephrolithiasis. Overall, 14 monogenic mutations account for 15% of nephrolithiasis/nephrocalcinosis, and genetic factors appear to explain about 20 to 35% of the interindividual variation in excretion of ions critical to stone formation.

Urinary oxalate is derived from endogenous metabolism of glyoxylate and ascorbic acid or from dietary sources, such as cocoa, nuts, tea, and certain leafy green vegetables such as spinach. The three main causes of hyperoxaluria are excessive oxalate ingestion *(dietary oxaluria)*, excessive intestinal absorption of oxalate *(enteric oxaluria)* that is paradoxically observed in malabsorptive gastrointestinal disorders, and excessive endogenous oxalate production seen in certain hepatic enzyme deficiencies (*primary hyperoxaluria*; Chapter 189). Additionally, ethylene glycol, a common automobile antifreeze, is metabolized to oxalate and can cause excessive urinary oxalate excretion in conjunction with severe metabolic acidosis and renal failure (Chapter 96).

Enteric oxaluria results in elevated urinary oxalate levels (60 to 100 mg/day).[6] In gastrointestinal malabsorptive conditions such as Crohn disease (Chapter 127), celiac sprue (Chapter 126), jejunoileal bypass (Chapter 201), and chronic pancreatitis (Chapter 130), malabsorbed fatty acids bind dietary calcium, thereby leaving oxalate free to pass into the colon, where it is more likely to be absorbed owing to the presence of bile acids; this excess oxalate is then subsequently filtered by the glomerulus and excreted in the urine. Intestinal bacteria also can influence oxalate levels by degrading it, preventing its absorption, or even stimulating its secretion from the circulation into the intestine.

Primary hyperoxaluria (Chapter 189) results from defects in hepatic enzymes in the liver glyoxylate pathway; the results are substantial endogenous oxalate production and a marked elevation of urinary oxalate (80 to 300 mg/day).[7] Oxalate deposits in numerous organs, including the heart, bone marrow, muscle, and renal parenchyma, where they lead to renal failure, cardiomyopathy, and bone marrow suppression at an early age. In type 1 primary hyperoxaluria, which accounts for about 80% of cases, the hepatic enzyme alanine glyoxylate aminotransferase, which converts glyoxylate to glycine, is deficient because of one of a large number of mutations in the *AGXT* gene. With deficient alanine glyoxylate aminotransferase, the glyoxylate is converted to oxalate. In the milder type 2 primary hyperoxaluria, which represents approximately 10% of cases, patients lack D-glycerate reductase and glyoxylate reductase owing to mutations in the *GRHPR* gene. Type 3 primary hyperoxaluria, which accounts for about 5% of cases, is a result of mutations in the *HOGA1* gene that catalyzes the cleavage of 4-hydroxy-2-oxoglutarate to pyruvate and glyoxylate.

Nephrolithiasis and nephrocalcinosis can also result from a variety of monogenic disorders, such as Dent disease (X-linked recessive nephrolithiasis; Chapter 113), McCune-Albright syndrome (Chapters 212 and 229), osteogenesis imperfecta type 1 (Chapter 239), and congenital lactase deficiency (Chapter 126).

Citrate inhibits stone formation by combining with calcium to form a soluble complex that reduces the availability of calcium to bind with oxalate or phosphate. The principal risk factor for hypocitraturia is a high protein intake. Men often have lower urinary citrate concentrations than women. Distal renal tubular acidosis (Chapter 104) promotes the formation of calcium phosphate stones owing to bone demineralization and an alkaline tubular pH.

Calcium oxalate kidney stones form on calcium phosphate deposits, termed Randall plaques, which are located in the renal papillae. Randall plaque formation is positively correlated with urine calcium excretion and negatively

ABSTRACT

The prevalence of kidney stones has increased over the last several decades, almost certainly due to changes in diet and the increased prevalence of obesity. Most kidney stones consist of calcium complexed with oxalate and/or phosphate. The most common metabolic abnormality found in kidney stone formers is idiopathic hypercalciuria, which is due to a systemic dysregulation of calcium transport at all major calcium transporting sites and has a strong genetic component. Stones form when the saturation of the major components of the stone exceeds the solubility of the associated solid phase. Stones often present as acute colic, and their spontaneous passage is directly correlated with their size. Alpha blockers such as tamsulosin can promote passage of smaller stones. Every patient who forms a kidney stone should undergo a metabolic evaluation to prevent recurrent stones. The depth of the evaluation is dependent on a number of factors, including the age when the first stone is diagnosed and the frequency of recurrent stones. Treatment for recurrent calcium stones rests on the 4 pillars of increased hydration (goal urine volume >2 liters per day), moderation of sodium intake (goal <2000 mg/day), moderation of protein intake (~1 g/kg/day), and an age- and gender-appropriate calcium intake derived mainly from dairy products and not from supplements. If these measures do not lower urinary supersaturation adequately, then thiazide diuretics and/or potassium citrate may be required. The recurrence rate of calcium oxalate nephrolithiasis is about 25% at 3 to 5 years.

correlated with urine volume and pH. These calcium phosphate crystals, in the form of apatite, originate around the thin loop of Henle and then extend into the interstitium without eroding into the tubular lumen or damaging the tubular cells. The crystals move toward the urinary space, where they form Randall plaques, which are visible on cystoscopy and also may be seen as medullary calcifications on computed tomography (CT). In the presence of urine that is supersaturated with respect to calcium oxalate, these ions may form a crystal that increases in size to several millimeters or even a centimeter. The stone can break off from the Randall plaque and then migrate to, irritate, and possibly obstruct the ureter.

Uric Acid Stones

The incidence of uric acid stones appears to be rising in the United States in parallel with the increase in obesity, which leads to renal insulin resistance and a very low urine pH.[8] Over 5 times as much uric acid is soluble in a urine with a pH of 6.5 compared with a pH of 5.3. Diarrhea and diets high in animal protein can contribute to an acidic urinary pH. Most patients with uric acid stones have a reduced urine pH, and some have low urine volumes or elevated urinary uric acid levels. Uric acid stone formers have greater body weight and a higher incidence of insulin resistance and type 2 diabetes mellitus. Insulin resistance also leads to impaired urinary ammonium excretion, thereby resulting in the excretion of more hydrogen ions as titratable acids and lower urine pH, which reduces the solubility of ammonium.

Hyperuricosuria may be seen in patients who ingest large quantities of dietary purine, such as organ meats, shellfish, certain fish (e.g., anchovies, sardines, herring, and mackerel), meat extracts (e.g., bouillon and consommé), and protein. Hyperuricemic disorders, including gout (Chapter 252), myeloproliferative disorders, tumor lysis syndrome, and certain inborn errors of metabolism, can also contribute to an increased urinary uric acid. Medications such as salicylates and probenecid can be hyperuricosuric.

Struvite Stones

Struvite stones, sometimes called *triple phosphate stones, magnesium ammonium phosphate stones*, and *infection stones*, comprise only about 10 to 25% of all stones but constitute the majority of staghorn calculi, which are large stones that extend beyond a single renal calyx.[9] Struvite stones are far more common in women than in men, in large part owing to women's increased susceptibility to upper urinary tract infections (Chapter 263). Similarly, any patient with urinary stasis, such as patients with neurogenic bladders, indwelling urinary catheters, or spinal cord lesions, is susceptible to struvite stones.

Struvite stones form only in the presence of both increased production of ammonium and an alkaline urine (pH ≥ 7), which occur only with urease-producing bacteria. *Proteus mirabilis* (Chapter 281) is a common urease-producing bacterium, but other gram-negative and gram-positive bacteria, such as *Klebsiella* spp. and *Staphylococcus epidermidis*, as well as *Mycoplasma* spp. (Chapter 293) and yeast species, have been implicated in urease production. By comparison, *Escherichia coli* does not produce urease.

Cystine Stones

Cystinuria (Chapter 113), which is an autosomal dominant disorder with incomplete penetrance or an autosomal recessive disorder caused by mutations of the *SLC3A1* gene or the *SLC7A9* gene, results in decreased renal tubular reabsorption and excessive urinary excretion of the dibasic amino acids cystine, ornithine, lysine, and arginine.[10] The resulting urinary excretion of cystine

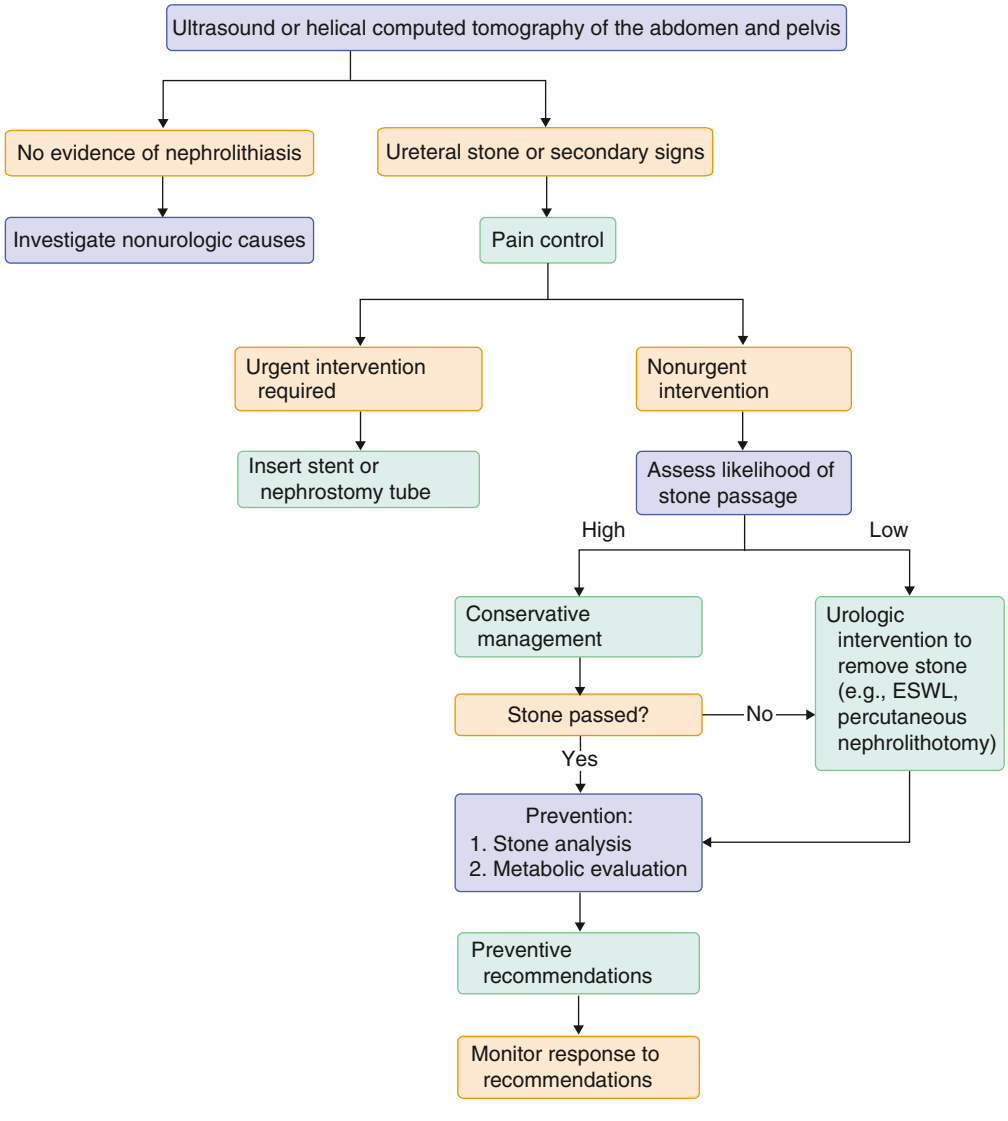

FIGURE 111-1. Algorithm for evaluation of suspected renal colic. ESWL = extracorporeal shock wave lithotripsy. (From Curhan GC. Nephrolithiasis. In: Goldman L, Schafer AI, eds. *Goldman's Cecil Textbook of Medicine*. 24th ed. Philadelphia: Elsevier Saunders; 2012.)

in the typical volume of urine exceeds its solubility of about 250 mg/L and enables stone formation. Although normal people excrete about 30 to 50 mg of cystine per day, heterozygotes for cystinuria excrete about 400 mg/day, and homozygotes often excrete about 600 mg/day. Thus, homozygotes must continually excrete more than 2 L of urine each day to avoid stone formation. Cystinuria is unrelated to the much more severe disorder *cystinosis* (Chapter 113), which results in extensive intracellular cystine accumulation.

CLINICAL MANIFESTATIONS

Patients with kidney stones often present with pain and/or hematuria, and less often present with urinary tract infections (Chapter 263) or acute kidney injury (Chapter 106), either owing to bilateral obstruction or unilateral obstruction in a single functioning kidney (Fig. 111-1). Patients often complain of severe ureteral colic. The pain is of abrupt onset and can intensify into severe, excruciating flank pain. The pain may migrate anteriorly along the abdomen and inferiorly to the groin, testicles, or labia majora as the stone moves down the ureter toward the ureterovesical junction. The pain resolves only after the stone passes or is removed. Microscopic or gross hematuria is common, and patients occasionally present with painless hematuria (see Fig. 100-3). The finding of a stone on radiographic examination does not preclude another cause. Conversely, even large calculi may be asymptomatic and be discovered during the investigation of unrelated symptoms. Obstruction caused by calculi may also be painless, and nephrolithiasis should always be considered in the differential diagnosis of unexplained acute or chronic kidney disease (Chapters 106 and 116).

DIAGNOSIS

The physical examination can provide clues to the diagnosis of kidney stones but is not diagnostic. Some patients have demonstrable flank tenderness, and a rare patient with hyperuricemia will have tophi (Chapter 252). However, the physical examination is most helpful for not showing other potential causes of pain. The suspicion of a kidney stone generally obligates radiographic evaluation. Radiographic studies can be deferred, however, in patients in whom the clinical diagnosis is clear, who have no evidence of infection, who are able to eat and drink, and who can be managed on oral analgesics.

Ultrasonography is an easy and rapid way to detect possible urinary obstruction without exposing the patient to ionizing radiation. Ultrasound can detect clinically significant renal calculi, with about an 85% sensitivity for detecting the ureteral stones that cause acute symptoms. Among emergency department patients with suspected nephrolithiasis, those who undergo ultrasonography have a lower cumulative radiation exposure than those randomized to CT without any significant differences in high-risk diagnoses, serious adverse events, pain scores, or subsequent rehospitalizations or emergency department visits.[A1] A helical CT scan or a low radiation CT scan without radiographic contrast can detect kidney stones with both a sensitivity and a specificity exceeding 95% (Fig. 111-2).[11] Based on the density of the stone, it also can often differentiate a calcium-containing stone from a cystine or uric acid stone. An added benefit is that helical CT is often helpful in determining the cause of nonstone abdominal pain (Chapter 119). In certain situations, such as in human immunodeficiency virus (HIV)–infected patients thought to have stones induced by a protease inhibitor, a helical CT scan with contrast is often required because the stones are not radiopaque and do not obstruct the ureter.

Approximately 90% of kidney stones are radiopaque and may be detected on a simple abdominal radiograph. Unfortunately, however, the stone is often obscured by stool, vertebrae, or abdominal gas, so the sensitivity of a plain abdominal radiograph is about 55%, and its specificity is only about 75%. Uric acid stones are radiolucent and cannot be detected radiographically without contrast.

Intravenous pyelography has a sensitivity of about 75% and a specificity of more than 90% for detecting renal calculi. Intravenous pyelography is also useful for identifying structural abnormalities of the urinary tract, such as a medullary sponge kidney (Chapter 112), that predisposes to stone formation. However, an intravenous pyelogram often does not detect nonobstructing radiolucent stones because they do not create a filling defect. An intravenous pyelogram exposes the patient to more radiation than a plain radiograph but less than a CT scan. It also carries the risk of radiographic contrast material, which is greater in individuals with underlying renal compromise. With the widespread availability of ultrasonography and helical CT scans, an intravenous pyelogram is rarely indicated.

TREATMENT

Medical Therapy

Because the pain of renal colic can be excruciating, pain control is critical after the definitive diagnosis has been made. If nausea and vomiting prevent the use of oral medication, parenteral medication is typically required. Nonsteroidal anti-inflammatory drugs (NSAIDs; Table 26-4) are as or more effective compared with opiates for renal colic and are preferred because they have fewer side effects.[A2,A3] An intravenous or intramuscular option is ketorolac (15 to 30 mg), and an oral option is ibuprofen (200 to 400 mg/dose every 4 to 6 hours with a maximum daily dose of 1.2 g) in patients who can tolerate oral medication. Because NSAIDs can cause acute kidney injury, especially in patients who are dehydrated or have pre-existing kidney injury, adequate hydration (e.g., normal saline at 75 to 150 mL/hour) is essential, but neither high-volume fluid therapy nor diuretics promote the passage of the stone. If necessary, oral oxycodone (5 to 15 mg every 4 to 6 hours as needed) may be added to ibuprofen for outpatient pain control. The dose and frequency of administration of oxycodone should be reduced in patients who have renal impairment.

Medical Expulsive Therapy

Kidney stones 5 mm or smaller have about a 70% probability of passing spontaneously, whereas stones between 5 and 7 mm have a 60% chance, stones 7 to 9 mm have a 48% chance, and stones 9 mm or larger have a 25% chance of passing spontaneously. Stones located more distally in the ureter are more likely to pass spontaneously. Medical expulsive therapy may be cautiously attempted with ureteral stones smaller than 10 mm diameter for 4 to 6 weeks if pain is controlled, kidney function is normal, and there is no evidence of urinary tract infection or significant obstruction.[12] The patient must be followed closely, generally with repeat ultrasound examinations every week or 2 weeks.

Expulsive therapy can reduce ureteral spasm and increase spontaneous passage rates by about 50%. Meta-analyses demonstrate an overall benefit for the α-blocker tamsulosin (0.4 mg orally daily),[A4,A5] which appears to promote the passage of the stone more quickly and effectively than the calcium-channel blocker nifedipine (nifedipine XL 30 mg daily or twice daily). Other options include a phosphodiesterase type 5 inhibitor (e.g., tadalafil 10 mg/day for 10 days) or a selective α_{1a}-receptor blocker (e.g., silodosin 4 mg/day). Silodosin appears more effective than tamsulosin for promoting the passage of large, distal ureteral stones.[A6]

Initial Surgical Treatment

Stones that cause obstruction, infection, acute kidney injury, or intractable pain must be removed expeditiously. In general, larger and more proximal stones are less likely to pass spontaneously, even with medical expulsive therapy, and are often an indicator for earlier intervention. Approximately 15% of all kidney stones require an intervention to remove them. For example, removal of small, asymptomatic kidney stones at the time of surgery to remove a ureteral or contralateral stone reduces the rate of relapse.[A7]

The approach to stone removal depends on its size, location, and composition, as well as on urinary tract anatomy. The major options for ureteral stone removal include percutaneous nephrolithotomy, extracorporeal shock wave lithotripsy, and ureteroscopy; open surgical extraction is rarely required. Percutaneous nephrolithotomy involves the passage of a flexible scope through the kidney and into the urinary space. Extracorporeal shock wave lithotripsy focuses external sound waves onto the kidney stone, thereby causing it to

fragment into smaller stones that can more easily be passed spontaneously. Ureteroscopy involves the passage of a ureteroscope into the ureter with removal or laser fragmentation of the stone. Meta-analyses suggest that ureteral stones should be treated with ureteroscopy or shock wave lithotripsy rather than percutaneous nephrolithotomy and that percutaneous nephrolithotomy is the treatment of choice for lower pole renal stones and the majority of large kidney stones (≥15 mm),[A8] because it results in longer stone-free rates and a lower need for retreatment, even though it is associated with more complications, usually minor, and a longer hospitalization compared with shock wave lithotripsy.

Medical Evaluation

After an initial stone episode, the recurrence rate in nontreated patients is estimated to be about 25% at 3 to 5 years and about 50% at 5 to 10 years. As a result, every patient who forms an initial stone should undergo evaluation with the goal of preventing recurrent stones. The history should focus on uncovering factors that predispose to stone formation. All stones should be analyzed to assist in defining the underlying metabolic abnormality and to guide therapy.[13]

A careful dietary history, including an estimate of fluid intake, is essential. Many stone formers are erroneously instructed to eliminate all calcium from their diet, a practice that not only increases stone formation but also may induce bone demineralization. Sodium intake should be estimated because sodium excretion obligates calcium excretion, thereby potentially leading to urinary supersaturation. Excessive animal protein intake increases metabolic acid production, which increases bone demineralization and calciuria.

Hypercalcemic disorders—including malignancy (Chapter 227), hyperparathyroidism (Chapter 227), and sarcoidosis (Chapter 83)—often result in hypercalciuria, increased urinary supersaturation, and calcium stone formation. Malabsorptive gastrointestinal disorders, such as Crohn disease (Chapter 127) and celiac disease (Chapter 126), or weight reduction surgery (Chapter 201), such as ileal resection or jejunoileal bypass, will often result in calcium oxalate stone formation from increased oxalate absorption and excretion as well as volume depletion.

Medications that can cause calcium stone formation include loop diuretics, which increase urinary calcium excretion, as well as salicylates and probenecid, which increase urinary uric acid excretion. Various medications that can themselves precipitate into stones include intravenous acyclovir, high-dose sulfadiazine, triamterene, and the antiretroviral agents indinavir and nelfinavir. Other medications that inhibit renal tubular carbonic anhydrase activity, such as acetazolamide and topiramate, can lead to metabolic acidosis, bone resorption, hypercalciuria, lower urinary citrate excretion, and higher urinary pH, all of which promote the formation of calcium phosphate stones.

The number and frequency of stones formed, the patient's age at the time of the first stone, the size of the stone, and an analysis of the composition of the stone are also important clues. Stones that develop at a young age suggest a genetic disorder, such as primary hyperoxaluria or cystinuria. Large staghorn calculi in elderly patients are consistent with struvite stones. A stone's response to intervention is also helpful: cystine stones do not fragment well with lithotripsy, and stones that recur frequently in a single kidney suggest a unilateral anatomic abnormality.

Basic laboratory testing should include levels of serum electrolytes (sodium, potassium, chloride, and bicarbonate), creatinine, calcium, phosphorus, uric acid, 25-hydroxyvitamin D, and thyroid-stimulating hormone. If the serum calcium is above and the serum phosphorus is below the midrange of normal, a serum parathyroid hormone level should be obtained.

An elevated urine specific gravity suggests inadequate fluid intake. Hematuria may indicate irritation to the urothelial lining by a stone. Characteristic crystals (see Fig. 100-10) are more common than in nonstone formers. The presence of hexagonal crystals (see Fig. 100-9) mandates that cystinuria be excluded. Patients with struvite stones generally have an elevated urine pH (>7.4) owing to the splitting of urea into ammonia and bicarbonate, whereas a low urinary pH (<5.5) raises the suspicion of uric acid stones. An elevated urine pH combined with bacteriuria (Chapter 263) suggests struvite stones. Because urease production may stimulate struvite stone formation despite low bacterial colony counts, the laboratory must identify all bacteria and determine antibiotic sensitivities even with low colony counts. If no bacteria are isolated, cultures for *Ureaplasma urealyticum* should be requested. The combination of an elevated urinary pH (6.5 to 7.2) with a low serum potassium and serum bicarbonate level strongly suggests distal renal tubular acidosis (Chapter 104).

In patients with recurrent stones and/or high-risk characteristics for recurrence, a 24-hour urine collection can determine the levels of calcium, oxalate, citrate, sodium, urate, phosphorus, and creatinine, as well as the calculation of supersaturation with respect to calcium oxalate, calcium phosphate, and uric acid (Table 111-1). Increased ion excretion of the components of a stone leads to increased rates of forming recurrent stones. An elevated supersaturation should lead the clinician to determine the individual components of the urine that are causing the increased supersaturation, and efforts can then be made to rectify these abnormalities. Cystine should also be measured at least once in every stone former to exclude cystinuria and regularly in patients who form cystine stones. Multivitamins should be discontinued about 5 days before the collection to prevent any antioxidant effect on the urine sample.

TABLE 111-1 OPTIMAL 24-HOUR URINE VALUES IN PATIENTS WITH NEPHROLITHIASIS

PARAMETER	VALUE
Volume	>2-2.5 L
pH	>5.5 and <7.0 (24-hr specimen not required)
Calcium	<250 mg
Oxalate	<40 mg
Sodium	<2000 mg
Uric acid	<750 mg
Phosphorus	<1100 mg
Citrate	>320 mg
Supersaturation with respect to calcium oxalate	<5
Supersaturation with respect to calcium phosphate	0.5-2
Supersaturation with respect to uric acid	0-1

Urine creatinine should be measured to ensure the adequacy of collection and should be >15 mg/kg in men and >10 mg/kg in women. Supersaturation is the ratio of the ion activity product and its solubility product.

PREVENTING RECURRENT STONES

Preventive treatment (Fig. 111-3) emphasizes advising the patient to increase oral fluid intake to produce a urine volume greater than 2 L per day, an oral intake that will reduce recurrent stone formation by about 50%.[A9,A10]

Calcium Stones

Because urine calcium excretion is directly correlated with urine sodium excretion, decreasing sodium intake will decrease urine calcium excretion and reduce supersaturation.[14] Patients with calcium stones should limit daily sodium intake to no more than 2 g per day and reduce animal protein intake to 0.8 to 1.0 g/kg per day.

The recommended calcium intake for a 19- to 50-year-old man or woman is 1000 mg of elemental calcium per day, and a number of studies demonstrate decreased formation of calcium stones when people consume diets adequate in calcium, presumably because appropriate calcium intake is needed for intestinal binding of dietary oxalate to prevent its absorption. Dairy products are preferred over calcium supplements because clinical studies indicate that women taking supplemental vitamin D and calcium have a significant increase in stone formation.

Patients with persistent hypercalciuria often benefit from longer-acting thiazide diuretics (e.g., chlorthalidone 12.5 to 25 mg/day), which directly lower urinary calcium and reduce recurrent stone formation by about 50%.[A11] However, a short-acting thiazide diuretic given once daily does not reduce symptomatic recurrences.[A12] Thiazides are effective only if patients restrict dietary sodium. In patients with hypercholesterolemia or hyperglycemia, indapamide (1.25 to 5 mg/day) can be used because it has less effect on these parameters. If patients develop hypokalemia, dietary potassium intake should be increased, or a potassium supplement can be administered. Allopurinol should be prescribed as for gout (300 mg daily; see Chapter 252). Potassium citrate (10 to 40 mEq/day) will increase urinary citrate excretion, bind urinary calcium, and further decrease recurrent stone formation.[A13] Potassium citrate is available as a wax-matrix tablet. A 24-hour urine collection can be repeated in a month or two to assess the response to therapy. Sodium-glucose cotransporter-2 (SGLT2) inhibitors appear to reduce the risk of nephrolithiasis by 50%[A14] but are not currently recommended for routine prophylactic use.

Patients with diet-related hyperoxaluria should be instructed to limit or avoid foods with high oxalate content such as cocoa, nuts, tea, and green leafy vegetables such as spinach. Because dietary calcium and oxalate bind in the gut, patients should consume these foods with calcium-containing foods. For enteric hyperoxaluria, treatment is first directed at the underlying disorder and then at instituting therapy for the cause of the steatorrhea (Chapter 126). Dietary oxalate should be restricted, and dietary calcium and oxalate should be ingested at the same meal. A diet that is low in fat; that is high in fruits, vegetables, and low-fat dairy products; that is rich in grains, fish, poultry, beans, seeds, and nuts; and that contains fewer sweets and less added sugar and red meat appears to be a reasonable alternative to a low-oxalate diet. Additional fluid intake and potassium citrate are often beneficial. Reloxaliase, which is an oral nonabsorbable oxalate-degrading enzyme,[15] is currently in clinical trials.

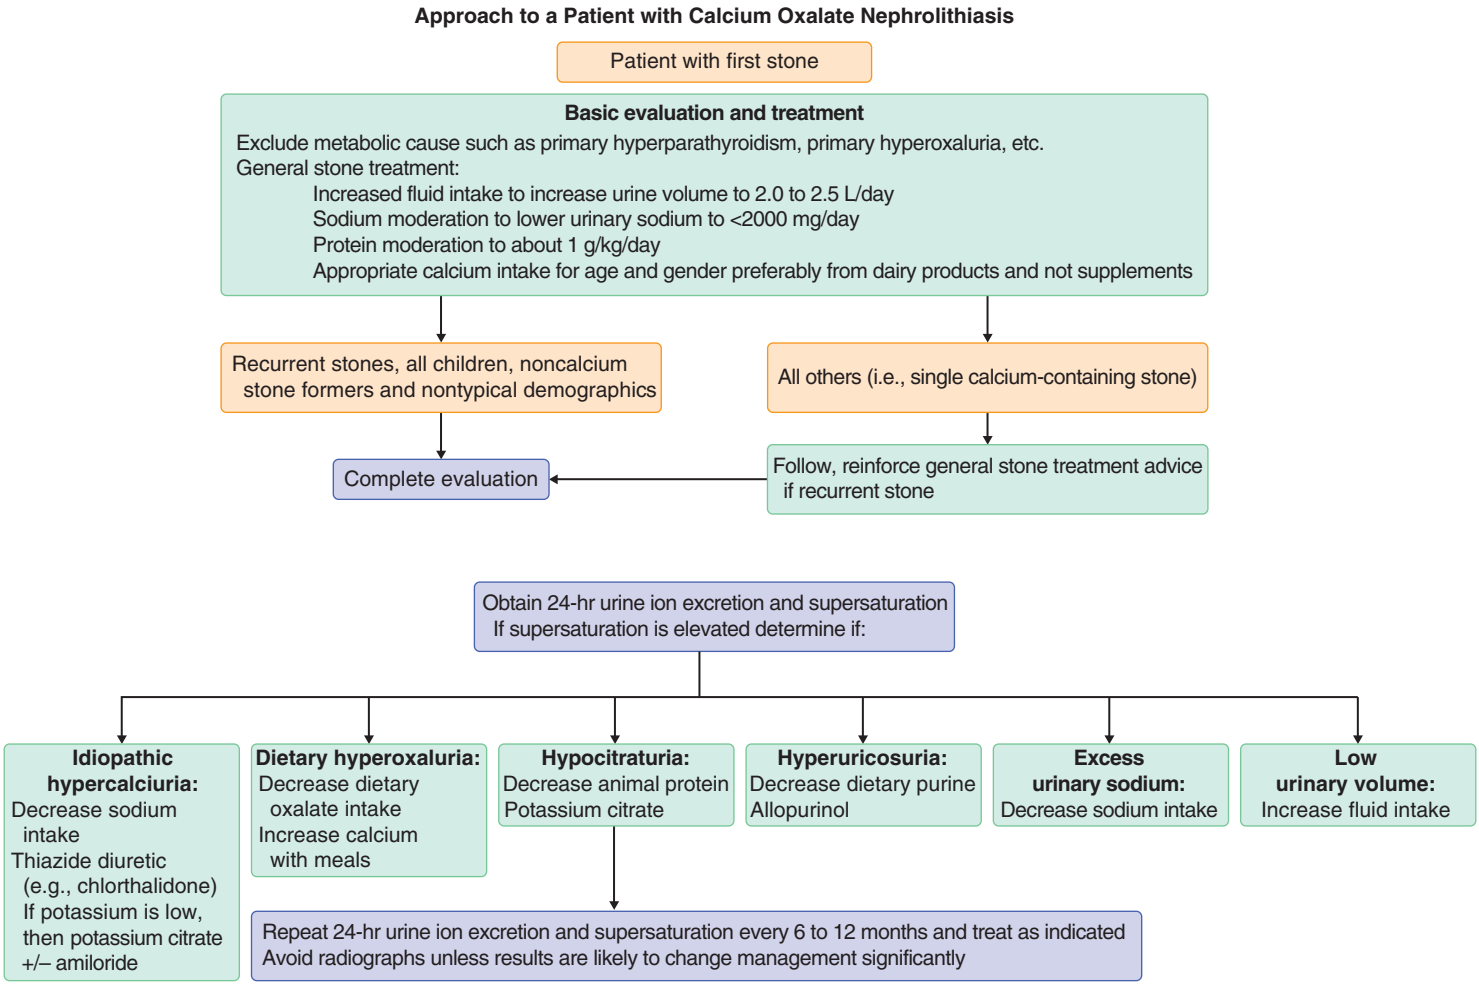

FIGURE 111-3. **Approach to a patient with calcium oxalate nephrolithiasis.**

In some patients with type 1 primary hyperoxaluria, pyridoxine (vitamin B_6) can increase enzyme activity and reduce oxalate production. These patients should also be treated with measures that reduce the precipitation of calcium oxalate, such as ample fluid intake and potassium citrate (10 to 40 mEq/day). Lumasiran, which is a small interfering RNA that decreases the levels of glycolate oxidase thereby resulting in less production of oxalate, reduces urinary oxalate levels by approximately 50% and reduces plasma oxalate levels into the normal range in patients who have type 1 primary hyperoxaluria.[A15] Lumasiran has the potential to eliminate the clinical manifestations, such as renal failure, of type 1 primary hyperoxaluria and to prevent the need for curative liver transplantation. All patients with type 1 primary hyperoxaluria should be seen by specialists and be considered for treatment with this therapy.

Calcium stones may be found in patients with hyperuricosuria. These patients often excrete excess amounts of urinary uric acid but normal amounts of urinary calcium and oxalate. Compared with patients with pure uric acid stones, they generally have a higher urinary pH (about 5.5). The mechanism by which uric acid promotes calcium stone formation is unclear. Therapy generally consists of dietary purine restriction, increased fluid intake, and the addition of allopurinol (300 mg daily) if necessary.

If moderation of dietary protein is not successful in patients with hypocitraturia, oral potassium citrate is given (10 to 40 mEq/day). Serum levels of potassium and bicarbonate must be closely monitored, especially in patients with chronic kidney disease.

Uric Acid Stones

Uric acid stones are radiolucent and are thus most often visualized with CT. Therapy for patients with uric acid stones begins with nonspecific measures such as increasing fluid intake, a low purine diet, and lowering animal protein intake to increase urinary pH. Ideally, the urinary pH should be elevated to approximately 6.5 to 7.0, a level that not only prevents new stone formation but also can dissolve existing uric acid stones without promoting calcium phosphate deposition. Potassium citrate (10 to 40 mEq/day) may be required to raise the urinary pH sufficiently. If all else fails, the carbonic anhydrase inhibitor acetazolamide (250 to 500 mg/day) may be initiated to raise urine pH. Because concomitant hyperuricemia may be present, allopurinol (100 to 300 mg daily) may be indicated to lower the serum uric acid level.

Struvite Stones

Struvite stones rapidly grow to a large size and may promptly recur if not completely removed. Therapy requires complete surgical stone removal coupled with appropriate long-term antibiotics (Chapter 263), selected on the basis of cultures of stone fragments retrieved from surgery. Antibiotics should be continued at full doses until the urine is sterile and then continued at a lower dose. Monthly surveillance cultures should be performed until the urine remains sterile for 3 consecutive months. Antibiotics can then be discontinued with monthly surveillance urine cultures for another year.

Cystine Stones

Cystine kidney stones, which usually develop by the second or third decade of life, are radiopaque and may appear as staghorn calculi or multiple stones. The disease should be suspected in any patient with an early onset of stones, frequently recurrent nephrolithiasis, and a family history of the disease. Although the presence of the classic hexagonal cystine crystals in the urine (see Fig. 100-9 in Chapter 100) may suggest the diagnosis, anyone suspected of the disorder should have a quantitative cystine measurement on a 24-hour urine sample.[16]

The goal of treatment is to lower the urinary cystine concentration below the limits of solubility.[17] Patients are advised to drink sufficient quantities of water to maintain excreted cystine in solution. Patients should moderate intake of sodium and animal protein foods, which contain large amounts of methionine, which is a precursor of cystine. Because cystine is more soluble at a higher pH, urinary alkalinization with potassium citrate (10 to 40 mEq/day) can be used to maintain a urinary pH ≥ 7.0. Chelating agents reduce the free cystine concentration by forming more soluble compounds and should be prescribed by a specialist owing to their high incidence of side effects.

PROGNOSIS

The recurrence rate of calcium oxalate nephrolithiasis is about 25% at 3 to 5 years and about 50% at 5 to 10 years, and the rate is higher for cystine, uric acid, and struvite stones.[18] For stones that have not yet caused symptoms, the risk of developing symptoms varies widely among studies, but the size of the stone is not predictive of future symptomatic nephrolithiasis.[19] Patients with kidney stones often have an increase in aortic calcification and a decrease in bone mineral density, thereby supporting the concept that there is dysregulation in calcium homeostasis in patients who form calcium-containing stones. Patients with nephrolithiasis have a higher risk of losing kidney function[20] and also have an increased risk for coronary heart disease and stroke.

112 CYSTIC KIDNEY DISEASES

M. AMIN ARNAOUT

DEFINITION AND EPIDEMIOLOGY

The term *cystic kidney diseases* refers to a heterogeneous group of hereditary and acquired disorders characterized by the presence of unilateral or bilateral renal cysts.[1] When acquired singly or in small numbers and in the absence of any other pathology, renal cysts are termed *simple cysts*, which are present in approximately 50% of individuals older than 40 years, are usually not loculated, and tend to bulge out from the renal surface (Fig. 112-1). The polycystic kidney diseases (PKDs), by comparison, constitute a clinically important group of genetically mediated disorders characterized by prominent, expanding, typically bilateral renal cysts. PKDs are classified as dominant, recessive, or X-linked, based on their pattern of inheritance. Autosomal dominant PKD,

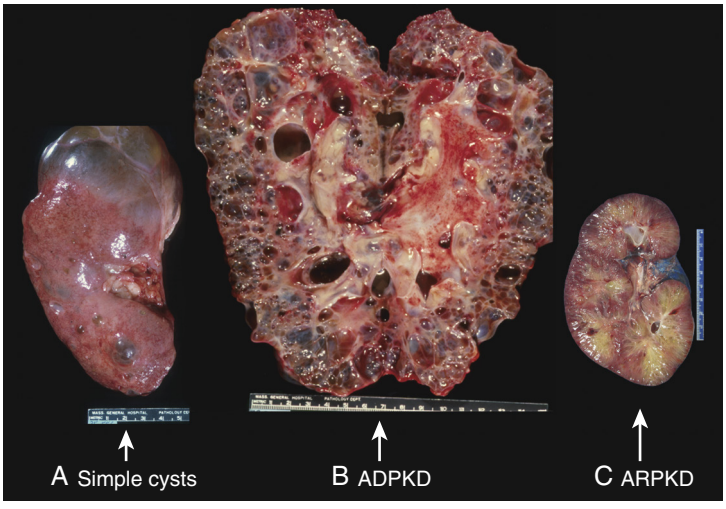

FIGURE 112-1. Gross pathology of selected cystic kidney diseases. A, Photograph of a kidney with multiple simple cysts. The cysts bulge out from the surface of a normal-sized kidney. **B**, Sagittal cross section of a kidney from an adult with autosomal dominant polycystic kidney disease (ADPKD). Multiple macroscopic cysts have resulted in an enlarged but still reniform kidney (note the evidence of prior hemorrhage within some of the cysts). (Courtesy Dr. Robert Colvin, Massachusetts General Hospital.) **C**, Sagittal cross section of a kidney segment from a patient with autosomal recessive polycystic kidney disease (ARPKD). It shows multiple, small, slit-like radially oriented cysts (ranging from 0.2 cm up to 1.8 cm in greatest dimension) that replace the entire cortex and medulla and are arranged perpendicular to the external surface. Patchy foci of hemorrhage are also present. (Courtesy Dr. Alyaa Al-Ibraheemi, Boston Children's Hospital.)

with a prevalence rate between 1 in 400 and 1 in 2000,[2] is among the most common monogenic diseases in humans and accounts for about 8 to 10% of all end-stage renal disease in the United States. Autosomal dominant PKD develops in an age-dependent manner and affects mainly adults. Autosomal recessive PKD, by contrast, is a relatively rare childhood disorder that appears in 1 in every 6000 to 50,000 live births. Renal cysts are also seen in several other rare hereditary kidney diseases and in several syndromic PKDs (Table 112-1). Collectively, the hereditary PKDs generally affect both sexes and all races equally and cost more than $1 billion annually to manage in the United States alone. *Acquired cystic kidney disease* refers to the multiple bilateral renal cysts that occur in 90% of patients who have received renal replacement therapy for 8 years or longer. Acquired cystic kidney disease is associated with increased rates of renal cell carcinoma.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

PATHOBIOLOGY

Autosomal dominant PKD is a systemic disorder characterized by cyst formation in multiple organs, including the kidneys, other ductal organs, and the cardiovascular system. Renal cysts originate as outpouchings of tubules and may arise from any portion of the nephron, with up to 1% of nephrons involved. The outpouchings expand and eventually separate from the parent tubules, yielding cysts (Fig. 112-2). Cyst growth is caused by proliferation of the cyst lining cells and by abnormal fluid accumulation that results when chloride-driven fluid secretion outpaces absorption. Cyst expansion and fibrosis (induced by cystic epithelium-derived chemokines, cytokines, and growth factors that attract macrophages and fibroblasts) cause compression and obstruction of noncystic normal tubules, thereby resulting in upstream tubular dilation. The kidneys become massively enlarged, and kidney function progressively declines.

Genetics

Heterogeneous mutations in *PKD1* and *PKD2* cause ADPKD and account for approximately 80% and 15% of the cases, respectively. Mutations in *GANAB*, *DNAJB11*,[3] and *ALG9*, which code for endoplasmic reticulum enzymes involved in the protein biosynthetic pathway, account for fewer than 1% of cases. Carriers of loss-of-function mutations in *GANAB*, which encodes GIIα, have mild autosomal dominant PKD and variable degrees of polycystic liver disease. Carriers of inactivating mutations in *DNAJB11*, which encodes the chaperon protein ERdj3, have a phenotypic hybrid of autosomal dominant PKD and autosomal dominant tubulointerstitial kidney disease (TKD), characterized

PROGNOSIS

The recurrence rate of calcium oxalate nephrolithiasis is about 25% at 3 to 5 years and about 50% at 5 to 10 years, and the rate is higher for cystine, uric acid, and struvite stones.[18] For stones that have not yet caused symptoms, the risk of developing symptoms varies widely among studies, but the size of the stone is not predictive of future symptomatic nephrolithiasis.[19] Patients with kidney stones often have an increase in aortic calcification and a decrease in bone mineral density, thereby supporting the concept that there is dysregulation in calcium homeostasis in patients who form calcium-containing stones. Patients with nephrolithiasis have a higher risk of losing kidney function[20] and also have an increased risk for coronary heart disease and stroke.

112 CYSTIC KIDNEY DISEASES

M. AMIN ARNAOUT

DEFINITION AND EPIDEMIOLOGY

The term *cystic kidney diseases* refers to a heterogeneous group of hereditary and acquired disorders characterized by the presence of unilateral or bilateral renal cysts.[1] When acquired singly or in small numbers and in the absence of any other pathology, renal cysts are termed *simple cysts*, which are present in approximately 50% of individuals older than 40 years, are usually not loculated, and tend to bulge out from the renal surface (Fig. 112-1). The polycystic kidney diseases (PKDs), by comparison, constitute a clinically important group of genetically mediated disorders characterized by prominent, expanding, typically bilateral renal cysts. PKDs are classified as dominant, recessive, or X-linked, based on their pattern of inheritance. Autosomal dominant PKD,

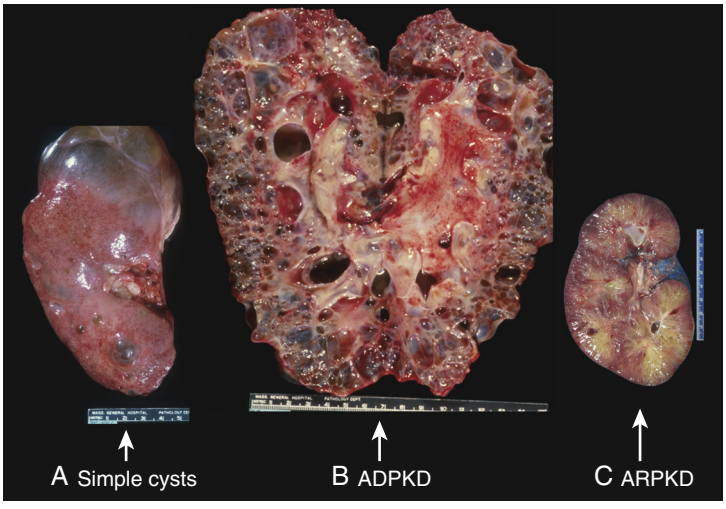

FIGURE 112-1. Gross pathology of selected cystic kidney diseases. A, Photograph of a kidney with multiple simple cysts. The cysts bulge out from the surface of a normal-sized kidney. **B**, Sagittal cross section of a kidney from an adult with autosomal dominant polycystic kidney disease (ADPKD). Multiple macroscopic cysts have resulted in an enlarged but still reniform kidney (note the evidence of prior hemorrhage within some of the cysts). (Courtesy Dr. Robert Colvin, Massachusetts General Hospital.) **C**, Sagittal cross section of a kidney segment from a patient with autosomal recessive polycystic kidney disease (ARPKD). It shows multiple, small, slit-like radially oriented cysts (ranging from 0.2 cm up to 1.8 cm in greatest dimension) that replace the entire cortex and medulla and are arranged perpendicular to the external surface. Patchy foci of hemorrhage are also present. (Courtesy Dr. Alyaa Al-Ibraheemi, Boston Children's Hospital.)

with a prevalence rate between 1 in 400 and 1 in 2000,[2] is among the most common monogenic diseases in humans and accounts for about 8 to 10% of all end-stage renal disease in the United States. Autosomal dominant PKD develops in an age-dependent manner and affects mainly adults. Autosomal recessive PKD, by contrast, is a relatively rare childhood disorder that appears in 1 in every 6000 to 50,000 live births. Renal cysts are also seen in several other rare hereditary kidney diseases and in several syndromic PKDs (Table 112-1). Collectively, the hereditary PKDs generally affect both sexes and all races equally and cost more than $1 billion annually to manage in the United States alone. *Acquired cystic kidney disease* refers to the multiple bilateral renal cysts that occur in 90% of patients who have received renal replacement therapy for 8 years or longer. Acquired cystic kidney disease is associated with increased rates of renal cell carcinoma.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

PATHOBIOLOGY

Autosomal dominant PKD is a systemic disorder characterized by cyst formation in multiple organs, including the kidneys, other ductal organs, and the cardiovascular system. Renal cysts originate as outpouchings of tubules and may arise from any portion of the nephron, with up to 1% of nephrons involved. The outpouchings expand and eventually separate from the parent tubules, yielding cysts (Fig. 112-2). Cyst growth is caused by proliferation of the cyst lining cells and by abnormal fluid accumulation that results when chloride-driven fluid secretion outpaces absorption. Cyst expansion and fibrosis (induced by cystic epithelium-derived chemokines, cytokines, and growth factors that attract macrophages and fibroblasts) cause compression and obstruction of noncystic normal tubules, thereby resulting in upstream tubular dilation. The kidneys become massively enlarged, and kidney function progressively declines.

Genetics

Heterogeneous mutations in *PKD1* and *PKD2* cause ADPKD and account for approximately 80% and 15% of the cases, respectively. Mutations in *GANAB*, *DNAJB11*,[3] and *ALG9*, which code for endoplasmic reticulum enzymes involved in the protein biosynthetic pathway, account for fewer than 1% of cases. Carriers of loss-of-function mutations in *GANAB*, which encodes GIIα, have mild autosomal dominant PKD and variable degrees of polycystic liver disease. Carriers of inactivating mutations in *DNAJB11*, which encodes the chaperon protein ERdj3, have a phenotypic hybrid of autosomal dominant PKD and autosomal dominant tubulointerstitial kidney disease (TKD), characterized

ABSTRACT

Kidney cysts affect nearly 50% of individuals older than age 40 years. Although most are simple cysts with no associated pathology, polycystic kidney disease (PKD) has multiple etiologies, with a variable onset, presentation, and rate of progression to end-stage renal disease. In PKD, cysts arise as tubule dilations involving any or specific renal tubular segments, are fueled by tubular cell proliferation, and expand by fluid secretion. Compression and obstruction of adjacent noncystic tubules and disruption of normal kidney architecture lead to fibrosis and progressive loss of kidney function. Large cysts are a prominent feature of autosomal dominant PKD, the most common form of PKD, whereas most other forms are characterized by small cysts. Both genetic and nongenetic factors are involved in controlling the rate of progression of kidney disease. PKD is most often inherited and is commonly associated with systemic manifestations that reflect the extrarenal loss of function of the defective gene. Many of the PKD genes are involved in the formation, maintenance, and/or regulating function of primary cilia, thus linking ciliary defects to PKD genesis. Diagnosis of PKD is aided by a positive family history, various imaging modalities, and genotyping, the latter being increasingly utilized especially in pre-implantation and prenatal diagnosis. Treatment varies with the underlying disease. Recent data show that inhibition of the vasopressin receptor 2 slows the decline in kidney function in autosomal dominant polycystic kidney disease. Other therapies are aimed at control of hypertension, infection, pain, nephrolithiasis, renal salt wasting, and metabolic complications.

TABLE 112-1 COMPARISON OF CLINICAL FEATURES OF CYSTIC KIDNEY DISEASES

DISEASE	INHERITANCE	FREQUENCY	GENE PRODUCT	AGE OF ONSET	CYST ORIGIN	RENOMEGALY	CAUSE OF ESRD	OTHER MANIFESTATIONS
Simple cysts	No	50% in persons age 40 yr and older	None*	Adulthood	Anywhere (usually cortical)	No	No	None
ACKD	No	90% of ESRD patients at 8 yr	None*	Years after onset of ESRD	Proximal and distal tubules	Rarely	No	None
ADPKD	AD	1 : 400-1000	Polycystin-1(PC1); Polycystin-2 (PC2); GIIα; ERdj3; ALG9	20s and 30s	Anywhere (including Bowman capsule)	Yes No (for ERdi3, ALG9)	Yes (for PC1, PC2, or ERdj3) No (for GIIα or ALG9)	Primarily in PKD1/PKD2-disease: liver cysts, cerebral aneurysms, hypertension, mitral valve prolapse, kidney stones, urinary tract infections
ARPKD	AR	1 : 10,000-40,000	Fibrocystin/polyductin; DZIP1L	First year of life	Distal nephron, collecting duct	Yes	Yes	Hepatic fibrosis Hypertension Pulmonary hypoplasia
NPH	AR	1 : 80,000	Nephrocystins (NPH1–20) MAPKBP1	Childhood or adolescence	Loop of Henle, distal convoluted tubule	No	Yes	Retinal degeneration Neurologic, skeletal, hepatic, and cardiac malformations
ADTKD-UMOD	AD	Rare	Uromodulin	Adolescence	Cortico-medullary	No	Yes	Gout
ADTKD-MUC1	AD	Rare	Mucin-1	Adolescence	Cortico-medullary	No	Yes	Gout (less prevalent and later onset)
ADTKD-REN	AD	Rare	Renin	Childhood	Cortico-medullary	No	Yes	Anemia Early-onset gout Hyperkalemia Mild hypotension
ADTKD-SEC61A1	AD	Rare	α1 subunit of Sec61 translocon	Childhood	Glomerular	No	Yes	Anemia Recurrent infections Early-onset gout Developmental defects Cognitive impairment
ADTKD-HNF1B	AD; spontaneous	Rare	HNF1β	Childhood or adulthood	Cortico-medullary	Rarely	Variable	Early-onset diabetes and pancreatic hypoplasia Hypomagnesemia Hyperthyroidism Liver function abnormalities Gout Renal and urogenital anomalies Intellectual disability Risk of renal cell carcinoma
MSK	No; AD	1 : 5000-20,000	None*	Adulthood	Medullary collecting duct	No	No	Kidney stones
Bardet-Biedl syndrome	AR	1 : 65,000-160,000	BBS 1-21	Childhood	Renal calyces	Rarely	Yes	Syndactyly and polydactyly Obesity Retinal dystrophy Male hypogenitalism Hypertension Intellectual disability
Oral-facial-digital syndrome-1	XD	1 : 250,000	OFD1 protein	Childhood or adulthood	Renal glomeruli	Rarely	Yes	Malformation of the face, oral cavity, and digits Liver cysts Intellectual disability
HIPKD	AR	Rare	Phospho-mannomutase 2	Childhood	Renal glomeruli	Yes	Yes	Hypoglycemic seizures Occasional liver cysts ARPKD-like phenotype
Tuberous sclerosis	AD	1 : 10,000	Hamartin (TSC1), tuberin (TSC2)	Childhood	Loop of Henle, distal convoluted tubule	Rarely	Rarely	Renal cell carcinoma Tubers Seizures Angiomyolipomas Hypertension
VHL syndrome	AD	1 : 40,000	VHL protein	20s	Cortical nephrons	Rarely	Rarely	Retinal angioma CNS hemangioblastoma Renal cell carcinoma Pheochromocytoma

*No known genetic susceptibility.

ACKD = acquired cystic kidney disease; AD = autosomal dominant; ADPKD = autosomal dominant polycystic kidney disease; ADTKD = autosomal dominant tubulointerstitial kidney disease; ALG9 = α-1,2-mannosyltransferase; AR = autosomal recessive; ARPKD = autosomal recessive polycystic kidney disease; CNS = central nervous system; DZIP1L = DAZ interacting protein 1-like; ERdj3 = ER DnaJ homologue glycoprotein encoded by DnaJ homolog subfamily B member 11; ESRD = end-stage renal disease; GIIα = glucosidase II alpha subunit; HIPKD = PKD with hyperinsulinemic hypoglycemia; HNF1β = hepatocyte nuclear factor 1 β; MSK = medullary sponge kidney; MUC1 = mucin-1; NPH = nephronophthisis; REN = renin; UMOD = uromodulin; VHL = von Hippel-Lindau; XD = X-linked dominant.

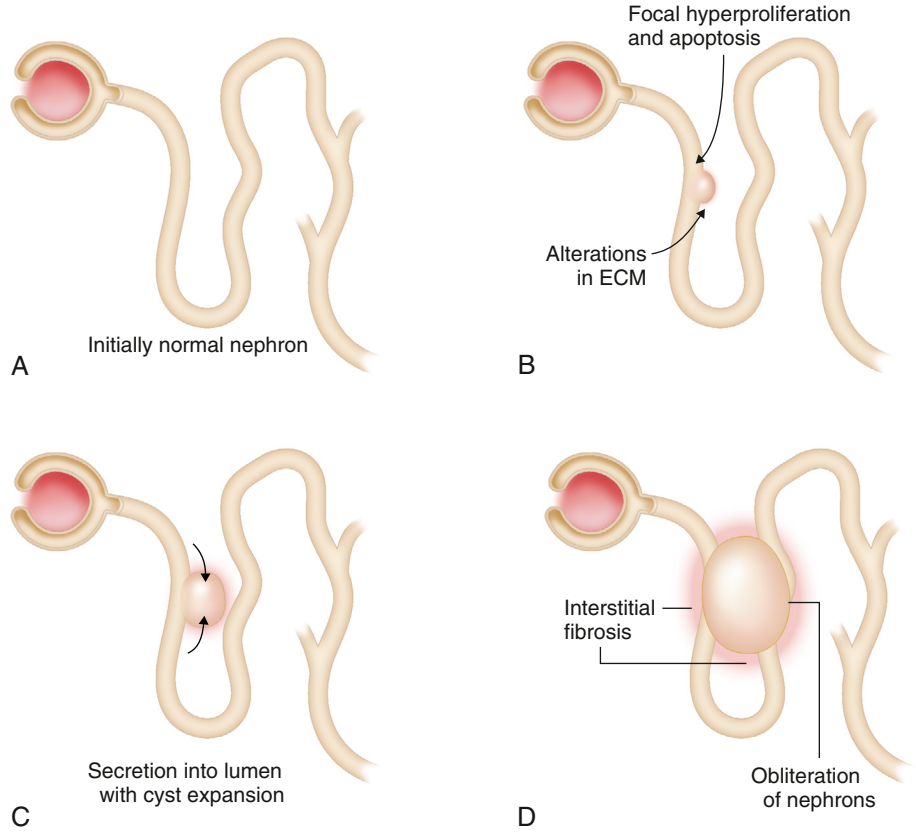

FIGURE 112-2. A to D, Steps involved in cyst formation in autosomal dominant polycystic kidney disease. Note that this process occurs hundreds or thousands of times during the natural history of the disease. ECM = extracellular matrix.

by normal-sized cystic kidneys, liver cysts, and progressive interstitial fibrosi that lead to late-onset end-stage renal disease and is reminiscent of autosomal dominant TKD-UMOD (defective proteostasis caused by *DNAJB11* variants might affect uromodulin trafficking as well). Carriers of inactivating mutations in *ALG9*, which encodes alpha-1,2-mannosyltransferase, develop both kidney and liver cysts, but they have milder disease than typical autosomal dominant PKD. In *GANAB*-, *DNAJB11*- and *ALG9*-associated ADPKD, cystogenesis appears to be driven by variable defects in the folding and maturation of PC1. In a minority of autosomal dominant PKD cases, no demonstrable mutations are found in these genes, thereby suggesting that additional genes may be involved.[4]

PKD1 is 54 kb long and is located on chromosome 16p13.3, adjacent to the tuberous sclerosis 2 (*TSC2*) gene. *PKD1* has 46 exons, generates a 14-kb transcript, and encodes a 4302-residue protein called polycystin-1 (PC1), the first described member of an expanding polycystin protein family. The 5′ region of human *PKD1* (to exon 33) is replicated on the same chromosome, resulting in approximately six copies of *PKD1*-like pseudogenes, which must be distinguished from the *PKD1* gene in direct mutational analysis. Most mutations in *PKD1* are inactivating truncation mutations or affect protein biogenesis, trafficking, or stability. To date, over 2300 mutations have been identified throughout the gene (http://pkdb.mayo.edu/) but especially in the 3′ half. Loss of function mutations and mutations in the 5′ half of the gene are associated with more severe disease, with only about 20% of patients retaining adequate renal function at 60 years of age (compared with about 40% of those with 3′ mutations).

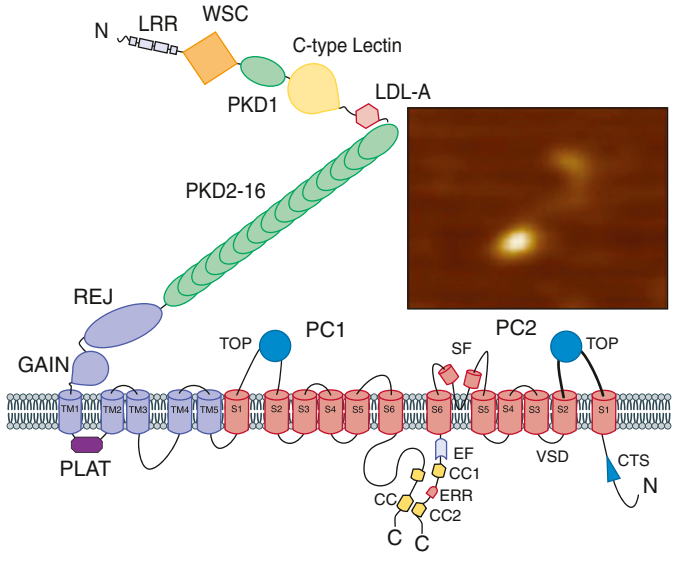
The 68-kb *PKD2* gene is located on chromosome 4q13-23, transcribes 15 exons, and generates a 5-kb transcript, which encodes a protein of 968 residues called polycystin-2 (PC2). To date, 278 heterogeneous mutations in *PKD2* have been identified. The greater number of cysts that occur at an early age in *PKD1* compared with *PKD2* disease is likely a result of a higher frequency of mutations in the longer *PKD1* coding region and the presence of six *PKD1*-like pseudogenes that may be involved in recombination-based gene conversion and rearrangements.

Because renal cysts develop from approximately 1% of nephrons, somatic inactivation of the normal *PKD1* or *PKD2* allele (somatic second hit model) has been proposed as the main mechanism of cyst initiation. Alternatively, the *PKD1* or *PKD2* haploinsufficiency state may produce wide stochastic fluctuations in levels of the normal gene product and may reduce it to below a critical disease-causing threshold in the absence of a somatic second hit (haploinsufficiency model). The genomic instability associated with the *PKD1* or *PKD2* haploid state may increase the likelihood of somatic second hits, which contribute to disease progression by providing cysts with a growth or survival advantage.

There are wide variations in the onset and severity of autosomal dominant PKD even among affected members of the same family. This variability could arise from variable frequency and timing of the somatic inactivation of the respective normal allele. Variability in disease onset and severity can also result from bilineal inheritance of *PKD1* and *PKD2* mutant alleles or by inheritance of hypomorphic or incompletely penetrant variants of either gene. Mosaicism in a parent in whom a mutation has arisen de novo could result in one sibling having the disease while another is disease free despite sharing the identical inherited haplotype at the *PKD* locus. Digenic inheritance of mutant *PKD1, PKHD1, TSC2*, or *HNF1B* alleles can result in ADPKD in infancy. Other modifier loci beyond the known disease genes as well as nongenetic risk factors (e.g., smoking, caffeine, acute kidney injury, and male sex hormones) may also modulate the formation of renal cysts.

Gene Products

PKD1 encodes PC1, which consists of a large 11-pass receptor-like glycoprotein with a relatively short cytoplasmic carboxyl terminus (E-Fig. 112-1). The PC1 ectodomain contains multiple functional motifs, which are also present in cell adhesion receptors, thereby suggesting a role in cell-cell or cell-matrix interactions or both. PC2, which is encoded by *PKD2*, is a 6-pass atypical transient receptor potential-type channel with cytoplasmic amino- and carboxy-termini. Its six-transmembrane segment exhibits homology to the carboxyl terminal six-transmembrane segment of PC1. PC1 binding to PC2 and the cleavage of PC1 at the G protein–coupled receptor proteolytic site (resulting in N-terminal and C-terminal fragments that remain tethered) are necessary for their normal folding and export from the endoplasmic reticulum to the Golgi apparatus and subsequently to the surface of the cell. Emerging evidence suggests that the primary function of the PC1/PC2 complex is in primary cilia that are ubiquitously expressed on cell surfaces. The PC1/PC2 complex



E-FIGURE 112-1. Schematic of polycystin-1 (PC1) and polycystin-2 (PC2). PC1 is a multidomain glycoprotein with 11 putative transmembrane (TM) segments, the C-terminal six of which (S1-S6, colored in rose) bear homology to the six transmembrane segments of PC2. PC1 contains a leucine-rich region (LRR); cell wall and stress component (WSC); C-type lectin; low-density lipoprotein receptor A-like domain (LDL-A); immunoglobulin-like domains (PKD1-16); receptor for egg jelly domain (REJ); G protein–couple receptor autoproteolysis-inducing domain (GAIN), which contains the G protein–coupled receptor proteolytic site (GPS) needed for PC1 activation; a PC1–lipoxygenase–α-toxin domain (PLAT); and a tetragonal opening for polycystins (TOP) domain. The PC1 schematic is drawn after atomic force microscopy imaging of PC1 (*inset*), where full-length PC1 appeared as two unequally sized blobs. The smaller one represents the N-terminal LRR, LDL-A, PKD1, and C-type lectin, whereas the larger one includes the REJ and GAIN domains. The 35-nm string connecting the two blobs likely consists of the tandem PKD2-16 domains. The PC2 monomer includes a TOP domain; a voltage sensor domain (VSD) comprising S1-S4; a pore domain between S5 and S6, which includes two pore helices that surround the selectivity filter (SF); an EF-hand calcium-binding motif; an endoplasmic reticulum retention signal (ERR); a coiled–coiled (CC) domain that interacts with a CC domain in PC1; and a ciliary targeting sequence (CTS).

transitions from the Golgi apparatus via polycystin-bearing vesicles to the transition fibers and then undergoes facilitated trafficking to enter the cilium.[5]

PC1 and PC2 are widely expressed with overlapping non-identical distributions in tissues. PC1 expression is highest during kidney development and progressively declines thereafter, becoming mainly limited to the collecting duct in the normal adult kidney, although it can be upregulated in response to renal injury. By comparison, renal expression of PC2 is maintained throughout development and predominates in the medullary thick ascending limb and distal cortical tubules in the normal adult kidney. Disruption of the PC1/PC2 complex in primary cilia appears to be critical to the genesis of the PKD phenotype, but the precise function the PC1/PC2 complex plays in primary cilia remains obscure.

Experimental studies have suggested that developing renal tubules with high proliferative indices are more sensitive to the reduction in PC1 or PC2 levels, with disease severity radically altered depending on the time of gene inactivation. Maintenance of higher proliferative indices in the distal nephron epithelium relative to that in the proximal nephron may explain the predominance of cysts in the distal nephron in adult human autosomal dominant PKD.

CLINICAL MANIFESTATIONS

Autosomal dominant PKD has a highly variable presentation, even within families. The clinical features of *PKD2*-associated autosomal dominant PKD are indistinguishable from those of *PKD1*-associated disease. However, *PKD2* disease is milder, with an older average age of onset—about 75 years versus 55 years for *PKD1*-associated disease—owing to the development of fewer cysts at an early age rather than to a slower cyst growth rate.

Despite an estimated 100% penetrance by age 90 years, only half the individuals with heterozygous mutations in *PKD1* or *PKD2* are ever diagnosed clinically with autosomal dominant PKD. Of these, the majority present in the third or fourth decade of life with symptoms referable to renal cystic disease. However, autosomal dominant PKD can develop at any age, including infancy, and it can have a nonrenal presentation. Renomegaly may predominate the clinical picture, with abdominal distention, discomfort, or pain; however, renomegaly also can be discovered incidentally on physical examination or after radiographic studies of the abdomen.

Nocturia, one of the earliest signs of abnormal renal function in autosomal dominant PKD, reflects the early impairment in the ability to concentrate urine owing to disruption of renal architecture by the cysts. Hematuria is typical, but proteinuria is less prominent than in many other renal diseases. Cyst hemorrhage and sometimes rupture, which can occur spontaneously or after trauma, present as sharp pain and hematuria. Recurrent cyst infection (Chapter 263), usually by common urinary tract-infecting organisms, is characterized by flank or abdominal pain, fever, rigors, leukocytosis, and occasionally sepsis. Kidney stones (Chapter 111) occur in 20 to 36% of patients, with uric acid stones slightly more common than calcium oxalate stones; predisposing factors include urinary stasis, defective trapping of urea in the medulla, low urine pH, hypocitraturia, hyperoxaluria, hypercalciuria, and hypomagnesuria. Anemia features less prominently than in other renal diseases, probably because of the relatively well-preserved secretion of erythropoietin.

Cardiovascular disease, which is common in autosomal dominant PKD, manifests as biventricular diastolic dysfunction even in young patients with normal blood pressure and renal function, thoracic and abdominal aortic aneurysms, and cervicocephalic and coronary aneurysms. Arterial hypertension is present in approximately 70% of cases before renal dysfunction is detected. Development of hypertension at a young age is associated with a four-fold increased risk of end-stage renal disease and increased cardiovascular morbidity. The risk for preeclampsia is also higher than in the general population.

Intracranial aneurysm occurs in 4 to 8% of asymptomatic autosomal dominant PKD patients, but the incidence is higher in patients with a family history of nonruptured (10% risk) or ruptured intracranial aneurysm (20% risk; Chapter 377). Autosomal dominant PKD-associated aneurysms tend to rupture at a smaller size and in younger individuals—on average, 10 years younger than among the general population. Although usually clinically silent, intact cerebral aneurysms can present with focal neurologic symptoms and headaches. By contrast, aneurysms that rupture lead to subarachnoid hemorrhage (Chapter 377) and have dramatic presentations that include severe headaches, seizures, altered sensorium, and death. Aortic and coronary artery aneurysms are also more prevalent in patients with autosomal dominant PKD, and the frequency of aortic insufficiency is increased.

Although almost never severe enough to cause end-stage liver disease, age-dependent hepatic cysts occur in 30 to 80% of patients with autosomal dominant PKD and can lead to signs and symptoms of mass effect, infection, hemorrhage, and rupture.[6] Estrogen intake and multiparity in women are risk factors for developing larger and more symptomatic liver cysts. The cysts that occasionally form in other organs, such as the pancreas, spleen, brain, ovaries, epididymis, and prostate, are usually asymptomatic. Sperm abnormalities and defective motility may occur but rarely cause male infertility. Bronchiectasis (Chapter 78) is three-fold more common, inguinal hernias may be more prevalent, and colonic diverticulosis and diverticulitis are more common in end-stage renal disease patients with autosomal dominant PKD.

DIAGNOSIS

Renomegaly, typically presenting in the third or fourth decade of life with a positive family history and common extrarenal manifestations, such as hypertension, are useful findings in making a presumptive diagnosis of autosomal dominant PKD. In these cases, renal ultrasonography is frequently diagnostic. Because only about 75% of individuals give a family history of autosomal dominant PKD, ultrasound screening of asymptomatic parents or grandparents may be required to uncover diagnostically relevant silent autosomal dominant PKD.[7]

A diagnosis of autosomal dominant PKD can be made in an asymptomatic individual by ultrasonography (Fig. 112-3A). To account for the common age-dependent appearance of simple cysts, autosomal dominant PKD is diagnosed if at least three renal cysts (distributed in one or both kidneys) are present in individuals 15 to 29 years old (sensitivity, 0.82; specificity, 1.0) or 30 to 39 years old (sensitivity, 0.96; specificity, 1.0), if at least two renal cysts are present in each kidney in individuals 40 to 59 years old (sensitivity, 1.0; specificity, 0.99), or if at least four renal cysts are detected in each kidney in individuals 60 years of age or older (sensitivity, 1.0; specificity, 1.0). Fewer than two renal cysts in an individual from an autosomal dominant PKD family with an unknown genotype age 40 years or older or the absence of renal cysts in such an individual age 30 to 39 years is sufficient to exclude the disease, with negative predictive values of 100% and 99.3%, respectively. A negative ultrasound result is less accurate in excluding disease in individuals younger than 30

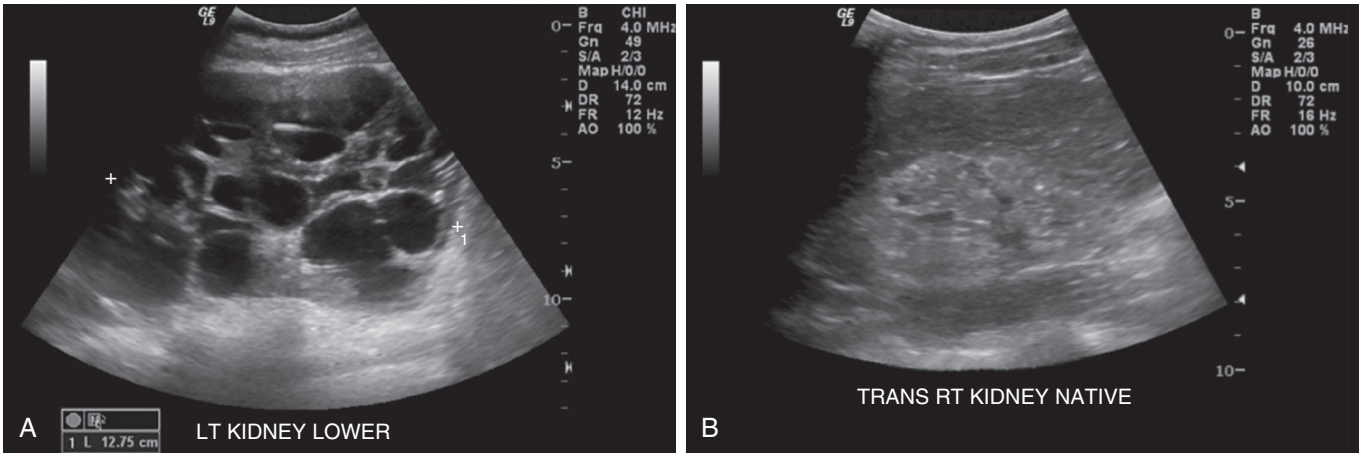


FIGURE 112-3. A, Ultrasound image of a kidney from a patient with autosomal dominant polycystic kidney disease. B, Ultrasound image of a kidney from a patient with autosomal recessive polycystic kidney disease. (Courtesy Dr. Javier M. Romero and Jennifer A. McDowell, Massachusetts General Hospital.)

years, so computed tomography (CT) or magnetic resonance imaging (MRI) is recommended. When a young relative is being considered as a potential kidney donor to a family member with end-stage autosomal dominant PKD, contrast-enhanced, three-dimensional CT or magnetic resonance angiography is required because these tests can detect 3-mm cysts compared with ultrasonography's ability to detect 10-mm cysts.

Cerebral aneurysms are increasingly being detected with MRI in autosomal dominant PKD patients. Four-vessel cerebral angiography remains the gold standard and is often used for surgical planning.

DNA-based diagnosis of autosomal dominant PKD by means of direct sequencing is commercially available and detects mutations in more than 90% of affected individuals. Whole-genome sequencing may have a much higher sensitivity and specificity for the diagnosis because it is better at distinguishing the *PKD1* gene from six similar pseudogenes.[8] It also can detect mosaicism, which accounts for about 10% of cases otherwise missed by genetic testing.[9] Testing is recommended when imaging study results are equivocal, in a young transplant donor from an autosomal dominant PKD family when imaging study results are negative, or to facilitate preimplantation genetic diagnosis.[10]

Monitoring Progressive Renal Disease

Despite ongoing renal cyst expansion, the glomerular filtration rate (GFR) and the serum creatinine level are generally maintained within the normal range in autosomal dominant PKD patients until the fourth to sixth decade of life. These markers are therefore insensitive for monitoring disease progression, especially in young patients. Reduced renal blood flow is the most sensitive prognostic indicator of renal progression. Estimating height-adjusted total kidney volume from measurements of kidney length, width, and thickness using MRI, CT, or ultrasonography can reliably monitor disease progression in the early stages of autosomal dominant PKD when the GFR is still in the normal range, and each 100-mL increment of height-adjusted total kidney volume increases the odds of reaching stage 3 chronic kidney disease by about 1.5-fold. Although gadolinium-enhanced MRI provides excellent detail of kidney structures, MRI without gadolinium is recommended to monitor kidney volume, especially in autosomal dominant PKD patients with a reduced GFR, because of concern about nephrogenic systemic fibrosis (Chapter 246) and further impairment of renal function associated with its use. Height-adjusted total kidney volume progressively increases in most patients who have autosomal dominant PKD but at widely differing rates, ranging from less than 1% to more than 10% annually. Renal function declines as the kidneys enlarge,[11] and patients who have rapidly progressive autosomal dominant PKD are most likely to benefit from treatment.[12]

PREVENTION AND TREATMENT

Management strategies are aimed at monitoring for complications of autosomal dominant PKD and treating them, as well as providing genetic counseling.[13] Frequent monitoring and effective treatment of hypertension (Chapter 64; see Tables 64-7 and 64-9) are essential because hypertensive patients have a greater annual increase in kidney volume, as well as a higher prevalence of left ventricular hypertrophy, ischemic heart disease, and stroke, compared with normotensive patients. The goals of blood pressure control are the same as for other patients with renal disease, including the attainment of a symptom-free blood pressure of 120/80 mm Hg or less. Angiotensin-converting enzyme inhibitors or angiotensin receptor blockers are the first-line antihypertensive drugs in autosomal dominant PKD. Hypertensive autosomal dominant PKD patients who are young (15 to 49 years), have stage 1 or 2 cystic kidney disease, and do not have diabetes mellitus or significant cardiovascular comorbidities may benefit from blood pressures of 95/60 to 110/75 mm Hg, a level associated with a slower increase in total kidney volume, a greater decline in left-ventricular-mass index, and a greater reduction in urinary albumin excretion, but not a delay in the reduction in the glomerular filtration rate. Dietary salt restriction also may be beneficial in the management of autosomal dominant PKD.

Oral tolvaptan (45 to 90 mg in the morning and 15 to 30 mg in the afternoon as tolerated) slows the increase in total kidney volume and the decline in kidney function in patients with normal creatinine clearance and in patients with moderate-to-advanced kidney disease.[A1,14,15] It can also reduce kidney pain.[A2] The small but significant clinical effect may be the result of reduced cell proliferation, direct intrarenal hemodynamic effects, or both. Tolvaptan induces a four-fold increased risk of hepatocellular injury, so liver function testing before initiation and at specific intervals (at 2 and 4 weeks, then monthly for 18 months, then every 3 months thereafter) is required in all patients with autosomal dominant PKD.[16] Overall, nearly 25% of patients do not tolerate tolvaptan, and it is not routinely used in children.

Treatment of urinary tract infection (Chapter 263) and prevention of nephrolithiasis (Chapter 111) are the same as in the general population and include standard antimicrobial therapy and increased fluid intake, respectively. Renal and hepatic cyst infections are optimally treated with lipophilic antibiotics that possess cyst-penetrating capabilities, including ciprofloxacin, trimethoprim, clindamycin, and vancomycin. Blood or urine cultures and sensitivities are used to guide the choice of antibiotic therapy.

Cyst hemorrhage and rupture, with resultant pain and hematuria, are usually managed conservatively with rest and analgesics; nonsteroidal anti-inflammatory drugs (NSAIDs) are avoided owing to their antiplatelet action and potential renal toxicity. Alternatives include acetaminophen 500 mg up to every 4 hours for mild to moderate pain, nonopiates such as tramadol 50 mg up to every 4 hours for moderate to severe pain, and the addition of an oral or transdermal opioid (see Table 26-6 in Chapter 26) as needed. Patients with enlarged kidneys should be advised to avoid playing contact sports, and those with massively enlarged kidneys should refrain from wearing belts and seatbelts. Some patients with unusually painful cysts respond to cyst fluid aspiration, cyst deroofing, or ethanol-induced sclerosis.

Nephrectomy is rarely indicated before the onset of end-stage renal disease. Renal replacement therapies, including renal transplantation (Chapter 117), are at least as effective as in other causes of end-stage renal disease.[17]

The massive cystic enlargement of the liver commonly seen by midlife in women with autosomal dominant PKD makes it prudent to avoid estrogen intake and repeated pregnancies. Partial hepatectomy has been successful in improving the quality of life in patients with massive liver enlargement, but liver transplantation is the only curative therapy.[18]

Magnetic resonance angiography screening is not routinely recommended for asymptomatic patients without a family history of cerebral aneurysm or subarachnoid hemorrhage, but it is recommended for patients with a positive personal or family history and for patients who experience a new onset of severe headache or central nervous system symptoms or signs. It also may be considered in those with high-risk occupations, such as airline pilots, and for patients with incapacitating anxiety. The risk of a patient with a positive family history developing a new aneurysm after an initially negative magnetic resonance angiography result is 2.6% at a mean follow-up period of 9.8 years, so rescreening every 5 to 10 years in such cases may be appropriate, especially in patients with early-onset hypertension or a history of heavy smoking. Asymptomatic patients with positive family history of cerebral aneurysms and positive magnetic resonance angiography results should be followed closely with a neurosurgeon and monitored by annual magnetic resonance angiography screening. The decision to perform surgical clipping or endovascular embolization should take into consideration the age of the patient, the size of the aneurysm and its location, and a previous history of cerebral bleeding (Chapter 377).

Patients should be advised that their children have a 50% probability of inheriting a disease-causing germline mutation. DNA-based diagnostics are most useful in identifying the germline mutation prenatally or preimplantation. As DNA-based diagnostics become more widely available and less expensive and as promising new treatment options are developed, genetic counseling will become an increasingly important component of prevention.

Experimental Therapies

Current therapeutic efforts are targeting increased cell proliferation of cystic epithelium and abnormal fluid secretion into cysts (E-Fig. 112-2).[19] The metabolically stable somatostatin analogue octreotide (long-acting release at a dose of 40 mg every 28 days)[20] can slow the expansion of renal cysts but does not slow the decline in renal function and also is associated with substantial side effects.[A3] Indirect inhibition of mTOR via activation of AMPK with metformin (E-Fig. 112-2) has shown promise in a phase II trial.[A4] Bosutinib, an oral dual Src/Bcr-Abl tyrosine kinase inhibitor, can reduce the rate of kidney enlargement but has not been shown to slow the decline in glomerular filtration.[A5] A trial evaluating the value of tesevatinib, which is a multi-kinase inhibitor, on the progression of height-adjusted total kidney volume in autosomal dominant PKD is ongoing.

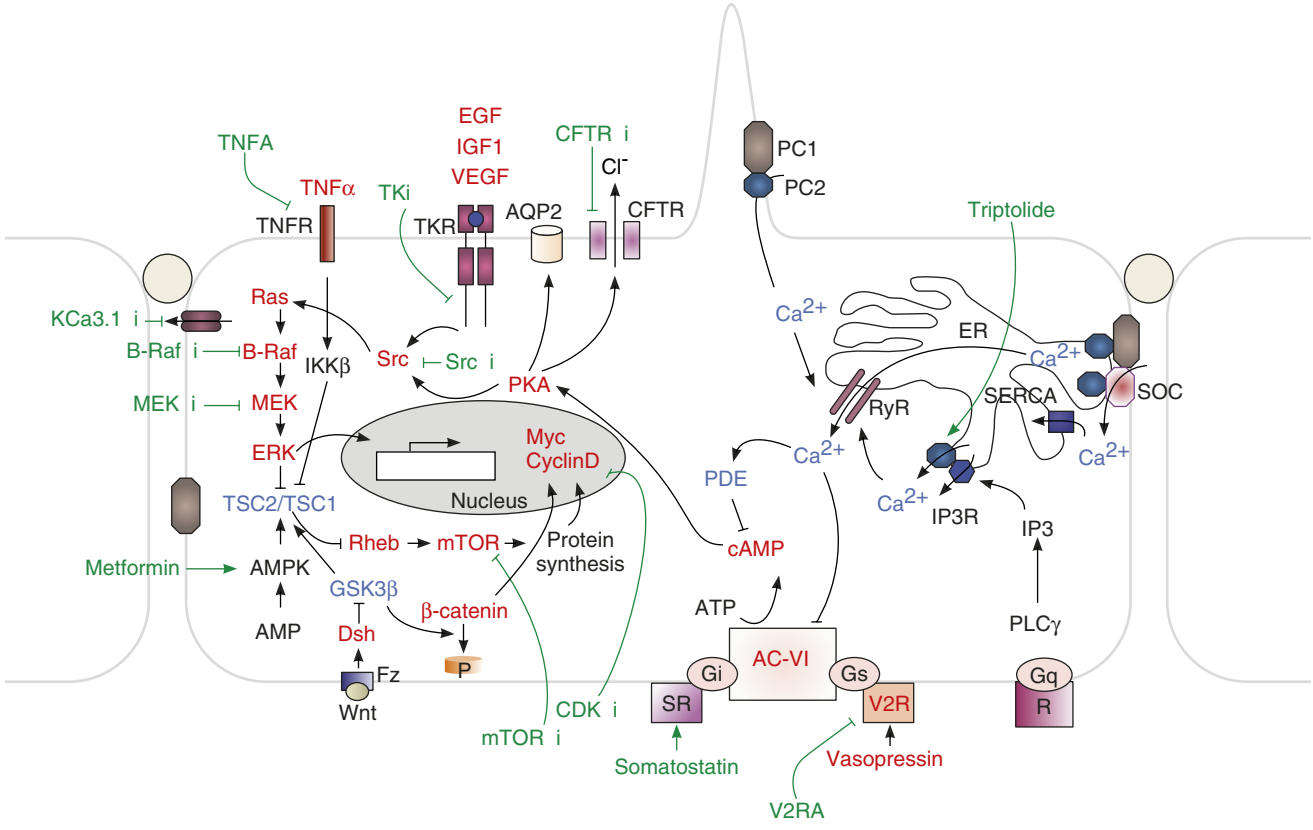
PROGNOSIS

The rate of progression of renal disease is highest in men with poorly controlled hypertension, an early age at diagnosis, mutations (particularly truncations) in *PKD1*, and higher initial height-adjusted total kidney volume.[21] Higher salt intake but not higher protein intake is associated with more rapidly progressive disease.[22] Kidney cysts develop earlier in *PKD1* than in *PKD2* disease, but the rate of expansion is similar, indicating that the basic difference in phenotype is in cyst initiation, not expansion. Whereas the presence of one affected family member who developed end-stage renal disease by age 60 years is highly predictive of PKD1 disease (positive predictive value, 100%; sensitivity, 75%), the development of end-stage renal disease after age 70 years in a family member is highly predictive of PKD2 disease (positive predictive value, 95%; sensitivity, 75%). Approximately 5% of all autosomal dominant PKD patients with cerebral aneurysms die from aneurysmal rupture.

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

DEFINITION AND EPIDEMIOLOGY

Autosomal recessive PKD is a multisystem childhood disorder characterized by severe and early PKD dominated by dilation of the kidney collecting ducts,



E-FIGURE 112-2. Signaling pathways that are upregulated or downregulated in polycystic kidney disease and sites of current therapeutic interventions. Upregulated pathways are in *red,* downregulated pathways are in *blue,* and potential drugs are in *green.* Ciliary PC1/PC2 complex appears to mediate calcium (Ca^{2+}) entry into the cell, where it triggers Ca^{2+} release from the endoplasmic reticulum (ER) via the ryanodine receptor (RyR). PC1/PC2 complex regulates Ca^{2+} channel (SOC) activity, and it interacts with inositol 1,4,5-triphosphate (IP3) receptor (IP3R) to regulate calcium release from the ER. Reduced PC1/PC2–mediated calcium influx increases intracellular cyclic adenosine monophosphate (cAMP, which stimulates, via protein kinase A (PKA), chloride and water secretion across the luminal membrane through cystic fibrosis transmembrane conductance regulator (CFTR) and the vasopressin-sensitive aquaporin-2 (AQP2) channels, respectively, and activates mitogen-activated protein kinase (MAPK) signaling. The ATP-activated chloride channel TMEM16A (not shown) may also contribute to chloride secretion. Phosphorylation of tuberin by MAPK, its inadequate targeting to the plasma membrane owing to defective interaction with PC1, upregulation of tumor necrosis factor-α (TNFα), or downregulation of 5′ AMP = activated protein kinase (AMPK) signaling may dissociate the tuberin-hamartin complex, leading to activation of *R*as *h*omolog *e*nriched in *b*rain (Rheb) guanosine triphosphate binding protein and mammalian target of rapamycin (mTOR). MAPK and mTOR activation promote G1/S transition and cell proliferation through upregulation of cyclin D and protein translation, respectively. Upregulation of Wnt signaling, via PI3K/NF-kB pathway (not shown), also activates mTOR and the β-catenin mitogenic pathway. Downregulation of the AMPK/TSC pathway and of GSK3β as well as upregulation of MYC and HIF1α (not shown) promote aerobic glycolysis that fuels cell proliferation. AC-VI = adenylate cyclase 6, the predominant AC in collecting duct principal cells; CDK = cyclin-dependent protein kinase; Dsh = dishevelled; Fz = frizzled receptor; Gq R = G-protein q–coupled receptors; GSK3β = glycogen synthase kinase 3 beta; HIF1α = hypoxia-inducible factor 1-alpha; i = inhibitor; KCa3.1 = Ca^{2+}-dependent K^+ channel 3.1; MYC = c-myc protooncogene; P = proteosome; PDE = phosphodiesterase (PDE1 in collecting duct principal cells); PKA = protein kinase A; PLCγ = phospholipase Cγ; SERCA = sarcoplasmic reticulum Ca^{2+} pump; SR = somatostatin sst2 receptor; TNFA = tumor necrosis factor antagonist; TSC = tuberous sclerosis proteins hamartin (TSC1) and tuberin (TSC2); V2R = vasopressin V2 receptor; V2RA = vasopressin V2 receptor antagonists. (Originally modified from Torres VE, Harris PC. Autosomal dominant polycystic kidney disease. *Kidney Int.* 2009;76:149-168.)

systemic hypertension, biliary ductal plate dysgenesis in neonates, and portal tract fibrosis in older children.[23]

PATHOBIOLOGY

Autosomal recessive PKD is mainly caused by heterogeneous mutations in *PKHD1* (polycystic kidney and hepatic disease 1) and rarely by mutations in *DZIP1L*. Located on chromosome 6q21, *PKHD1* has 67 exons and spans a genomic region of approximately 470 kb, the longest open reading frame of which is 12,222 base pairs long. *PKHD1* encodes a unique type I membrane protein, fibrocystin/polyductin, comprising 4074 amino acids, with a large extracellular segment that contains multiple IPT/TIG (*I*g-like, *P*lexins, *T*ranscription factors) domains, a PA14 domain, a PbH1 (*P*arallel β-helix repeat) domain, 2 G8 domains, a cleavage site, and a short cytoplasmic carboxyl terminus that includes a cilia targeting signal. The precise physiologic function of fibrocystin/polyductin in collecting duct and biliary duct epithelium is not clear, but its domains are known to mediate cell motility and invasion (IPT domains), extracellular protein and carbohydrate binding, and catalytic processing (PA14, PbH1, and G8 domains). Alternatively spliced transcripts of *PKHD1* encode a membrane protein with variable extracellular domains, as well as forms lacking the transmembrane segment. Biallellic truncating mutations in *PKHD1* are associated with perinatal renal disease, whereas patients with biallelic missense mutations may present later because some functional protein is produced.

Fibrocystin is predominantly expressed in the cortical and medullary collecting ducts, the thick ascending limbs of Henle and bile ducts. It is also found to a lesser degree in the pancreas, liver, and lungs, which are also affected in autosomal recessive PKD. Fibrocystin interacts with PC2 within the PC1/PC2 complex, where loss of fibrocystin downregulates PC2. Fibrocystin–PC2 interactions may regulate function of the ciliary PC1/PC2 complex.

Located on chromosome 3q22, 1-q23 *DZIP1L* encodes DZIP1L, which is widely expressed and is localized primarily to the centrioles and distal end of basal bodies. The localization of PC1 and PC2 to the ciliary membrane is compromised in DZIP1L-mutant cells, thereby suggesting that DZIP1L is required for regulating the integrity of the transition zone.

CLINICAL MANIFESTATIONS

Although autosomal recessive PKD can present as renal cysts discovered radiographically either antenatally or during adulthood, it usually manifests as bilateral abdominal masses and renal insufficiency in infancy. It carries a 30% mortality rate owing to severe pulmonary hypoplasia; oligohydramnios, presumably linked to in utero renal disease, likely accounts for the pulmonary hypoplasia. Hypertension is almost universal, typically develops before renal impairment is apparent, and probably accelerates the decline in renal function. Findings related to renal tubular dysfunction may be present and include polyuria, enuresis, hyponatremia, and hyperchloremic metabolic acidosis. Cystic complications related to infection and rupture also occur, although hematuria is an infrequent finding.

Hepatic fibrosis, secondary to dilation of the intrahepatic and extrahepatic bile ducts, manifests as recurrent ascending cholangitis (Chapter 141) and portal hypertension with splenomegaly and esophageal varices. Pancreatic fibrosis is rarely a clinical concern.

DIAGNOSIS

The demonstration by abdominal ultrasonography (see Fig. 112-3B) or CT of symmetrically enlarged polycystic kidneys that retain their reniform shape (owing to uniform microcystic dilation of the distal tubules and collecting ducts) and hepatic fibrosis is sufficient to diagnose autosomal recessive PKD. In contrast to autosomal dominant PKD cysts, autosomal recessive PKD cysts tend to retain their connections with the originating nephron.

Aside from an occasional affected sibling, a family history is often not elicited. Distinguishing autosomal recessive PKD from autosomal dominant PKD, especially in patients presenting in childhood or adulthood, may require a liver biopsy to document otherwise undetectable hepatic fibrosis. Gene-based diagnostics in autosomal recessive PKD are helpful in making a firm diagnosis,[24] especially in patients with late-onset disease, and they are useful in preimplantation and prenatal diagnosis. Mutations in *DZIP1L* is considerably rarer than mutations in *PKHD1,* perhaps in part owing to the larger size of *PKHD1*.

TREATMENT AND PREVENTION

In the absence of specific therapy for autosomal recessive PKD, management goals focus on early detection and on treatment of the complications of hypertension, urinary tract or cyst infection, end-stage renal disease, and portal hypertension. Kidney transplantation may be necessary in late childhood in patients with autosomal recessive PKD who present with renal disease perinatally. Treatment of portal hypertension may require liver transplantation or portosystemic shunting (Chapter 140). Treatment of hypertension begins with ACE inhibitors and angiotensin receptor blockers (see Tables 64-7 and 64-9 in Chapter 64), which are generally effective. As in all children with end-stage renal disease, attention to nutrition and renal osteodystrophy is paramount (Chapter 116). With improving sensitivity of gene-based diagnostics, prenatal counseling will play a more active role in prevention.

PROGNOSIS

For patients with autosomal recessive PKD, the highest mortality rates occur during the first year of life. Males and females are equally affected. Approximately 50 to 80% of patients who survive this period live past 15 years of age. End-stage renal disease with macroscopic cysts, interstitial fibrosis, and shrunken kidneys can take up to 20 years to develop; but in rare instances, it never occurs.

NEPHRONOPHTHISIS

DEFINITION AND EPIDEMIOLOGY

Nephronophthisis is the most common genetic cause of end-stage renal disease in childhood and adolescence, during which it accounts for 5 to 15% of cases of end-stage renal disease. It is an autosomal recessive kidney disorder caused by mutations in a number of genes that encode nephronophthisis proteins (nephrocystins), which are expressed in the centrosome and basal body of primary cilia, with some also localizing to adherens junctions or focal adhesions in epithelia.[25] Homozygotic and compound heterozygotic mutations in at least 20 known genes (*NPH1* through *NPH20* and *MAPKBP1*) account for about 30% of cases. Infantile, juvenile, and adolescent variants have been described based on the median age of onset of ESRD. Infantile nephronophthisis is characterized by mutations in the *NPH2* gene. The juvenile form is the most common and is caused by mutations in *NPH1*. The adolescent form is caused by mutations in *NPH3*. Mutations in *MAPKBP1*, which encodes MAPKABP1, a microtubule-binding protein, are a rare cause of late-onset cilia-independent nephronophthisis.

Nephronophthisis is characterized pathologically by renal interstitial fibrosis, tubular atrophy with basement membrane thickening and disruption, and renal cysts and diverticula that are largely restricted to the loops of Henle and distal tubules at the corticomedullary junctions. Kidney size is generally normal or reduced, except in the rare infantile variant that leads to end-stage renal disease by 3 years of age. Expression of *NPH* genes at extrarenal sites accounts for the associated retinal, neural, liver, and skeletal abnormalities. Each of the *NPH* genes is associated with a somewhat different phenotype, although some share common phenotypes, explained by protein-protein interactions between two or more nephrocystins. Cerebello-ocular-renal syndromes associated with nephronophthisis can sometimes include early-onset retinitis pigmentosa when the syndrome is caused by mutations in *NPH5* and *NPH6*.

CLINICAL MANIFESTATIONS

Presenting symptoms include polyuria, growth failure, and anemia. Polyuria occurs early, owing to reduced urinary concentrating ability and to salt wasting. A decreased growth rate is related to chronic dehydration, and growth failure and anemia occur with the onset of end-stage renal disease. Blood pressure is normal, and edema is absent before the onset of renal failure. Hematuria and proteinuria are absent or minimal. Patients with mutations in specific *NPH* genes may also present with eye defects, oculomotor apraxia, congenital amaurosis, retinitis pigmentosa, neural anomalies, cerebellar ataxia, seizures, liver fibrosis, skeletal defects, scoliosis, cleft palate, and situs inversus.

DIAGNOSIS

The diagnosis relies on clinical suspicion of the disorder in a pediatric or adolescent patient who presents with end-stage renal disease and extrarenal manifestations such as abnormal eye movements, intellectual disability, and polydactyly. Differential diagnosis includes renal dysplasia, early-onset autosomal dominant PKD, urinary tract obstruction, autosomal dominant TKD, and autosomal recessive PKD. Abdominal ultrasonography, MRI (without gadolinium), electroretinography, and full neurologic and ophthalmologic

evaluations should assess the patient's renal, liver, retinal, and neurologic status. Renal ultrasonography showing loss of corticomedullary differentiation, increased parenchymal echogenicity, and occasionally small medullary or corticomedullary cysts in normal-sized or moderately small kidneys is highly suggestive of juvenile nephronophthisis in a child with severe uremia. Genetic testing may be required for a conclusive diagnosis. A renal biopsy showing evidence of chronic tubulointerstitial nephritis may be necessary to confirm the diagnosis if genetic testing is not available.

TREATMENT AND PREVENTION

Treatment is largely supportive, focusing on the progressive renal failure and the need for dialysis and transplantation. Prenatal genetic testing in families with a genetic diagnosis of nephronophthisis is feasible. DNA-based diagnostics are most useful in identifying the germline mutation prenatally or preimplantation.

AUTOSOMAL DOMINANT TUBULOINTERSTITIAL KIDNEY DISEASE (MEDULLARY CYSTIC KIDNEY DISEASE)

Autosomal dominant tubulointerstitial kidney disease is a group of genetic disorders characterized by an autosomal dominant inheritance, medullary cysts, and slowly progressive loss of kidney function beginning in the teenage years.[26] It shares a number of histologic features with nephronophthisis, including tubular basement membrane disintegration, tubular cyst formation, and tubulointerstitial inflammation and fibrosis.

Mutations in one of five genes—*UMOD/MCKD2*, *MUC1/MCKD1*, *REN*, *SEC61A1* and *HNF1B*—cause autosomal dominant tubulointerstitial kidney disease. *UMOD* on chromosome 16p12 encodes an 85-kD nonciliary protein, uromodulin, which is expressed on the luminal side of renal epithelium in the thick ascending limb of Henle loop and early distal convoluted tubules. Uromodulin kidney disease (also known as familial juvenile hyperuricemic nephropathy type 1, uromodulin storage disease, and glomerulocystic kidney disease) is the most common subtype, accounting for the majority of cases. Recent data indicate that *UMOD* mutations in uromodulin are encountered in 2 to 3% adults with chronic kidney disease. The mutations impair trafficking of furosemide-sensitive Na-K-2Cl transporter to the apical membrane of the thick ascending limb, thereby causing mild sodium wasting and volume contraction, with a secondary increase in proximal tubule urate reabsorption and hyperuricemia. Intracellular accumulation of the mutant protein causes tubular cell death. Affected patients do not have an increased incidence of urinary tract infections or renal calculi.

MUC1 on chromosome 1q21 encodes mucin-1, a transmembrane protein expressed in the distal nephron, the gastrointestinal and respiratory tracts, and skin, with no known function. The autosomal dominant TKP-MUC1 phenotype, which is limited to the kidneys, accounts for approximately 30% of autosomal dominant tubulointerstitial kidney disease. Gout and hyperuricemia occur late, secondary to loss of kidney function.

Mutations in *REN*, which encodes renin on chromosome 1q32.1, are rarer causes of autosomal dominant tubulointerstitial kidney disease. The clinical and laboratory manifestations resemble other low renin states. Anemia, caused by decreased levels of angiotensin II (a positive regulator of erythropoiesis), precedes the development of chronic kidney disease. Hyperuricemia develops early, likely owing to relative hypotension and increased proximal absorption of uric acid. Accumulation of the abnormal renin leads to tubular cell death and chronic kidney disease.

HNF1B nephropathy results from mutations in the gene encoding the widely expressed transcription factor hepatocyte nuclear factor-1-beta. *HNF1B* is located on chromosome 17q12 and mediates the development of a variety of tissues, including the kidney, liver, pancreas, and genital tract. This cystic renal disease may be accompanied by variable renal and extra renal manifestations (see Table 112-1). Renal function may be normal or may decline to end-stage renal disease. Neither mutation type nor position correlates with severity of disease.

DIAGNOSIS

Corticomedullary cysts, which are present in most adult patients with autosomal dominant tubulointerstitial kidney disease, cannot always be recognized on ultrasonography or computed tomography because they tend to be very small. A presumptive diagnosis is based on a strong family history and a bland urinary sediment with minimal proteinuria. Mutational analysis is necessary to make a definitive diagnosis.

TREATMENT

Except for the treatment of hyperuricemia and gout, when present (Chapter 252), the management of pancreatic insufficiency (in autosomal dominant tubulointerstitial kidney disease—HNF1B) and of low blood pressure and hyperkalemia (in autosomal dominant tubulointerstitial kidney disease—REN) is similar to that of patients with nephronophthisis.

MEDULLARY SPONGE KIDNEY

Medullary sponge kidney, a rare disorder of unknown pathogenesis, is characterized by congenitally acquired inner medullary and papillary collecting duct dilations, hypercalciuria, and a mild defect in urinary concentration and acidification secondary to tubular dysfunction.[27] Medullary sponge kidney is usually nonhereditary, but autosomal dominant inheritance has been described in several families.

Patients present with microscopic or gross hematuria and recurrent kidney stones, usually by the second or third decade of life. Medullary sponge kidney also may be an incidental finding on an intravenous pyelogram that shows the characteristic pooling of contrast material within the cystic collecting ducts. Differential diagnosis includes other causes of medullary nephrocalcinosis such as hyperparathyroidism, renal tubular acidosis type I, hypervitaminosis D, milk-alkali syndrome, and sarcoidosis.

TREATMENT AND PROGNOSIS

Basic treatment is aimed at controlling stone formation by stabilizing urinary pH. End-stage renal disease is uncommon, and long-term prognosis is excellent.

OTHER INHERITED CYSTIC SYNDROMES

TUBEROUS SCLEROSIS AND VON HIPPEL-LINDAU SYNDROME

Autosomal dominant renal cyst formation is seen in tuberous sclerosis and von Hippel-Lindau syndrome (Chapter 385). In tuberous sclerosis, cyst formation is commonly associated with hypertension; this disorder can resemble autosomal dominant PKD and is associated with about a 5% incidence of renal cell carcinoma. In von Hippel-Lindau syndrome, cyst formation can also lead to features of autosomal dominant PKD; more importantly, the syndrome is associated with a 25% incidence of renal cell carcinoma.

TREATMENT

Treatment is discussed in Chapter 385.

RARE CHILDHOOD SYNDROMES

Bardet-Biedl syndrome is an autosomal recessive disorder characterized by vision loss, obesity, hypertension, delayed development of motor skills, behavioral problems, and dystrophy of the hands, kidneys, and male genitals. Mutations in at least 21 genes involved in maintenance and function of cilia have been identified. About 45% of cases result from mutations in *BBS1* or *BBS10*, but in about 25% of cases, the defective gene remains to be identified. Calyceal cysts and calyceal clubbing predominate the renal lesion and are best diagnosed by intravenous urography rather than ultrasonography. Renal impairment is frequent and is an important cause of death.

Oral-facial-digital syndrome is a rare neurodevelopmental ciliopathy characterized by malformations of the brain, face, oral cavity, and digits. It is inherited in an X-linked dominant pattern and is caused by defects in the *OFD1* gene, which encodes OFD1 protein expressed in the centrosome and basal body of primary cilia but has an undetermined function. Renal (primarily glomerular) cysts are found in as many as 50% of patients, all females; males carrying the mutation die in utero. End-stage renal disease has been reported in affected girls and women ranging in age from 11 to 72 years.

Polycystic kidney disease with hyperinsulinemic hypoglycemia, is caused by biallelic mutations in *PMM2*, which encodes phosphomannomutase 2, an isomerase involved in synthesis of dolichol-P-oligosaccharides. Hyperinsulinemic hypoglycemic polycystic kidney disease presents in early childhood with hypoglycemic seizures owing to altered insulin secretion, enlarged glomerulocystic kidneys and occasional liver cysts. The severity of cystic kidney disease is variable, with few patients progressing to end-stage renal disease.[28]

TREATMENT

Control of blood pressure (Chapter 64) is important. For hyperinsulinemic hypoglycemic polycystic kidney disease, chronic diazoxide therapy can treat the hypoglycemia. No specific treatments are currently available for these conditions, and the affected children should be managed at specialized centers.

ACQUIRED CYSTIC KIDNEY DISEASE

Acquired cystic kidney disease is largely confined to the end-stage renal disease population on dialysis (Chapter 117). Cysts arise from proximal and distal tubule dilations in small end-stage kidneys regardless of cause, mode of dialysis, or presence of a functioning kidney transplant. Identifiable risk factors include duration of end-stage renal disease, older age, male sex, Black race, and chronic hypokalemia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Acquired cystic kidney disease is usually asymptomatic, but it occasionally leads to enlarged kidneys with associated abdominal discomfort and pain. Cyst hemorrhage, which is more common than cyst infection, presents with flank pain, anemia, or hematuria. The most significant complication of acquired cystic kidney disease is malignant conversion of cysts into renal cell carcinoma (Chapter 182). Carcinomas commonly present as hematuria and are 2 to 200 times more common in patients with acquired cystic kidney disease than in the general dialysis population.

Acquired cystic kidney disease is diagnosed by ultrasonography or computed tomography (CT), demonstrating multiple and bilateral renal cysts in a patient with preexisting chronic renal failure or end-stage renal disease. In contrast to autosomal dominant or recessive PKD, the kidneys are usually not enlarged, and there is no family history of PKD. Renal CT or MRI is preferable to detect cysts in small kidneys and to assess for malignant conversion.

TREATMENT AND PREVENTION

No strategies are available to prevent the appearance or delay the expansion of renal cysts in patients on hemodialysis, but cysts may stabilize or regress after successful renal transplantation. New or frank hematuria raises the concern of renal cell carcinoma (Chapter 182), which should be assessed using ultrasonography and contrast-enhanced CT. Any evidence of septa formation, solid material, or contrast enhancement within a cyst is suspicious for carcinoma and warrants consideration of nephrectomy.

PROGNOSIS

Asymptomatic acquired cystic kidney disease does not affect survival. The incidence of renal cell carcinoma in patients with acquired cystic kidney disease is approximately 0.18% per year. Although metastasis is less common at the time of diagnosis in patients with acquired cystic kidney disease than in other patients with renal cell carcinoma, the 5-year mortality rates are higher, likely related to the almost invariable coexistence of end-stage renal disease.

HEREDITARY NEPHROPATHIES AND DEVELOPMENTAL RENAL/URINARY ABNORMALITIES

LISA M. GUAY-WOODFORD

HEREDITARY NEPHROPATHIES

The proximal tubule is responsible for reclaiming most of the filtered glucose, amino acids, uric acid, phosphate, bicarbonate, and low-molecular-weight proteins. The loop of Henle and the distal nephron reabsorb approximately 30% of the filtered sodium chloride and 50% of the filtered divalent cations. The collecting duct, under the regulatory control of aldosterone, fine-tunes sodium reabsorption and secretes hydrogen and potassium ions. In the terminal collecting duct, antidiuretic hormone regulates water reabsorption and urinary concentration.

Inherited renal tubular disorders are a group of conditions in which the normal renal tubular reabsorption of ions, organic solutes, and water (Chapter 102) is disrupted because of defects in single genes.[1] These defects can be categorized by the nephron segment affected (Table 113-1).

DISORDERS OF PROXIMAL TUBULE FUNCTION

CYSTINURIA

Cystinuria is characterized by defective proximal tubular reabsorption of cystine and dibasic amino acids, thereby resulting in increased excretion of cystine and the risk of forming cystine-containing urinary stones (Chapter 111).[2] This autosomal recessive trait has an estimated prevalence of 1 in 7000 individuals. Two cystinuria genes have been identified: *SLC3A1,* which encodes the heavy subunit, rBAT; and *SLC7A9,* which encodes the light subunit, $b^{O,+AT}$. Several large studies indicate that mutations in *SLC3A1* are more common than mutations in *SLC7A9*. Mutations in *SLC3A1* cause cystinuria type A, mutations in *SLC7A9* cause cystinuria type B, and mutations in both genes cause mixed genotype cystinuria.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Although the severity of the disease is similar in all types of cystinurias, the clinical presentation can be quite variable, and the onset of disease may occur from infancy to the seventh decade of life. Cystine stones are radiopaque and often form the nidus for secondary calcium oxalate stones. Symptoms include renal colic, which may be associated with urinary tract obstruction and/or infection. Affected children can be identified by elevated urinary cystine levels, but testing must be performed after tubular transport has fully matured (at age 2 years). Genetic testing is available, but not mandatory for diagnosis, which can be established by stone analysis and/or quantitative 24-hour urine analysis.

TREATMENT

Conservative therapy with hydration (target specific gravity <1.005), reduced intake of sodium (children 1 to 1.5 mEq/day; adults 100 mEq/day), reduced intake of dietary methionine, and urinary alkalinization is sufficient for many patients with cystinuria. However, recurrent stones may cause renal damage, so such patients should be treated with thiol-containing agents such as D-penicillamine (pediatric dose, 20 to 30 mg/kg/day in four divided doses; adult dose, 0.5 to 1.2 g/day in four divided doses) or tiopronin (pediatric dose, 15 to 40 mg/kg/day in three divided doses; adult dose 800 to 1500 mg/day divided in three doses). Therapy should maintain the unbound urinary cystine concentration below 250 mg/L.

CYSTINOSIS

Cystinosis is the most common inherited cause of renal Fanconi syndrome. It also affects the eyes, muscles, central nervous system, lungs, and various endocrine organs. This autosomal recessive disorder is caused by mutations in the gene *CTNS,* which encodes cystinosin, a lysosomal cystine transporter. Defects in this transporter lead to the accumulation of intralysosomal cystine crystals and widespread cellular destruction.

TREATMENT

Control of blood pressure (Chapter 64) is important. For hyperinsulinemic hypoglycemic polycystic kidney disease, chronic diazoxide therapy can treat the hypoglycemia. No specific treatments are currently available for these conditions, and the affected children should be managed at specialized centers.

ACQUIRED CYSTIC KIDNEY DISEASE

Acquired cystic kidney disease is largely confined to the end-stage renal disease population on dialysis (Chapter 117). Cysts arise from proximal and distal tubule dilations in small end-stage kidneys regardless of cause, mode of dialysis, or presence of a functioning kidney transplant. Identifiable risk factors include duration of end-stage renal disease, older age, male sex, Black race, and chronic hypokalemia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Acquired cystic kidney disease is usually asymptomatic, but it occasionally leads to enlarged kidneys with associated abdominal discomfort and pain. Cyst hemorrhage, which is more common than cyst infection, presents with flank pain, anemia, or hematuria. The most significant complication of acquired cystic kidney disease is malignant conversion of cysts into renal cell carcinoma (Chapter 182). Carcinomas commonly present as hematuria and are 2 to 200 times more common in patients with acquired cystic kidney disease than in the general dialysis population.

Acquired cystic kidney disease is diagnosed by ultrasonography or computed tomography (CT), demonstrating multiple and bilateral renal cysts in a patient with preexisting chronic renal failure or end-stage renal disease. In contrast to autosomal dominant or recessive PKD, the kidneys are usually not enlarged, and there is no family history of PKD. Renal CT or MRI is preferable to detect cysts in small kidneys and to assess for malignant conversion.

TREATMENT AND PREVENTION

No strategies are available to prevent the appearance or delay the expansion of renal cysts in patients on hemodialysis, but cysts may stabilize or regress after successful renal transplantation. New or frank hematuria raises the concern of renal cell carcinoma (Chapter 182), which should be assessed using ultrasonography and contrast-enhanced CT. Any evidence of septa formation, solid material, or contrast enhancement within a cyst is suspicious for carcinoma and warrants consideration of nephrectomy.

PROGNOSIS

Asymptomatic acquired cystic kidney disease does not affect survival. The incidence of renal cell carcinoma in patients with acquired cystic kidney disease is approximately 0.18% per year. Although metastasis is less common at the time of diagnosis in patients with acquired cystic kidney disease than in other patients with renal cell carcinoma, the 5-year mortality rates are higher, likely related to the almost invariable coexistence of end-stage renal disease.

113 HEREDITARY NEPHROPATHIES AND DEVELOPMENTAL RENAL/URINARY ABNORMALITIES

LISA M. GUAY-WOODFORD

HEREDITARY NEPHROPATHIES

The proximal tubule is responsible for reclaiming most of the filtered glucose, amino acids, uric acid, phosphate, bicarbonate, and low-molecular-weight proteins. The loop of Henle and the distal nephron reabsorb approximately 30% of the filtered sodium chloride and 50% of the filtered divalent cations. The collecting duct, under the regulatory control of aldosterone, fine-tunes sodium reabsorption and secretes hydrogen and potassium ions. In the terminal collecting duct, antidiuretic hormone regulates water reabsorption and urinary concentration.

Inherited renal tubular disorders are a group of conditions in which the normal renal tubular reabsorption of ions, organic solutes, and water (Chapter 102) is disrupted because of defects in single genes.[1] These defects can be categorized by the nephron segment affected (Table 113-1).

DISORDERS OF PROXIMAL TUBULE FUNCTION

CYSTINURIA

Cystinuria is characterized by defective proximal tubular reabsorption of cystine and dibasic amino acids, thereby resulting in increased excretion of cystine and the risk of forming cystine-containing urinary stones (Chapter 111).[2] This autosomal recessive trait has an estimated prevalence of 1 in 7000 individuals. Two cystinuria genes have been identified: *SLC3A1,* which encodes the heavy subunit, rBAT; and *SLC7A9,* which encodes the light subunit, $b^{O,+AT}$. Several large studies indicate that mutations in *SLC3A1* are more common than mutations in *SLC7A9*. Mutations in *SLC3A1* cause cystinuria type A, mutations in *SLC7A9* cause cystinuria type B, and mutations in both genes cause mixed genotype cystinuria.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Although the severity of the disease is similar in all types of cystinurias, the clinical presentation can be quite variable, and the onset of disease may occur from infancy to the seventh decade of life. Cystine stones are radiopaque and often form the nidus for secondary calcium oxalate stones. Symptoms include renal colic, which may be associated with urinary tract obstruction and/or infection. Affected children can be identified by elevated urinary cystine levels, but testing must be performed after tubular transport has fully matured (at age 2 years). Genetic testing is available, but not mandatory for diagnosis, which can be established by stone analysis and/or quantitative 24-hour urine analysis.

TREATMENT

Conservative therapy with hydration (target specific gravity <1.005), reduced intake of sodium (children 1 to 1.5 mEq/day; adults 100 mEq/day), reduced intake of dietary methionine, and urinary alkalinization is sufficient for many patients with cystinuria. However, recurrent stones may cause renal damage, so such patients should be treated with thiol-containing agents such as D-penicillamine (pediatric dose, 20 to 30 mg/kg/day in four divided doses; adult dose, 0.5 to 1.2 g/day in four divided doses) or tiopronin (pediatric dose, 15 to 40 mg/kg/day in three divided doses; adult dose 800 to 1500 mg/day divided in three doses). Therapy should maintain the unbound urinary cystine concentration below 250 mg/L.

CYSTINOSIS

Cystinosis is the most common inherited cause of renal Fanconi syndrome. It also affects the eyes, muscles, central nervous system, lungs, and various endocrine organs. This autosomal recessive disorder is caused by mutations in the gene *CTNS,* which encodes cystinosin, a lysosomal cystine transporter. Defects in this transporter lead to the accumulation of intralysosomal cystine crystals and widespread cellular destruction.

ABSTRACT

Renal tubular disorders are a heterogeneous group of hereditary and acquired conditions that disrupt the normal, regulated reabsorption of ions, organic solutes, and water in various nephron segments. The clinical consequences involve fluid losses, as well as abnormalities in electrolyte and acid-base homeostasis. This chapter focuses on the inherited renal tubular disorders, highlights the genes involved, describes the resulting nephron segment dysfunction, and provides guidelines for clinical management. Congenital abnormalities of the kidney and urinary tract (CAKUT) occur in 1 : 500 newborns and comprise approximately 20 to 30% of all anomalies identified in the prenatal period. CAKUT disorders result from disruption of normal nephrogenesis, due to single gene defects and/or environmental factors. Some urinary tract anomalies are asymptomatic and inconsequential, but many renal tract malformations are important causes of infant mortality, as well as morbidity in older children and adults, including the progression to renal failure. This chapter presents an overview of the CAKUT disorders and the associated structural defects that involve the kidneys and urinary tract.

TABLE 113-1 HEREDITARY NEPHROPATHIES BY NEPHRON SEGMENT

NEPHRON SEGMENT	DISORDER	INHERITANCE	MAJOR RENAL FEATURES
PROXIMAL TUBULE			
	Renal glycosuria	AR	Isolated glycosuria
	Proximal renal tubular acidosis	AR	Hyperchloremic, hypokalemic, metabolic acidosis
	Carbonic anhydrase II deficiency	AR	Mixed proximal and distal renal tubular acidosis
	Hartnup disease	AR	Neutral aminoaciduria
	Lysinuric protein intolerance	AR	Protein intolerance, basic aminoaciduria
	Cystinuria	AR	Type A: Urinary calculi Type B: Urinary calculi
	Cystinosis	AR	Infantile: Renal Fanconi syndrome Late-onset: Renal Fanconi syndrome Non-nephropathic: Renal Fanconi syndrome
	Hypophosphatemic rickets	X-linked AD AR	Renal phosphate wasting, hypophosphatemia Renal phosphate wasting, hypophosphatemia Renal phosphate wasting, hypophosphatemia
	Dent disease	X-linked	Dent disease 1: Nephrocalcinosis, urinary calculi; low-molecular-weight proteinuria Dent disease 2: Nephrocalcinosis, urinary calculi; low-molecular-weight proteinuria
	Lowe syndrome	X-linked	Renal Fanconi syndrome
	Hereditary fructose intolerance	AR	Renal Fanconi syndrome
	Tyrosinemia, type I	AR	Renal Fanconi syndrome
	Wilson disease	AR	Renal Fanconi syndrome
	Fanconi-Bickel syndrome	AR	Renal Fanconi syndrome with hepatorenal glycogenosis
	Renal hypouricemia	AR	Hypouricemia, nephrolithiasis, and exercise-induced acute renal failure
LOOP OF HENLE			
	Bartter syndrome	AR AD	Type 1: Hypokalemic, hypochloremic metabolic alkalosis Type 2: Hypokalemic, hypochloremic metabolic alkalosis Type 3: Hypokalemic, hypochloremic metabolic alkalosis Type 4: Hypokalemic, hypochloremic metabolic alkalosis Type 5: Hypokalemic, hypochloremic metabolic alkalosis
DISTAL TUBULE			
	Gitelman syndrome	AR	Hypokalemic, hypochloremic, metabolic alkalosis
	Familial hypomagnesemia with hypercalciuria	AR	Severe renal magnesium and calcium wasting
	Isolated hypomagnesemia	AD	Renal magnesium wasting
	SeSAME syndrome (EAST syndrome)	AR	Hypokalemia, metabolic alkalosis, and hypomagnesemia
COLLECTING DUCT			
	Liddle syndrome	AD	Low renin hypertension
	Glucocorticoid-remediable hyperaldosteronism	AD	Low renin hypertension
	Apparent mineralocorticoid excess	AR	Low renin hypertension
	Pseudohypoaldosteronism, type 1	AR AD	AR: Hyponatremic, hypokalemic, metabolic acidosis AD: Hyponatremic, hypokalemic, metabolic acidosis
	Pseudohypoaldosteronism, type 2 (Gordon syndrome)	AD	Low renin hypertension with hyperkalemia
	Distal renal tubular acidosis	AR AD	AR: Hyperchloremic, hypokalemic, metabolic acidosis AD: Hyperchloremic, hypokalemic, metabolic acidosis
	Carbonic anhydrase II deficiency	AR	Mixed proximal and distal renal tubular acidosis
	Nephrogenic diabetes insipidus	X-linked AR and AD	X-linked: Urinary concentrating defect AR and AD: Urinary concentrating defect

AD = autosomal dominant; AR = autosomal recessive; SeSAME = seizures, sensorineural deafness, ataxia, intellectual disability (mental retardation), and electrolyte imbalances.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Three clinical presentations have been described. The most severe is infantile (classic) cystinosis, which manifests in the first year of life with renal tubular acidosis, impaired growth, and evidence of renal Fanconi syndrome, including aminoaciduria, glucosuria, phosphaturia, and low-molecular-weight proteinuria.

In untreated patients, progressive renal damage results in end-stage kidney disease by 10 years of age. A less severe, late-onset (juvenile or intermediate) form causes renal dysfunction in adolescence and involves cystine deposits in the cornea. The mildest form, an ocular, non-nephropathic form, features photophobia but no renal issues.

TREATMENT AND PROGNOSIS

The mainstay of therapy is oral cysteamine (dose: 60 to 90 mg/kg/day or 1.35 to 1.90 g/m^2/day, divided every 6 hours), which is an aminothiol that can lower intracellular cystine content by 90%.[3] In well-treated patients, cysteamine delays renal functional decline, enhances growth, prevents hypothyroidism, and lowers muscle cystine content. Therefore, early diagnosis and prompt, proper treatment are critical for preventing or significantly delaying the complications of cystinosis. Twice-daily dosing with delayed-release cysteamine bitartrate (at approximately 70% of the patient's usual dose) is as efficacious as cysteamine for reducing white blood cell cystine levels in patients with nephropathic cystinosis.

DENT DISEASE

Dent disease is an X-linked recessive renal tubular disorder characterized by low-molecular-weight proteinuria, hypercalciuria with nephrocalcinosis, and progressive renal failure. Low-molecular-weight proteinuria is the most consistent clinical feature, but there is wide variability in other manifestations of proximal tubular dysfunction. Atypical presentations have been reported, including amino aciduria, glycosuria, uricosuria/hypouricemia, kaliuresis/hypokalemia, and phosphaturia/hypophosphatemia. In two thirds of patients, the disease is caused by mutations in the *CLCN5* gene (Dent-1). A smaller proportion of patients (15 to 20%) have mutations in *OCRL* (Dent-2), the gene associated with Lowe oculocerebrorenal syndrome.

TREATMENT AND PROGNOSIS

No specific treatment is available, so treatment is designed to reduce nephrolithiasis and nephrocalcinosis with thiazide diuretics and often potassium citrate (see Chapter 111). End-stage kidney disease occurs at a median age of 40 years.[4]

DISORDERS OF LOOP OF HENLE AND DISTAL TUBULE FUNCTION

THE BARTTER-GITELMAN DISORDERS

The Bartter-Gitelman syndromes are a group of disorders that are characterized by markedly reduced salt transport in the thick ascending limb of Henle (Bartter syndrome) or in the distal convoluted tubule (Gitelman syndrome).[5]

Bartter syndrome is an autosomal recessive disorder that is caused by mutations in one of five genes—*SLC12A2,* encoding the sodium-potassium-chloride cotransporter NKCC2; *KCNJ1,* encoding the ROMK1 potassium ion channel; *CLCNKB,* encoding the ClC-Kb basolateral chloride ion channel; *BSND,* encoding barttin, a regulatory subunit required for basolateral chloride channel targeting to the membrane; and *MAGED,* encoding the melanoma antigen D2 (MAGE-D2). Defects in these genes cause Bartter syndrome types I, II, III, IV, and V, respectively. All five syndromes are characterized by disrupted salt transport in the thick ascending limb. In addition, severe gain-in-function mutations in *CASR,* the gene encoding the extracellular calcium ion–sensing receptor CaSR, can cause a Bartter-like phenotype (referred to as the Bartter-like subform of familial hypocalcemia) that is distinguished from the others by autosomal dominant transmission and associated hypocalcemic hypercalciuria. Most patients with Gitelman syndrome have defects in *SLC12A3,* the gene that encodes the sodium-chloride cotransporter NCCT. However, a minority of patients with the Gitelman phenotype have mutations in *CLCNKB.*

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Individuals with Bartter syndrome exhibit renal salt wasting, lowered blood pressure, polyuria, hypokalemic metabolic alkalosis,[6] and hypercalciuria with a variable risk of nephrocalcinosis. Bartter syndrome mimics the effects of long-term furosemide treatment (E-Fig. 113-1). In comparison, individuals with Gitelman syndrome have a disorder resembling the effects of long-term thiazide administration: milder renal salt wasting, normal blood pressure, hypokalemic metabolic alkalosis, hypomagnesemia, and hypocalciuria. Clinical differences between Bartter and Gitelman syndromes relate to the severity of salt wasting, whereas phenotypic differences among Bartter types I through V correlate with the specific physiologic roles played by the individual transporters or channels in the kidney and other organs.

Genetic testing can confirm these diagnoses by detecting the specific mutation. However, it is not usually required in clinical practice.

TREATMENT

The mainstay of treatment includes replacing salt and water losses and providing potassium supplementation to maintain serum levels greater than 3 mEq/dL.[7] For patients with perinatal (types I, II, IV, V) Bartter syndrome, nonsteroidal anti-inflammatory drugs (e.g., indomethacin 2 to 4 mg/kg/day in two to four divided doses) may be beneficial. In patients with Gitelman syndrome and some patients with Bartter syndrome type III, oral magnesium supplementation may be required to maintain serum levels above 1.2 mg/dL. In patients who have Gitelman syndrome with persistent symptomatic hypokalemia despite therapeutic adherence or who have unacceptable side effects, treatment with potassium-sparing diuretics (e.g., amiloride 10-20 mg/day), a selective aldosterone antagonist (eplerenone 150 mg/day), or a combination of these agents may be effective.

DISORDERS OF COLLECTING DUCT FUNCTION

LIDDLE SYNDROME (PSEUDOALDOSTERONISM)

Liddle syndrome is an autosomal dominant form of salt-sensitive hypertension (Chapter 64) caused by mutations in the β or γ subunit of the epithelial sodium channel, which is expressed at the apical surface of collecting duct cells and plays a critical role in maintaining salt balance and blood pressure.[6] Both the β and γ subunits regulate the channel activity of the α subunit. Mutations in either of these regulatory subunits result in increased epithelial sodium channel activity and Liddle syndrome. Severe hypertension typically manifests in childhood, with features of hypokalemic metabolic alkalosis that resemble primary aldosteronism. However, the secretion of renin and aldosterone is suppressed in this disorder.

TREATMENT

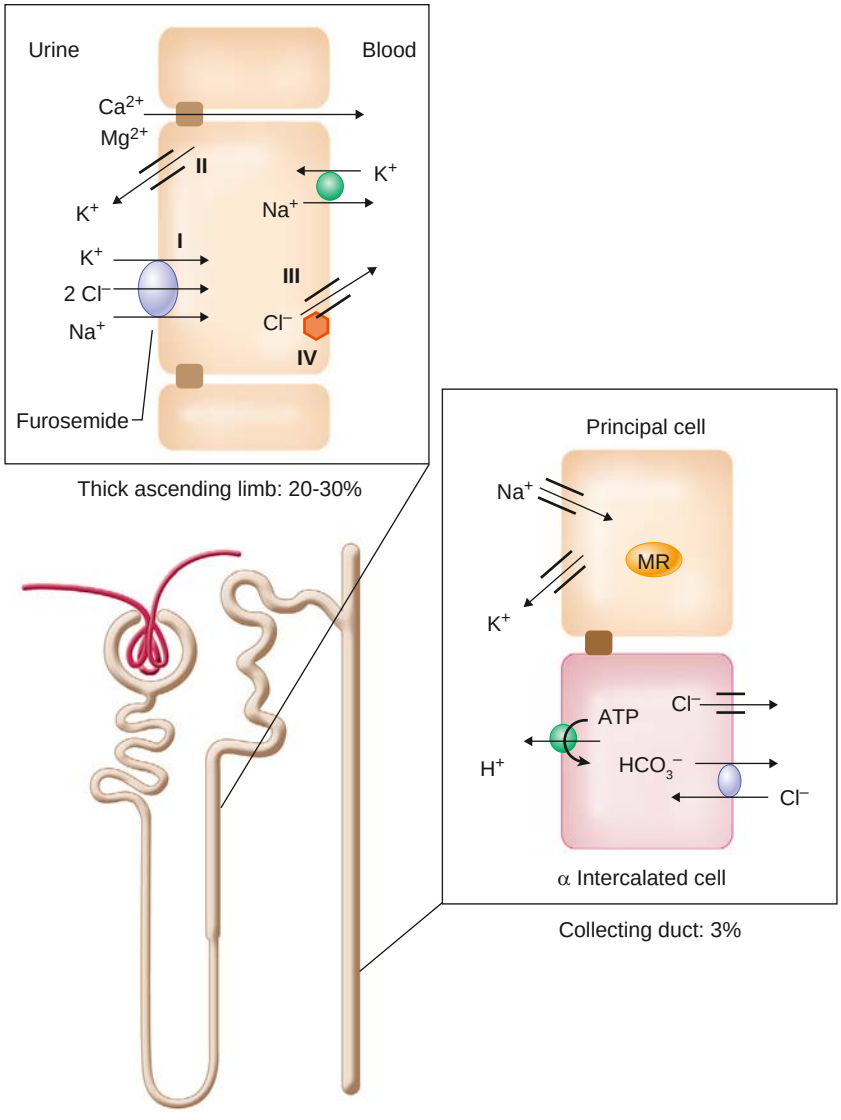
The clinical abnormalities can be ameliorated by a low-salt diet plus a potassium-sparing diuretic (e.g., amiloride 5 to 20 mg/day or triamterene 100 to 200 mg twice daily), which acts as an antagonist of the epithelial sodium channel. Spironolactone is not useful because genetic alterations in the regulatory subunits disrupt mineralocorticoid regulation of the channel.

DISTAL RENAL TUBULAR ACIDOSIS

Distal renal tubular acidosis results from failure of the collecting duct α-intercalated cells to excrete fixed acids (see Fig. 104-1 in Chapter 104). Both autosomal dominant and autosomal recessive forms of distal renal tubular acidosis have been described. Mutations in the *CA2* gene encoding carbonic anhydrase II or the *SLC4A1* gene encoding the chloride-bicarbonate exchanger AE1 cause autosomal dominant distal renal tubular acidosis and are rarely associated with recessive forms of the disease. Mutations in genes encoding subunits of the vacuolar hydrogen–adenosine triphosphatase (V-type H^+-ATPase) proton pump are the primary causes of autosomal recessive distal renal tubular acidosis. V-type ATPases are ubiquitous, multisubunit protein complexes that mediate the ATP-dependent transport of protons. In the kidney, V-type ATPases are the major proton-secreting pumps in the distal nephron and are involved in net proton secretion (bicarbonate generation) or proton reabsorption (net bicarbonate secretion). Defects in two genes, *ATP6V1B1* and *ATP6V0A4,* which encode subunits of the H^+-ATPase, cause distal renal tubular acidosis with or without associated sensorineural deafness.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical consequences include hypokalemic, hyperchloremic metabolic acidosis; impaired growth; hypercalciuria; hypocitraturia; nephrocalcinosis; nephrolithiasis; rickets in children; and osteomalacia in adults. Classic distal renal tubular acidosis can be distinguished from other metabolic acidoses by an inappropriately high urine pH (>5.5), diminished net acid excretion,



E-FIGURE 113-1. Transport in the thick ascending limb (TAL) and the pathophysiology of Bartter syndrome. Sodium (Na^+), potassium (K^+), and chloride (Cl^-) are reabsorbed across the apical membrane via the sodium-potassium-chloride cotransporter NKCC2 (defective in Bartter syndrome type I). NKCC2 can be inhibited by furosemide. Mutations in the gene encoding MAGE-D2 cause a transient decrease in NKCC2 expression, resulting in Bartter syndrome type V. The optimal function of NKCC2 requires the binding of all three ions. Potassium is recycled through the ROMK1 channel (defective in Bartter syndrome type II). These apical transport processes result in a relative excess of positive charges in the tubular lumen, providing the driving force for paracellular absorption of calcium (Ca^{2+}) and magnesium (Mg^{2+}). Na^+ exits across the basolateral membrane via the sodium-potassium adenosine triphosphatase (Na^+, K^+-ATPase) pump, whereas Cl^- exits through the chloride channels ClC-Kb (defective in Bartter syndrome type III) and ClC-Ka. Both channels require barttin (defective in Bartter syndrome type IV) for proper membrane localization. The TAL reabsorbs approximately 25% of the filtered sodium load, whereas the collecting duct (CD) is responsible for reabsorbing about 3% of the sodium load. The profound defect in TAL sodium reabsorption leads to salt wasting, stimulation of the renin-aldosterone system, and an aldosterone-induced increase in potassium and hydrogen ion secretion in the CD, with resultant hypokalemic metabolic alkalosis. HCO_3^- = bicarbonate; MR = mineralocorticoid receptor.

positive urinary anion gap, and low urinary ammonium concentration (Table 113-2).[8]

TREATMENT

Treatment with alkali supplementation as citrate salts (1 to 2 mEq/kg/day in adults and 3 to 6 mEq/kg/day in children) corrects the metabolic acidosis as well as the hypocitraturia, thereby preventing nephrolithiasis.[9] In contrast to proximal renal tubular acidosis, urinary potassium wasting can be ameliorated with alkali therapy alone.

DEVELOPMENT OF THE KIDNEY AND URINARY TRACT

The human kidney and urogenital tract develop from three principal embryonic structures: the metanephric mesenchyme, the mesonephric (wolffian) duct, and the cloaca (Fig. 113-1). At 4 to 5 weeks of gestation, the ureteric bud originates as a diverticulum of the mesonephric duct. Reciprocal interactions between the branching ureteric bud and the metanephric mesenchyme induce kidney development, with the metanephros undergoing an epithelial transformation to form the glomeruli and the proximal and distal tubules. The ureteric bud branches give rise to the collecting ducts, the renal pelvis, the ureter, and the bladder trigone. Approximately 60% of the nephron mass is formed in the second half of gestation, and the number of nephrons in the normal human kidney varies widely from about 250,000 to over 2 million.

Concurrent with the initial nephrogenic events, the urorectal fold divides the cloaca into the urogenital sinus and the future rectum. The mesonephric duct develops into the trigone of the urinary bladder, which is the posterior part of the bladder wall. Between 5 and 6 weeks of gestation, the second genital duct (müllerian duct) appears and runs in parallel with the wolffian duct. In males, the müllerian duct subsequently regresses, and the wolffian duct proceeds to form the epididymis, the vas deferens, the seminal vesicle, and the ejaculatory duct. In females, the wolffian duct regresses, and the müllerian ducts fuse to form the ureterovaginal primordium, which merges with the urogenital sinus and eventually gives rise to the uterus, the oviducts, and the proximal vagina. The remnants of the allantois form the urachus, a fibrous cord that connects the bladder to the umbilicus.

ABNORMALITIES OF THE URINARY TRACT

Congenital abnormalities of the kidney and urinary tract encompass a diverse set of structural malformations that result from defects in the developing urinary system.[10] These abnormalities occur in 3 to 11% of the population and account for approximately 50% of all congenital abnormalities.[11] Although 10 to 20% of cases are attributable to single gene mutations or genomic disorders, the majority of sporadic cases appear to involve complex interactions of multiple genetic variants and environmental factors.[12,13]

The most common malformation (~20%) is ureteropelvic junction obstruction. Renal parenchymal anomalies include agenesis, hypoplasia, dysplasia, malrotation, and ectopia. Pelviureteral abnormalities include megaureter, ectopic ureter, horseshoe kidney, duplex collecting system, and vesicoureteral reflux. Abnormalities of posterior urethral valves can occur concurrently. Prenatal ultrasonographic surveillance has substantially improved detection and prompt initiation of treatment, but these disorders remain important causes of infant mortality, as well as morbidity in older children and adults, including progression to renal failure.

RENAL AGENESIS

Renal agenesis reflects a complete failure of nephrogenesis. Unilateral agenesis can occur as an isolated abnormality or as a component of syndromic disorders, such as Turner syndrome (Chapter 214). As an isolated entity, the complete absence of one kidney occurs in 1 in 1000 to 1500 individuals. The incidence is higher in males and occurs somewhat more frequently on the left side; in about half the patients, the ipsilateral ureter and hemitrigone are also absent. The remaining kidney is usually enlarged owing to compensatory hypertrophy, but it may be ectopic or malrotated. Vesicoureteral reflux is observed on the contralateral side in about 30% of patients.

Renal agenesis is commonly associated with genital anomalies, thereby suggesting that it represents a developmental field defect. In females, absence of the ipsilateral oviduct and malformation of the uterus and vagina result from maldevelopment of the müllerian duct, whereas in males, wolffian duct–derived structures, such as the vas deferens and the seminal vesicles, are often absent. Other associated anomalies can involve the cardiovascular system (30%), musculoskeletal system (14%), and adrenal gland (10%). Unilateral renal agenesis is found in 30% of patients with the VACTERL syndrome, an association of vertebral, anal, cardiac, trachea-esophageal, renal, and limb defects.

Bilateral renal agenesis has an estimated incidence of 1 in 4000 births and is associated with the Potter sequence, which includes pulmonary hypoplasia, a characteristic facies, and deformities of the spine and limbs. At birth, these neonates have a critical degree of pulmonary hypoplasia that is incompatible with survival. The familial association of unilateral and bilateral renal agenesis, renal dysplasia, and congenital hydronephrosis occurs in hereditary renal adysplasia syndrome (Online Mendelian Inheritance in Man entry 191830), a rare autosomal dominant disorder with variable penetrance.

RENAL HYPOPLASIA

The term *renal hypoplasia* describes small kidneys with normally differentiated nephrons that are reduced in number. *Oligomeganephronia* describes a form of bilateral renal hypoplasia with a marked reduction in nephron number and associated hypertrophy of individual glomeruli and tubules. This abnormality occurs sporadically as an isolated developmental defect that must be differentiated from acquired renal atrophy and the genetic disorders nephronophthisis and autosomal dominant tubulointerstitial kidney disease (formerly known as medullary cystic kidney disease). Renal function declines slowly, with progression to end-stage kidney failure in the second to third decade of life.

RENAL DYSPLASIA

Renal dysplasia, which can be associated with various abnormalities of kidney size, results from abnormal metanephric differentiation that causes anomalous and/or incompletely differentiated renal elements. Small dysplastic kidneys are commonly referred to as *aplastic*. Large dysplastic kidneys are often cystic; the most extreme type is referred to as *multicystic dysplastic kidney*.

Unilateral dysplasia may be asymptomatic well into adult life. Small aplastic and large multicystic dysplastic kidneys are nonfunctioning and can be distinguished from renal agenesis by imaging studies. The ipsilateral ureter is typically atretic. Contralateral malformations, including obstruction and vesicoureteral reflux, are common. Unilateral multicystic kidneys involute over time and often disappear. Unilateral aplasia and multicystic dysplasia may be manifestations of the hereditary renal adysplasia syndrome. Bilateral multicystic dysplastic kidneys are incompatible with neonatal survival.

TABLE 113-2 FEATURES OF THE INHERITED RENAL TUBULAR ACIDOSES

DISORDER	RENAL TRANSPORT DEFECT	MINIMAL URINE pH DURING ACIDOSIS	ALKALI SUPPLEMENTATION	UAG DURING ACIDOSIS
Proximal renal tubular acidosis	↓ Proximal bicarbonate reabsorption	<5.5	Children: 10-15 mEq HCO_3^-/kg/day	0 or +
Carbonic anhydrase II deficiency	↓ Proximal bicarbonate reabsorption and ↓ distal acidification	Variable	Variable	0 or +
Distal renal tubular acidosis	↓ Distal acidification	>5.5	Adults: 1-2 mEq HCO_3^-/kg/day Children: 3-6 mEq HCO_3^-/kg/day	+ +

HCO_3^- = bicarbonate; UAG = urinary anion gap = $[Na^+] + [K^+] - [Cl^-]$. In renal tubular acidosis, the UAG is usually 0 or positive. By comparison, the UAG is negative in metabolic acidosis associated with diarrheal illness.

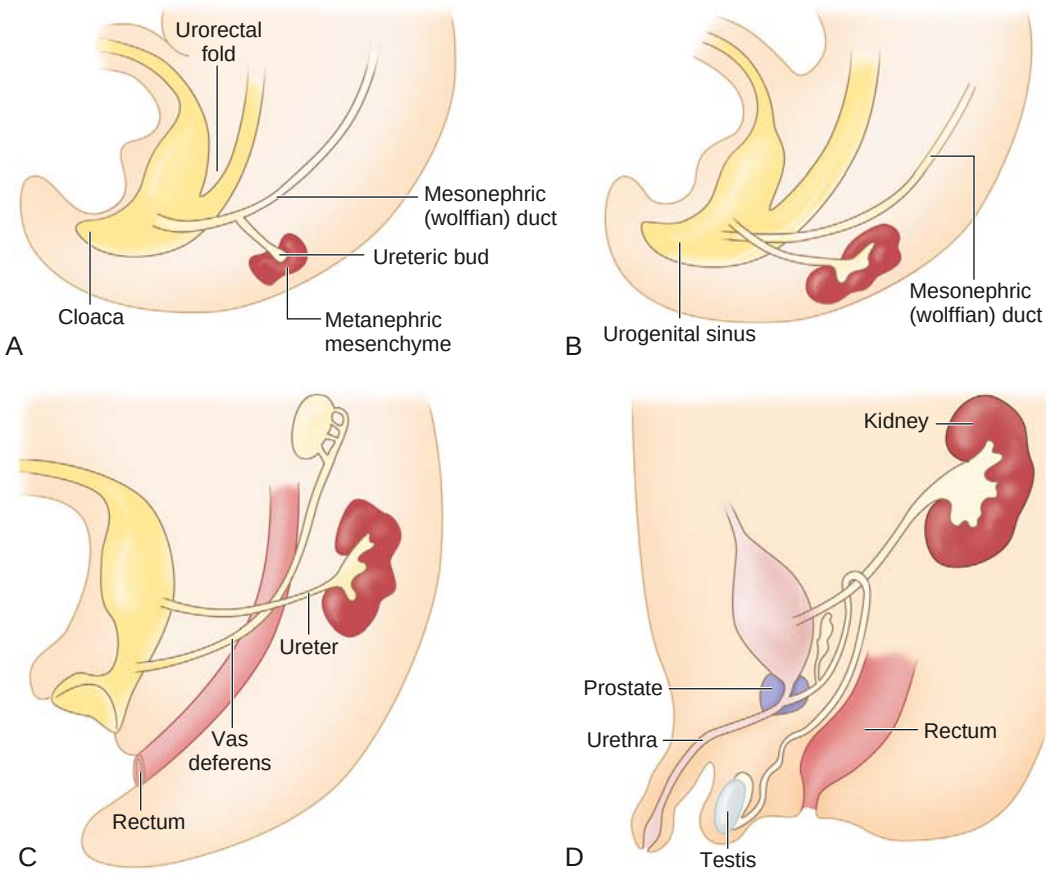


FIGURE 113-1. Key events in the development of the male urinary tract. In the 4-week embryo, the ureteric bud emerges from the wolffian duct (**A**). Reciprocal interactions between the branching ureteric bud and the metanephric mesenchyme induce kidney development. Concurrently, the cloaca is divided by the urorectal fold into the urogenital sinus and the future rectum (**B**). In the 8-week male embryo, the wolffian duct begins to give rise to the epididymis, the seminal vesicles, and the caudal part of the vas deferens (**C**). By 9 weeks, axial growth of the fetal spine prompts the developing kidney to ascend from the pelvis to its final lumbar position. The external genitalia develop between 8 and 16 weeks, and testicular descent begins in month 7 of gestation (**D**).

RENAL AND URETERAL STRUCTURAL ABNORMALITIES

RENAL MALROTATION AND ECTOPIA

Metanephric kidney development begins caudally. By 9 weeks of gestation, the kidney has ascended to its normal level (L1-L3), and the renal pelvis has rotated 90 degrees toward the midline. Anomalies of ascent and/or failure of rotation are common. Bilateral renal ectopia is often associated with kidney fusion. The most common fusion anomaly is the horseshoe kidney, which occurs in 1 in 500 newborns with a 2 : 1 male predominance. Renal ascent is prevented by the root of the inferior mesenteric artery (Fig. 113-2A). Crossed renal ectopia can occur with or without fusion. Supernumerary (extra) kidneys are typically ectopic and vary in location. Although almost one third of patients with renal ectopia remain asymptomatic, the associated malrotation of the renal pelvis increases the risk of hydronephrosis, infection, and stone formation.

PELVIURETERAL ABNORMALITIES

Obstruction of the ureteropelvic junction impedes the flow of urine from the renal pelvis into the ureter. It is one of the most frequently occurring urinary tract anomalies in infants, occurring in 1 in 1000 live births with male predominance. In congenital obstruction of the ureteropelvic junction, urologic anomalies in the contralateral system are common, including renal agenesis, renal dysplasia, multicystic dysplasia, and vesicoureteral reflux. Ureteropelvic junction obstruction may occur in adults secondary to external compression, kinking, or stenosis of the proximal ureter. Surgical intervention is indicated if there is associated renal function impairment, pyelonephritis, stones, or pain.

Hydrocalyx or *hydrocalycosis* refers to dilation of a major calyx that can result from intrinsic obstruction, such as in infundibular stenosis, or in the context of extrinsic compression of the pelvis, caused by a vessel or a parapelvic cyst. In comparison, *megacalycosis* represents a nonobstructive, dysplastic lesion found primarily in males, in which the calyces are dilated and usually increased in number. Associated renal medullary hypoplasia causes malformation of the renal papillae.

Calyceal diverticula are cystic structures connected by a narrow channel to an adjacent minor calyx. In imaging studies, these diverticula typically fill with contrast material, which distinguishes them from renal parenchymal cysts.

Partial duplication of the renal pelvis and ureter is a common anomaly that occurs more frequently in females, is typically unilateral, and is clinically insignificant.

URETERIC ANOMALIES

Ectopic ureters usually reflect complete ureteric and renal duplication. Approximately 10% are bilateral. The ectopic ureter typically drains the dysplastic upper pole of a duplex kidney and inserts below the normal vesicoureteral junction into the lower trigone of the bladder or the proximal urethra. Ectopic ureters occur more frequently in females, and the insertion sites can include the vagina and the vulva, with resulting incontinence. An ectopic ureter is often associated with a ureterocele, which is a cystic dilation of the terminal ureter (see Fig. 113-2B). In children, ureteroceles can be associated with urinary tract infection and obstruction of the bladder neck or even of the contralateral ureter. In adults, the clinical presentation usually involves associated infection, ureteric stones, or both.

A *megaureter,* or grossly dilated ureter, has multiple potential causes, including intrinsic ureteric obstruction by a stone, bladder outflow obstruction, vesicoureteral reflux, and external compression of the distal ureter. In contrast, primary megaureter results from a functional obstruction of the distal ureter caused by an aperistaltic segment (see Fig. 113-2C).

VESICOURETERAL REFLUX

In the normal urinary tract, urinary reflux from the bladder into the ureters is prevented by a functional valve-like mechanism at the vesicoureteral junction. The competence of this valve is dependent on several critical factors, such as the intramural length of the ureter, the position of the ureteric orifice in the bladder, and the integrity of the bladder wall musculature.

Primary vesicoureteral reflux results from incompetence of the vesicoureteral junction owing to the shortened length of the ureter's submucosal segment

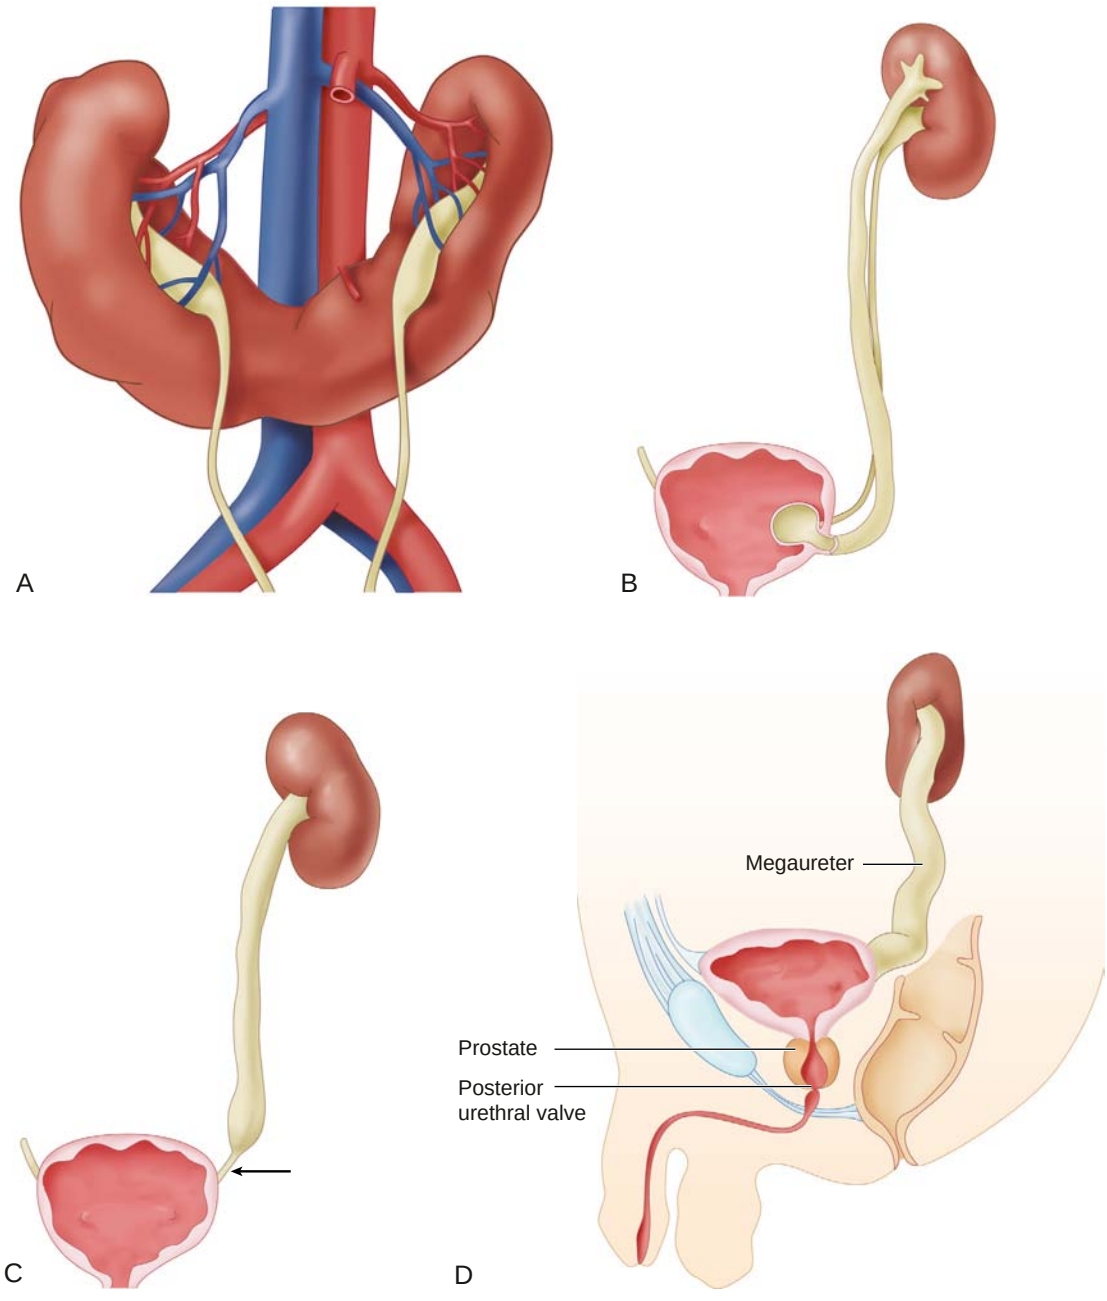

FIGURE 113-2. Developmental abnormalities of the urinary tract. A, Horseshoe kidney. B, Ectopic ureter associated with a ureterocele. C, Megaureter with the aperistaltic segment *(arrow)*. D, Bladder outlet obstruction caused by posterior urethral valves.

and the lateral, ectopic position of its orifice. It is estimated to occur in 1 to 2% in children. Familial clustering of vesicoureteral reflux suggests that genetic factors contribute to the pathogenesis, but each implicated gene accounts for only a small number of affected patients.[14]

As the intramural ureter lengthens with age, primary vesicoureteral reflux tends to remit or disappear. Vesicoureteral reflux can also occur secondary to obstructive maldevelopment of the lower urinary tract in children, such as in triad syndrome and posterior urethral valves, or secondary to masses that obstruct the bladder or urethra (in adults). In both primary and secondary vesicoureteral reflux, intrarenal reflux can lead to the development of reflux nephropathy, a tubulointerstitial lesion (Chapter 108) associated with gross scarring at the renal poles. In addition, the development of a glomerular lesion consistent with focal and segmental glomerulosclerosis (Chapter 107) can cause proteinuria, hypertension, and progressive loss of renal function.

Primary vesicoureteral reflux is diagnosed in about 30 to 40% of children who have imaging studies after urinary tract infections (Chapter 263). Frequent urinary tract infection, higher grades of vesicoureteral reflux, and the presence of bladder and bowel dysfunction are risk factors for renal cortical scarring, and the rates of spontaneous resolution of reflux and of endoscopic surgical success depend upon bladder and bowel dysfunction.

TREATMENT

For children with grade I through IV vesicoureteral reflux, antimicrobial prophylaxis does not decrease the risk of renal scarring,[A1] which occurs significantly more frequently in kidneys with grade IV reflux than in kidneys with low-grade or no reflux. For most patients, conservative management is preferred, using an individualized, risk-based approach under expert supervision. One endoscopic injection of a dextranomer/hyaluronic acid copolymer provides an efficient and safe long-term treatment in about 80% of treated patients with advanced vesicoureteral reflux,[15,16] but surgery has a higher cure rate.[A2] Further studies are needed to determine whether this minimally invasive approach should replace traditional surgical correction as the first-line therapy in many patients.

LOWER URINARY TRACT ABNORMALITIES

TRIAD SYNDROME (PRUNE-BELLY SYNDROME, EAGLE-BARRETT SYNDROME)

Triad syndrome, also referred to as prune-belly syndrome or Eagle-Barrett syndrome, involves a constellation of anomalies including congenital absence or deficiency of the abdominal wall musculature, gross ureteral dilation, bladder wall thickening, prostatic hypoplasia, and bilateral undescended testes (cryptorchidism). The full syndrome is expressed only in males, and surviving individuals are typically infertile. Patients with an incomplete syndrome can have anomalies of the abdominal wall musculature, bladder, and upper urinary tract; 3 to 5% of these patients are females. Although the specific molecular causes have yet to be defined, defects in mesenchymal development appear to cause poor prostate and bladder differentiation, ureteral smooth muscle aplasia with consequent ureteral aperistalsis, and varying degrees of renal dysplasia. Patients with triad syndrome have associated anorectal malformations, musculoskeletal anomalies, and, rarely, cardiac anomalies. In the immediate postnatal period, prognosis depends on the severity of extra-genitourinary defects. Long-term outcome correlates with the degree of renal dysplasia and the success of urodynamic management.

BLADDER ABNORMALITIES

Bladder exstrophy results from a midline closure defect involving the lower anterior abdominal wall, the bladder, and the external genitalia. These abnormalities have been attributed to a primary defect in the differentiation of the cloacal membrane, but the precise molecular events remain unclear. Variants in genes involved the morphogenesis of the urinary tract are linked to the pathogenesis of bladder exstrophy.[17] In severe cases, bladder exstrophy may be associated with imperforate anus and rectal atresia. Clinical studies suggest a correlation between the success of bladder reconstruction and long-term preservation of renal function.

In adults, neuropathic or neurogenic bladder (Chapter 115) has numerous etiologic contributors, including central nervous system trauma, stroke, disorders such as Parkinson disease, spinal trauma, multiple sclerosis, and peripheral nerve damage caused by trauma or surgery. In children, myelomeningocele (spina bifida) is the most common cause of neurogenic bladder dysfunction. Other forms of myelodysplasia, such as spinal dysraphism (spina bifida occulta) and sacral agenesis, are less common causes.

TREATMENT

Treatment focuses on the management of incontinence (Chapter 115) and the prevention and treatment of urinary tract infections (Chapter 263).

POSTERIOR URETHRAL VALVES

In male infants, posterior urethral valves are the most common cause of bladder outflow obstruction, with resulting bilateral hydronephrosis and megaureters. However, among all infants with hydronephrosis, only 10% have posterior urethral valves. The urethral obstruction results from defective reabsorption of mucosal folds in the posterior urethra, just distal to the verumontanum of the prostatic urethra. As a result, dilation of the proximal urethra, bladder wall hypertrophy and trabeculation, associated vesicoureteral reflux, and varying degrees of renal dysplasia are present (see Fig. 113-2D). Surgical management strategies are dictated by the age of the child and the degree of associated renal insufficiency. Survival and long-term renal outcome depend on the severity of the associated renal dysplasia.

BENIGN PROSTATIC HYPERPLASIA AND PROSTATITIS

STEVEN A. KAPLAN

BENIGN PROSTATIC HYPERPLASIA

DEFINITION

The prostate gland is composed of four zones: peripheral, central, transitional, and stroma. It can also be divided by lobes: anterior, posterior, lateral, and median (Fig. 114-1).

A normal prostate volume in young men is about 20 mL (where 1 mL is equivalent to 1 gram), but it increases from an average of about 24 mL to 38 mL between ages 50 to 80 years. In benign prostatic hyperplasia (BPH), the calculated volume exceeds 30 mL, but the degree of prostatic enlargement that causes symptoms is highly variable.

EPIDEMIOLOGY

Age is the major risk factor for BPH. A histologic diagnosis of BPH will develop in approximately 50% of men older than 50 years of age and 90% of men in their 80s. Of these men, approximately 50% will develop notable lower urinary tract symptoms, which increase in prevalence in a linear fashion between the ages of 40 and 80 years. With increasing worldwide longevity, BPH has become a major global challenge.[1]

PATHOBIOLOGY

As the bladder fills with urine, it normally is able to maintain a low intravesical pressure via sympathetic nerve stimulation despite the increasing volume. However, an enlarged prostate may cause lower urinary tract symptoms by directly obstructing the flow of urine or by increasing the muscle tone of the prostate. Men with bladder outlet obstruction due to BPH often have overactive bladder detrusor function, thereby resulting in urinary retention. In addition, changes in the vascularity of the prostate or the urinary bladder can contribute to the development of symptoms. The growth of the prostate gland is dependent on androgens and androgen receptors, and it is reduced by 5α-reductase inhibitors that block the conversion of testosterone to dihydrotestosterone.[2]

BENIGN PROSTATIC HYPERPLASIA AND PROSTATITIS

STEVEN A. KAPLAN

BENIGN PROSTATIC HYPERPLASIA

DEFINITION

The prostate gland is composed of four zones: peripheral, central, transitional, and stroma. It can also be divided by lobes: anterior, posterior, lateral, and median (Fig. 114-1).

A normal prostate volume in young men is about 20 mL (where 1 mL is equivalent to 1 gram), but it increases from an average of about 24 mL to 38 mL between ages 50 to 80 years. In benign prostatic hyperplasia (BPH), the calculated volume exceeds 30 mL, but the degree of prostatic enlargement that causes symptoms is highly variable.

EPIDEMIOLOGY

Age is the major risk factor for BPH. A histologic diagnosis of BPH will develop in approximately 50% of men older than 50 years of age and 90% of men in their 80s. Of these men, approximately 50% will develop notable lower urinary tract symptoms, which increase in prevalence in a linear fashion between the ages of 40 and 80 years. With increasing worldwide longevity, BPH has become a major global challenge.[1]

PATHOBIOLOGY

As the bladder fills with urine, it normally is able to maintain a low intravesical pressure via sympathetic nerve stimulation despite the increasing volume. However, an enlarged prostate may cause lower urinary tract symptoms by directly obstructing the flow of urine or by increasing the muscle tone of the prostate. Men with bladder outlet obstruction due to BPH often have overactive bladder detrusor function, thereby resulting in urinary retention. In addition, changes in the vascularity of the prostate or the urinary bladder can contribute to the development of symptoms. The growth of the prostate gland is dependent on androgens and androgen receptors, and it is reduced by 5α-reductase inhibitors that block the conversion of testosterone to dihydrotestosterone.[2]

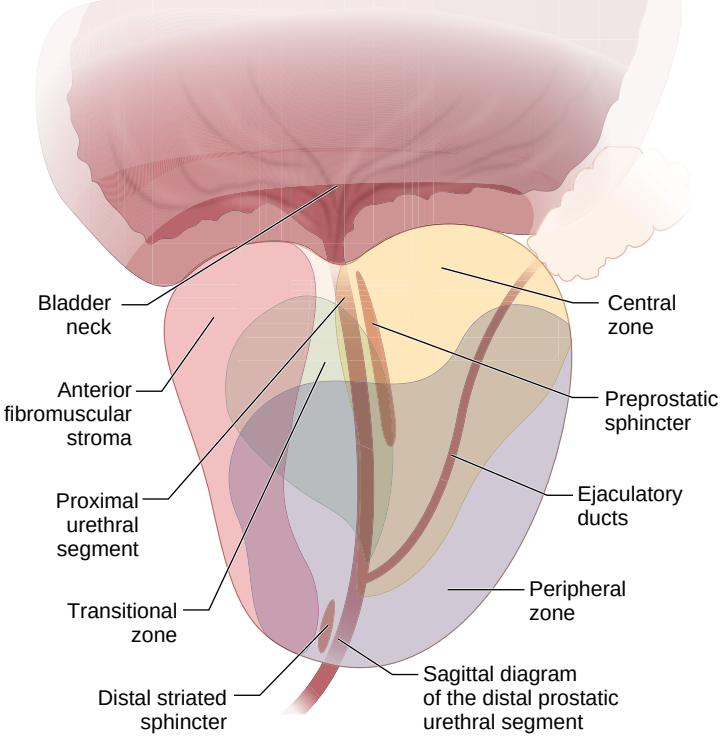

FIGURE 114-1. Anatomy of the prostate.

ABSTRACT

Benign prostatic hyperplasia develops in about 50% of men over age 50 years and 90% of men in their 80s. About half of these men will develop clinically important lower urinary tract symptoms, including urgency, hesitancy, frequency, nocturia, and incomplete emptying. Treatment emphasizes alpha adrenergic antagonists, 5-alpha-reductase inhibitors, and phosphodiesterase type 5 inhibitors; many men require combination therapy. When medications are inadequate, a variety of minimally invasive surgical options can remove sufficient prostate tissue to reduce symptoms substantially. Prostatitis, which is inflammation of the prostate gland, is typically chronic and often associated with local discomfort as well as symptoms similar to benign prostatic hypertrophy. Chronic bacterial prostatitis may respond, at least transiently, to empiric antibiotic therapy. Acute bacterial prostatitis requires urgent antibiotics, with the intravenous route sometimes required.

KEYWORDS

benign prostatic hypertrophy
prostatic hypertrophy
prostatitis
bacterial prostatitis
chronic pelvic pain syndrome

Enlargement typically is a combination of stromal hypertrophy and glandular hyperplasia, mostly in the central zone. BPH is a histologic diagnosis defined by the proliferation of smooth muscle and epithelial cells within the prostatic transition zone.

CLINICAL MANIFESTATIONS

Benign prostatic hyperplasia can lead to lower urinary tract symptoms, which can have a significant negative impact on quality of life. The presence of lower urinary tract symptoms is often indicative of bladder outlet obstruction secondary to BPH. Symptoms may significantly impair health-related quality of life and are classified as voiding (i.e., hesitancy, weak stream, straining, and prolonged voiding), storage (i.e., frequency, urgency, nocturia, urge incontinence, and voiding of small volumes), or postmicturition (i.e., postvoid dribble, incomplete emptying).[3] Most patients who have lower urinary tract symptoms present with a combination of these symptoms. The symptoms of overactive bladder (Chapter 115) and lower urinary tract symptoms secondary to BPH often overlap.

DIAGNOSIS

Assessment should begin with a medical history and review of the patient's medications. The medical history should include any causes that may lead to bladder dysfunction, such as cerebrovascular disease, previous surgical procedures, and a history of prostatic disease. Diuretics and over-the-counter preparations, such as nasal decongestants and antihistamines, may exacerbate the patient's urinary symptoms. Furthermore, dietary factors such as water, caffeine, alcohol, and artificial sweeteners can be important contributors to the overall clinical manifestations of symptoms because they serve as direct bladder irritants and diuretics. Urinary symptoms should be assessed in a standardized fashion with validated instruments such as the International Prostate Symptom Score (IPSS) (Fig. 114-2) and observed over time.

Abdominal examination should be performed to identify the presence of a palpable bladder, which could be a sign of urinary retention. The physical examination should include a prostate examination to evaluate its size and the possible presence of nodules. The digital rectal examination gives only an approximate estimate of size because only the posterior half is palpated. A focused neurologic examination is also important to assess a patient's mental status, ambulatory status, lower extremity neuromuscular function, and anal sphincter tone.

Laboratory Findings

Urinalysis should be performed to screen for hematuria and urinary tract infection (Chapter 263). A serum prostate-specific antigen (PSA) level should be measured because it can detect asymptomatic prostate cancer (Chapter 186) that may require treatment even in men who would not be candidates for treatment if they were asymptomatic. However, the results must be interpreted with caution because the serum PSA level correlates with prostatic volume even in the absence of cancer. Objective parameters such as maximum urinary flow by uroflowmetry and bladder postvoid residual by ultrasound should also be measured if the diagnosis is in question.[4] Although there is not a direct correlation between lower urinary tract symptoms and objective parameters such as prostate size or flow rate, prostate volume and serum PSA levels generally predict worsening of symptoms. Long-standing bladder outlet obstruction can progress to incomplete bladder emptying, bilateral hydroureteronephrosis, and ultimately acute and/or chronic renal insufficiency. Given the myriad of new minimally invasive and surgical therapeutic options, measurement of prostate volume by either the abdominal or transrectal route should be considered.

Other causes of bladder dysfunction that should be considered during the assessment of men presenting with lower urinary tract symptoms include bladder cancer (Chapter 182), diabetes (Chapter 210), urethral strictures, and bladder stones. The absence of hematuria makes bladder cancer very unlikely, but patients with BPH symptoms require cystoscopy if they also have hematuria. Neurologic disorders including Parkinson disease (Chapter 378) and multiple sclerosis (Chapter 380) may also cause lower urinary tract symptoms in men.

TREATMENT

The treatment of BPH aims to improve subjective symptoms and quality of life as well as to prevent progression of the disease.[5] Over time, treatment has evolved away from surgical therapy and largely to medical therapy.[6,7]

Men who are mildly symptomatic, defined as a score of 7 or less on the IPSS questionnaire, can be observed (Fig. 114-3). Lifestyle changes that may improve symptoms include fluid restriction, timed voiding, and double voiding. Patients who have moderate symptoms, defined as 8 to 19 points on the IPSS, and who are not seriously bothered by their symptoms may also be observed with periodic reassessment to monitor whether urinary retention, refractory hematuria, infections, or other complications develop. Men with more substantial symptoms should be treated medically.[8]

Medications

α-Adrenergic antagonists, which decrease bladder outlet resistance by relaxing urethral smooth muscle and possibly striated sphincter tone, are considered the first-line treatment of male lower urinary tract symptoms[A1] (Table 114-1). Their side effects include orthostatic hypotension, sexual dysfunction, and dizziness. All medications in this class should be discontinued before cataract surgery for fear of floppy-iris syndrome.

The 5α-reductase inhibitors dutasteride and finasteride are also effective for the treatment of BPH, with evidence suggesting that dutasteride is preferred.[A2] These agents reduce prostate size by suppressing testosterone and dihydrotestosterone production. As a result, these agents reduce the number of episodes of acute urinary retention and decrease the need for surgical treatment of BPH, and they are particularly helpful for the treatment of patients with higher prostate volumes. Side effects of these medications include erectile dysfunction, reduced libido, and decreased ejaculate volume.

The phosphodiesterase type 5 inhibitor tadalafil also improves lower urinary tract symptoms and IPSS scores secondary to BPH.[A3] However, tadalafil is not as efficacious as α-adrenergic antagonists or 5α-reductase inhibitors for improving maximal urinary flow.

Antimuscarinic agents, which target the muscarinic cholinergic receptors in the bladder to reduce overactivity that occurs as a result of changes in detrusor function, are safe and efficacious for the treatment of BPH. Options include tolterodine, solifenacin, and fesoterodine.

Another class of agents used to treat overactive bladder symptoms are β_3-agonists such as mirabegron and vibegron. Mirabegron and vibegron stimulate β_3-receptors, thereby causing smooth muscle relaxation in the bladder.[A4]

Combination drug therapy is an option when single-drug therapy is insufficient. Data suggest that the best combination is adding a 5α-reductase inhibitor to an α-adrenergic blocker,[A5] although the combination of an α-adrenergic blocker and a phosphodiesterase 5 inhibitor is also efficacious.[A6,A7] Similarly, the combination of tamsulosin, dutasteride, and an antimuscarinic agent or A β_3-agonists (see Table 114-1) can improve overactive bladder symptoms that have responded inadequately to tamsulosin alone.[A8] Saw palmetto, the most commonly used phytotherapeutic agent, does not improve urinary parameters during a treatment period of 12 months in randomized trials and is not recommended even as add-on therapy.

Surgical Treatments

Many minimally invasive treatment options are available for BPH.[9,10] Prostatic urethral lift delivers permanent transprostatic implants through a cystoscope to open the prostatic parenchyma mechanically. This treatment is limited to patients with a prostate smaller than 80 g and without significant middle lobe hypertrophy, in whom it is as good as or better than surgical prostatectomy.[A9] Transurethral radiofrequency-induced water therapy induces a delayed coagulation necrosis of prostatic tissue, thereby resulting in a decrease in prostate volume.[A10] The advantages of these procedures (i.e., lower risks for retrograde ejaculation, strictures, hematuria, and blood transfusions) must be balanced against increased risks for dysuria, urinary retention, recurrent symptoms, and the need for retreatment compared with transurethral resection of the prostate.[A11]

Electrosurgically based transurethral resection of the prostate, either via a monopolar or bipolar approach, is the "gold standard" in endoscopic treatment of symptomatic BPH. Because of improvements in medical therapy and minimally invasive options, the number of transurethral resection of the prostate procedures performed in the United States has declined, although it still remains the most commonly performed urologic procedure.

Bipolar transurethral resection of the prostate uses bipolar instead of monopolar electrocautery and saline as an irrigant. This procedure resects large amounts of prostatic tissue from the transitional zone and central zone but decreases complications, such as hyponatremia and perioperative bleeding requiring transfusion. For patients with very large prostate glands (i.e., 80 g and larger), transurethral resection of the prostate procedures may require prolonged operative times, and an open surgical approach may be necessary for adequate debulking of the obstructing prostatic tissue.

Other surgical technologies include various laser vaporization techniques[A12] or microwave therapy.[A13] Laser technologies can be effective alternatives to electrosurgical approaches, although their long-term durability remains to be defined. Prostatic artery embolization is another possible treatment, though data on its efficacy and safety are limited.[A14]

FIGURE 114-2. International Prostate Symptom Score (IPSS). The seven symptom questions constitute a scale initially developed by the American Urological Association. The eighth question about quality of life is scored separately. (From Barry MJ, Fowler FJ Jr, O'Leary MP, et al. The American Urological Association symptom index for benign prostatic hyperplasia: the Measurement Committee of the American Urological Association. *J Urol*. 1992;148:1549.)

PROGNOSIS

Over time, the symptoms of BPH often increase and require medications or a procedure. Recurrent episodes of prostatitis can exacerbate symptoms. Patients should be counseled about the likelihood of progression, the natural history of lower urinary tract symptoms (including the risk for urinary tract infections [Chapter 263]) related to BPH, and the treatment options that can be offered.

PROSTATITIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Prostatitis is usually a clinical diagnosis based on signs and symptoms that occur as a result of inflammation of the prostate gland. The overall prevalence of prostatitis is approximately 8%, and it affects men of a wide age range. Swelling or inflammation of the prostate gland, which may be due to various causes, can have a significant impact on quality of life. The current classification system defines the various types of prostatitis on the basis of whether it is acute or chronic, associated with infection, or associated with pelvic pain (Table 114-2).

The causative organisms of acute bacterial prostatitis are usually similar to those that cause other common genitourinary infections (Chapter 263) and include *Escherichia coli* and *Enterococcus* spp. About 60% of patients with chronic bacterial prostatitis have evidence of ongoing infection based on polymerase chain reaction (PCR) testing of their expressed prostatic secretions, with *Chlamydia trachomatis, Ureaplasma urealyticum, Mycoplasma genitalium,* and *Mycoplasma hominis* the most common organisms detected. The pathogenesis of chronic prostatitis/chronic pelvic pain syndrome, however, remains unclear.

CLINICAL MANIFESTATIONS

Acute bacterial prostatitis (type I) is characterized by acute infection of the prostate gland. Presenting symptoms include pelvic, perineal, penile, or ejaculatory pain as well as irritative or obstructive voiding symptoms and sexual dysfunction. Patients with severe infections can present with fever and chills and can become septic (Chapter 94). Type II prostatitis is characterized by recurrent or relapsing infection caused by the same organism. These patients tend to be less sick during each episode and usually present with voiding symptoms and pain.

Type III prostatitis is characterized by pelvic discomfort or pain for more than 3 of the 6 months before evaluation. Type III patients have repeatedly negative urine cultures. Classification into type IIIa or IIIb is contingent on the presence of leukocytes in semen, post–prostate massage urine, or prostatic secretions. Patients with type IV prostatitis do not experience any symptoms of prostatitis. Leukocytes or inflammatory cells are found in prostate tissue, semen, or expressed prostatic secretions.

DIAGNOSIS

The diagnosis of prostatitis requires a careful history, physical examination, and examination of the urine. The physician must ask pertinent questions about voiding history, sexual history, symptoms, pain, neurologic disorders, and prior pelvic surgery. The National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI), which is a standardized tool for the evaluation and assessment of prostatitis, consists of nine parts that outline three major areas of prostatitis: pain, urinary symptoms, and quality of life (Fig. 114-4). The NIH-CPSI is not specifically for making the diagnosis of prostatitis, but it is very useful for longitudinally monitoring changes in symptoms over time after a diagnosis of prostatitis has been established. The physical examination should include an abdominal, external genital, perineal, and digital rectal examination. Attention should be placed on identifying pelvic wall discomfort, structural abnormalities, or prostatic pain on digital rectal examination.

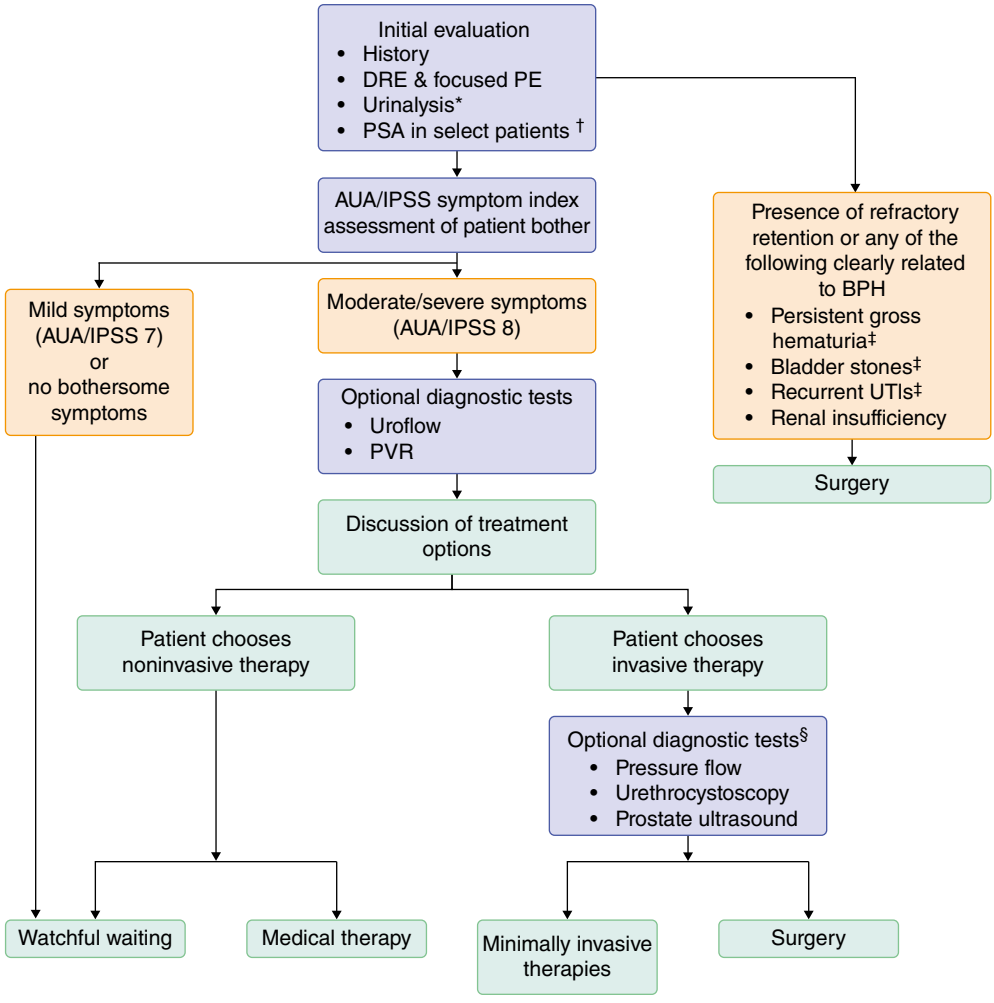

FIGURE 114-3. **Algorithm of management of benign prostatic hyperplasia (BPH).** *In patients with clinically significant prostatic bleeding, a course of a 5 alpha-reductase inhibitor may be used. If bleeding persists, tissue ablative surgery is indicated. †Patients with at least a 10-year life expectancy for whom knowledge of the presence of prostate cancer would change management or patients for whom the PSA measurement may change the management of voiding symptoms. ‡After exhausting other therapeutic options. §Some diagnostic tests are used in predicting response to therapy. Pressure-flow studies are most useful in men prior to surgery. Characteristics	Acute infection of prostate gland	Recurrent or relapsing infection caused by the same organism; not acute	90% of cases of chronic prostatitis are presumed to be nonbacterial; diagnosis of exclusion Characteristic symptoms Discomfort or pain in pelvic region for more than 3 months within the past 6 months Pelvic, perineal, penile, or ejaculatory pain; irritative or obstructive voiding symptoms, sexual dysfunction No documented recurrent urinary tract infections; repeated negative cultures Classification into IIIa or IIIb determined by presence of leukocytes in semen, post–prostate massage urine, or prostatic secretion	No symptoms of prostatitis Leukocytes or inflammatory cells present in prostate tissue, semen, or expressed prostatic secretions

Laboratory Evaluation

Urinalysis and urine culture should be performed for every patient. Historically, the four-specimen test was recommended, with specimens obtained from the initial voided bladder urine, midstream voided bladder urine, expressed prostatic secretions obtained during prostate massage, and voided bladder urine collected after prostate massage. Leukocytes in the third specimen suggest the diagnosis of prostatitis. Leukocytes without bacteria suggest inflammation consistent with nonbacterial prostatitis. However, this four-step approach is rarely used today because it has not proved to be useful as a diagnostic tool or for directing treatment. It has been replaced by either a semen culture or a midstream urine culture and by examination of a voided urine specimen after prostate massage.

Urodynamic methods offer valuable insight for patients experiencing predominantly voiding symptoms. Other conditions, such as prostatic obstruction, primary bladder neck obstruction, dysfunctional voiding, urethral obstruction, and detrusor-sphincter dyssynergia, may be defined with the help of postvoid residual, pressure-flow urodynamics, or videourodynamics. These conditions, in comparison to prostatitis, have many effective treatment options.

Measurement of a postvoid residual urine volume by ultrasound can be used to assess incomplete emptying because urinary retention can be a risk factor for recurrent infections.[11] Low maximum urine flow rates suggest bladder outlet obstruction, decreased detrusor contractility, or both as an alternative explanation for lower urinary tract symptoms and poor flow. However, for those who fail to respond to treatment, PCR analysis of semen to evaluate for possible fastidious organisms (e.g., *C. trachomatis, U. urealyticum, Mycoplasma* species, and *Neisseria gonorrhoeae*) may be useful for the evaluation of chronic prostatitis. Cultures of urethral swabs may be used to evaluate patients with potentially undiagnosed sexually transmitted diseases (Chapter 264). Other diagnostic tests include semen analysis and culture, which are useful for patients with complaints of abnormal-smelling semen or infertility.

Cystoscopy is an adjunct to urodynamics in the evaluation of chronic prostatitis/chronic pelvic pain syndrome, especially before any surgical intervention. Cystoscopy is also performed for evaluation of hematuria or abnormal cytology findings because prostate cancer (Chapter 186) or bladder cancer (Chapter 182) can cause symptoms similar to chronic pelvic pain syndrome.

PSA testing should be ordered on the basis of prostate cancer screening (Chapter 186) but has no specific role in evaluation of prostatitis symptoms. Acute prostatitis can increase the serum level of PSA, but it usually returns to normal levels with appropriate antibiotics within 1 to 3 months. PSA can be elevated and even can wax and wane in patients with chronic prostatitis/chronic pelvic pain syndrome. Patients with chronic prostatitis have a less well-defined decrease in PSA after a course of antibiotics. Anywhere from one third to two thirds of men undergoing prostate biopsy have chronic inflammation, but the correlation with symptoms of prostatitis is unclear.

Transrectal ultrasound can identify a prostatic abscess and is generally recommended for patients who have recurrent prostatitis or who do not respond to treatment. The potential utility of pelvic computed xerographic scanning and transrectal magnetic resonance imaging is unclear.

TREATMENT

Acute Bacterial Prostatitis

Oral or intravenous antibiotics are usually effective for curing acute prostatitis, and progression to chronic bacterial prostatitis is uncommon.[12] Typical first-course antibiotics include oral fluoroquinolones (e.g., levofloxacin 500 mg once daily or ofloxacin 300 mg twice daily) and sulfonamides (e.g., trimethoprim/sulfamethoxazole 160 mg/800 mg twice daily) for 6 weeks. Patients who are unable to tolerate oral medications and patients with signs of sepsis may require broad-spectrum intravenous antibiotics (e.g., ampicillin 2 g every 6 hours plus gentamicin 1.5 mg/kg every 8 hours until afebrile) followed by 6 weeks of oral therapy as before. A prostatic abscess may require interventional therapy.[13]

Chronic Bacterial Prostatitis

Antibiotic therapy is the mainstay of treatment for chronic bacterial prostatitis.[14] Antibiotics with good lipid solubility, good enteric bacterial coverage, and a high pK_a have the best prostatic penetration. These antibiotics include quinolones, sulfa-based preparations, macrolides, tetracyclines, and aminoglycosides. The fluoroquinolones (e.g., ciprofloxacin 500 mg twice daily, levofloxacin 500 mg once daily, or ofloxacin 300 mg twice daily) have equivalent success rates in patients with chronic bacterial prostatitis and are generally the first-line treatment. In cases in which atypical bacteria, such as chlamydia, are suspected to be the cause of chronic bacterial prostatitis, better results may be achieved by macrolide antibiotics, such as azithromycin (500 mg twice daily). Most studies demonstrate effective treatment with 30 days of therapy, but some clinicians prescribe 6 weeks of therapy as for acute prostatitis because the recurrence rate is as high as 40% within a year. Delivery of antibiotics by intraprostatic injection or anal submucosal injection is rarely used.

Treatments for Chronic Prostatitis/Chronic Pelvic Pain Syndrome

The optimal regimen for the treatment of chronic prostatitis/chronic pelvic pain syndrome is not known, and the response to treatment is often disappointing.[15] Prolonged courses of antibiotics generally are not effective. One option is to perform PCR testing of expressed prostatic secretions and to use antibiotics only if the test result is positive. Current empirical therapy uses a combination of α-blockers, adrenergic antagonists, phosphodiesterase 5 inhibitors,[A15,A16] and anti-inflammatory agents (e.g., ibuprofen 400 mg three times daily or naproxen 200 mg twice daily). Neuroleptics, such as gabapentin, have been tried but appear to be no better than placebo and have side effects. The potential value of allopurinol is unclear. Many phytotherapies have been tried, but improvements have not been dramatic or consistent in various trials.

Conservative supportive therapies include warm sitz baths and special diets that avoid spicy foods, caffeine, alcohol, and other urinary irritants. Behavioral therapies and stress reduction can augment the efficacy of medications,[A17] and therapies that aim to improve relaxation and to re-educate pelvic floor muscle function can improve symptoms in highly stressed individuals with dysfunctional voiding. Options include biofeedback and bladder retraining. Unproven treatments include trigger point massage combined with relaxation and electromagnetic pelvic floor therapy, acupuncture, and percutaneous tibial nerve stimulation.[A18] Prostate massage can be combined with other therapies, but its efficacy has been variable.

PROGNOSIS

Most patients with type I prostatitis are effectively treated with oral or intravenous antibiotics, although some cases do not respond to treatment and

115 URINARY INCONTINENCE

NEIL M. RESNICK AND CATHERINE E. DUBEAU

DEFINITION

Urinary incontinence is the involuntary leakage of urine sufficient to be a health or social problem.

EPIDEMIOLOGY

More than twice as common in women than in men, the prevalence of incontinence increases with age, although at least some degree of urinary incontinence is reported by 11% of women aged 22 to 27 years.[1] Incontinence afflicts 15 to 30% of older adults living at home, one third of those in acute care settings, and more than half of those in nursing homes. Its estimated cost in the United States exceeded $83 billion in 2020, with out-of-pocket costs for patients of more than $500.

Urinary incontinence predisposes to perineal rashes, pressure ulcers, urinary tract infections, falls, and fractures, and it is associated with embarrassment, stigmatization, isolation, depression, anxiety, sexual dysfunction, and risk for institutionalization. Many seriously ill elderly consider it an outcome worse than death.

Despite its prevalence and adverse consequences, geriatric incontinence remains largely neglected, by patients and physicians alike. This neglect is unfortunate because its increased prevalence with age relates more to age-associated diseases and functional impairments than to age itself. Most important, incontinence is usually treatable and often curable at all ages, even in the frail, although the approach in older patients must be broader than that employed in younger patients.[2]

PATHOBIOLOGY

At any age, continence depends not only on the integrity of lower urinary tract function but also on the presence of adequate mentation, mobility, motivation, and manual dexterity. Although incontinence in younger patients is rarely associated with deficits in these domains, such deficits occur commonly in older patients and can cause or exacerbate incontinence or influence therapeutic approaches. Some data suggest that genomics[3] and the microbiome[4] may play a role in increasing susceptibility, particularly for urge incontinence.

With age, bladder capacity does not change, but bladder sensation and contractility decrease.[5] At the cellular level, detrusor smooth muscle develops a "dense band pattern" characterized by dense sarcolemmal bands with depleted caveolae. This depletion may mediate the age-related decline in bladder contractility. In addition, an incomplete disjunction pattern characterized by scattered protrusion junctions develops and may underlie the high prevalence of involuntary bladder contractions (detrusor overactivity) in older adults of both sexes. Bladder ischemia and/or inflammation likely also contribute.[6] Urethral length and sphincter strength decrease in women, whereas the prostate enlarges in most men and causes obstruction in about 50% of them. The postvoid residual volume in the bladder also increases in both sexes but normally to less than 100 mL. In addition, older persons often excrete most of their fluid intake at night, even in the absence of venous insufficiency, renal disease, heart failure, or prostatic obstruction. Because this shift in nocturnal fluid excretion is coupled with an age-associated increase in sleep disorders, most older adults have at least one episode of nocturia per night.

None of these age-related changes causes incontinence, but all predispose to it. This predisposition, combined with the increased likelihood that an older person will encounter an additional pathologic, physiologic, or pharmacologic insult, explains the increased prevalence of incontinence with age. Thus, the onset or exacerbation of incontinence in an older person is often due to precipitants that are outside the lower urinary tract and that are amenable to medical intervention.

Causes of Transient Incontinence

Incontinence is transient in up to one third of community-dwelling elderly individuals and in up to half of acutely hospitalized patients. Although most transient causes are outside the lower urinary tract (Table 115-1), three points warrant emphasis. First, the risk for transient incontinence is increased if, in addition to physiologic changes of the lower urinary tract, there also are pathologic changes. Anticholinergic agents are more likely to cause retention and overflow incontinence in individuals with a weak or obstructed bladder, whereas excess urine output is more likely to cause urge incontinence in individuals with detrusor overactivity or impaired mobility. Second, these transient causes may persist if left untreated and should not be dismissed merely because incontinence is long-standing. Third, identification of the most common cause is of little value because causes vary among individuals, and geriatric incontinence is rarely due to just one cause.

Causes of Established Incontinence Related to the Lower Urinary Tract

Detrusor Overactivity

Detrusor overactivity, also called involuntary bladder contraction or *overactive bladder*, generally causes *urge incontinence* and is the most common type of lower urinary tract dysfunction in incontinent elderly people, in whom it accounts for about two thirds of cases. Histologically, detrusor overactivity is associated with the complete disjunction pattern, with widening of the intercellular space, reduction of normal (intermediate) muscle cell junctions, and emergence of novel protrusion junctions and ultraclose abutments that connect cells together in chains. These connections may mediate a change in cell coupling from a mechanical to an electrical mechanism that results in involuntary bladder contraction. Other potential causes include ischemia, abnormalities in suburothelial myofibroblasts, and changes in central nervous system structural and functional control mechanisms.

At any age, detrusor overactivity is usually idiopathic, but it can be associated with a variety of other causes that may affect prognosis and management. Such conditions include cerebral disease, upper motor neuron lesions (Chapters 369 and 387), urethral obstruction, stress incontinence, bladder calculus, and bladder carcinoma (Chapter 182).

Stress Incontinence

Stress incontinence, which is the second most common cause of incontinence in older women and the dominant cause in middle-aged women, usually reflects

115 URINARY INCONTINENCE

NEIL M. RESNICK AND CATHERINE E. DUBEAU

DEFINITION

Urinary incontinence is the involuntary leakage of urine sufficient to be a health or social problem.

EPIDEMIOLOGY

More than twice as common in women than in men, the prevalence of incontinence increases with age, although at least some degree of urinary incontinence is reported by 11% of women aged 22 to 27 years.[1] Incontinence afflicts 15 to 30% of older adults living at home, one third of those in acute care settings, and more than half of those in nursing homes. Its estimated cost in the United States exceeded $83 billion in 2020, with out-of-pocket costs for patients of more than $500.

Urinary incontinence predisposes to perineal rashes, pressure ulcers, urinary tract infections, falls, and fractures, and it is associated with embarrassment, stigmatization, isolation, depression, anxiety, sexual dysfunction, and risk for institutionalization. Many seriously ill elderly consider it an outcome worse than death.

Despite its prevalence and adverse consequences, geriatric incontinence remains largely neglected, by patients and physicians alike. This neglect is unfortunate because its increased prevalence with age relates more to age-associated diseases and functional impairments than to age itself. Most important, incontinence is usually treatable and often curable at all ages, even in the frail, although the approach in older patients must be broader than that employed in younger patients.[2]

PATHOBIOLOGY

At any age, continence depends not only on the integrity of lower urinary tract function but also on the presence of adequate mentation, mobility, motivation, and manual dexterity. Although incontinence in younger patients is rarely associated with deficits in these domains, such deficits occur commonly in older patients and can cause or exacerbate incontinence or influence therapeutic approaches. Some data suggest that genomics[3] and the microbiome[4] may play a role in increasing susceptibility, particularly for urge incontinence.

With age, bladder capacity does not change, but bladder sensation and contractility decrease.[5] At the cellular level, detrusor smooth muscle develops a "dense band pattern" characterized by dense sarcolemmal bands with depleted caveolae. This depletion may mediate the age-related decline in bladder contractility. In addition, an incomplete disjunction pattern characterized by scattered protrusion junctions develops and may underlie the high prevalence of involuntary bladder contractions (detrusor overactivity) in older adults of both sexes. Bladder ischemia and/or inflammation likely also contribute.[6] Urethral length and sphincter strength decrease in women, whereas the prostate enlarges in most men and causes obstruction in about 50% of them. The postvoid residual volume in the bladder also increases in both sexes but normally to less than 100 mL. In addition, older persons often excrete most of their fluid intake at night, even in the absence of venous insufficiency, renal disease, heart failure, or prostatic obstruction. Because this shift in nocturnal fluid excretion is coupled with an age-associated increase in sleep disorders, most older adults have at least one episode of nocturia per night.

None of these age-related changes causes incontinence, but all predispose to it. This predisposition, combined with the increased likelihood that an older person will encounter an additional pathologic, physiologic, or pharmacologic insult, explains the increased prevalence of incontinence with age. Thus, the onset or exacerbation of incontinence in an older person is often due to precipitants that are outside the lower urinary tract and that are amenable to medical intervention.

Causes of Transient Incontinence

Incontinence is transient in up to one third of community-dwelling elderly individuals and in up to half of acutely hospitalized patients. Although most transient causes are outside the lower urinary tract (Table 115-1), three points warrant emphasis. First, the risk for transient incontinence is increased if, in addition to physiologic changes of the lower urinary tract, there also are pathologic changes. Anticholinergic agents are more likely to cause retention and overflow incontinence in individuals with a weak or obstructed bladder, whereas excess urine output is more likely to cause urge incontinence in individuals with detrusor overactivity or impaired mobility. Second, these transient causes may persist if left untreated and should not be dismissed merely because incontinence is long-standing. Third, identification of the most common cause is of little value because causes vary among individuals, and geriatric incontinence is rarely due to just one cause.

Causes of Established Incontinence Related to the Lower Urinary Tract

Detrusor Overactivity

Detrusor overactivity, also called involuntary bladder contraction or *overactive bladder*, generally causes *urge incontinence* and is the most common type of lower urinary tract dysfunction in incontinent elderly people, in whom it accounts for about two thirds of cases. Histologically, detrusor overactivity is associated with the complete disjunction pattern, with widening of the intercellular space, reduction of normal (intermediate) muscle cell junctions, and emergence of novel protrusion junctions and ultraclose abutments that connect cells together in chains. These connections may mediate a change in cell coupling from a mechanical to an electrical mechanism that results in involuntary bladder contraction. Other potential causes include ischemia, abnormalities in suburothelial myofibroblasts, and changes in central nervous system structural and functional control mechanisms.

At any age, detrusor overactivity is usually idiopathic, but it can be associated with a variety of other causes that may affect prognosis and management. Such conditions include cerebral disease, upper motor neuron lesions (Chapters 369 and 387), urethral obstruction, stress incontinence, bladder calculus, and bladder carcinoma (Chapter 182).

Stress Incontinence

Stress incontinence, which is the second most common cause of incontinence in older women and the dominant cause in middle-aged women, usually reflects

ABSTRACT

Urinary incontinence is prevalent, morbid, and costly, especially in women and older individuals. Although urinary incontinence is never normal at any age, can be effectively treated, and often can be cured, the majority of patients with incontinence remain unknown to their physician and untreated. Among younger patients, incontinence is usually caused by abnormalities of the lower urinary tract: stress incontinence associated with pelvic floor laxity in women and urge incontinence associated with detrusor overactivity ("overactive bladder") in men. Although an overactive bladder may occur in men with or without concurrent prostatic obstruction, women are rarely obstructed. Men rarely have stress incontinence unless they have had a prior *radical* prostatectomy. Middle-aged women often have a combination of urge and stress ("mixed") incontinence. Among older adults, detrusor overactivity is the most frequent cause in both sexes. At all ages, comorbidity, functional impairment, fluid intake, frequency of voiding, medications, urinary tract infection, and constipation can contribute to incontinence, but these factors are especially important among the elderly; addressing them can often improve or cure incontinence, even in the presence of urinary tract dysfunction. For patients with persistent urgency incontinence or prostatic obstruction, pharmacotherapy can complement lifestyle and behavioral approaches. Anticholinergic and β-3 adrenergic agents are equally effective, although the former can have adverse cognitive effects. An α-adrenergic antagonist can be used for men in whom prostate obstruction is suspected; a 5-α reductase inhibitor may be added, although its clinical benefit is delayed for months. Surgical correction of obstruction is also effective. For women with stress incontinence, pelvic muscle exercises, weight loss, and physical maneuvers can reduce or eliminate leakage; if these approaches fail, surgical correction is effective.

TABLE 115-1 CAUSES OF TRANSIENT INCONTINENCE: DIAPERS MNEMONIC

Delirium	Result of underlying illness or medication; incontinence is secondary and abates once the cause of delirium is corrected	
Infection—*symptomatic* UTI	Acute, symptomatic UTI may cause or worsen incontinence, but the far more common *asymptomatic* bacteriuria does not	
Atrophic urethritis/vaginitis	Characterized by vaginal erosions, telangiectasia, petechiae, and friability; may cause or contribute to incontinence	
Pharmaceuticals	*Drug type:*	*Potential effects on continence:*
	Sedative-hypnotics (e.g., long-acting benzodiazepines; alcohol)	Sedation, delirium, decreased mobility
	Anticholinergics (dicyclomine, disopyramide, sedating antihistamines, antipsychotics, tricyclic antidepressants, cyclobenzaprine, anti-Parkinson, antidepressants [not SSRIs])	Urinary retention, overflow incontinence, delirium, impaction; the antipsychotics also decrease mobility
	Opiates	Urinary retention, stool impaction, sedation, delirium
	α-Adrenergic antagonists	Relax sphincter; may induce stress incontinence in women
	α-Adrenergic agonists	Urinary retention in men (tighten sphincter, prostate)
	Calcium-channel blockers, especially the dihydropyridines	Nocturnal diuresis due to fluid retention
	"Loop" diuretics (thiazide-like agents only rarely cause it)	Polyuria, frequency, urgency
	NSAIDs	Nocturnal diuresis due to fluid retention
	Thiazolidinediones	Nocturnal diuresis due to fluid retention
	Some nociceptives (gabapentin, pregabalin)	Nocturnal diuresis due to fluid retention; sedation; delirium
	Dopamine receptor agonists (e.g., ropinirole, pramipexole)	Nocturnal diuresis due to fluid retention
	Angiotensin-converting enzyme inhibitors	Drug-induced cough leads to stress incontinence in women
	Vincristine	Urinary retention due to neuropathy
	Cholinesterase inhibitors	Urinary incontinence
Excess urine output	From large intake, diuretic agents (caffeinated beverages, alcohol), and metabolic disorders (hyperglycemia, hypercalcemia); nocturnal incontinence may result from obstructive sleep apnea or mobilization of peripheral edema (heart failure, venous insufficiency, side effects of medications)	
Restricted mobility	Often results from overlooked, correctable conditions such as arthritis, pain, foot problems, postprandial hypotension, or fear of falling	
Stool impaction	May cause both fecal and urinary incontinence that remit with disimpaction	

NSAIDs = nonsteroidal anti-inflammatory drugs; SSRI = selective serotonin reuptake inhibitor; UTI = urinary tract infection.
Adapted from Resnick NM, Tadic SD, Yalla SV. Geriatric incontinence and voiding dysfunction. In: Wein AJ, Novick AC, Partin AW, et al, eds. *Campbell-Walsh Urology*, 10th ed. St. Louis: Elsevier; 2012.

insufficient urethral support plus some degree of sphincter weakness. Obese women are more likely to progress to mixed incontinence over time.[7] Stress incontinence is rare in men but can result from sphincter damage following radical, but not transurethral, prostatectomy.

Urethral Obstruction

Urethral obstruction is the second most common cause of established incontinence in older men, although most obstructed men are not incontinent. When obstruction is associated with incontinence, it usually presents as urge incontinence owing to the associated detrusor overactivity; overflow incontinence is uncommon. Outlet obstruction is rare in women but may result from a bladder neck suspension or from urethral kinking associated with a large cystocele.

Detrusor Underactivity

Detrusor underactivity is usually idiopathic. When it causes incontinence, it is associated with overflow incontinence (<10% of incontinence).

Damaged Innervation

Damage to lower urinary tract innervation can cause several types of dysfunction. A brain lesion may cause detrusor overactivity. A spinal cord lesion (Chapters 175 and 369) above the sacral level can cause both detrusor overactivity and detrusor-sphincter dyssynergia, a condition in which the sphincter contracts rather than relaxes during detrusor contraction; the result can be severe outlet obstruction and hydronephrosis. A spinal cord lesion below the sacral level can cause detrusor underactivity, sphincter weakness, or both. Peripheral and autonomic nerve damage can cause still additional problems, such as decreased bladder emptying and sensation in postural tachycardia syndrome.[8] Thus, because *neurogenic bladder* is such a nonspecific term, it is preferable to refer to the specific dysfunction causing incontinence.

Causes of Incontinence Unrelated to the Lower Urinary Tract (Functional Incontinence)

"Functional" incontinence, which is often cited as a distinct type of geriatric incontinence and attributed to deficits of cognition and mobility, implies that urinary tract function is normal. However, normal urinary tract function is the exception, even in continent elderly people, and is rarely observed in incontinent elderly people. Moreover, incontinence is not inevitable, even with dementia or immobility. Among the most severely demented institutionalized residents, nearly 20% are continent; among those who can transfer from a bed to a chair, nearly half are continent. Functionally impaired individuals also are the most likely to suffer from factors that cause transient incontinence, and a diagnosis of functional incontinence may result in failure to detect these reversible causes. Finally, if functionally impaired individuals also have urethral obstruction or stress incontinence, they may benefit from targeted therapy. Nonetheless, functional impairment often contributes to incontinence, and addressing its causes and those of transient incontinence may ameliorate incontinence sufficiently to obviate the need for further investigation.

CLINICAL MANIFESTATIONS

The manifestations of transient incontinence depend on the underlying condition. Occasionally, patients present with incontinence that is more difficult to characterize clinically without further testing.

Detrusor Overactivity

Detrusor overactivity usually manifests as *urge incontinence*, characterized by leakage that follows the *abrupt* onset or intensification of a desire to void and the leakage of a moderate to large amount of urine. Urinary frequency (>8 voids/day) and nocturia are also frequently present. Some patients with detrusor overactivity may present with precipitant leakage without urgency symptoms.

Detrusor overactivity exists as two subsets in elderly people: one in which contractile function is preserved and one in which it is impaired. The latter condition, termed *detrusor hyperactivity with impaired contractility*, has several implications. First, because the bladder is weak, these patients may develop urinary retention, which can mimic that seen in patients with outlet obstruction and detrusor underactivity. Second, even in the absence of retention, detrusor hyperactivity with impaired contractility mimics other lower urinary tract causes of incontinence. For instance, if the involuntary detrusor contraction occurs coincident with a stress maneuver and if the weak contraction is not detected, detrusor hyperactivity with impaired contractility will be misdiagnosed as stress incontinence. Alternatively, because detrusor hyperactivity with impaired contractility may be associated with urinary urgency, frequency, weak flow rate, elevated residual urine (e.g., >150 mL), and bladder trabeculation, in men, it may mimic prostatic obstruction. Third, use of a bladder relaxant for detrusor hyperactivity with impaired contractility may result in urinary retention owing to bladder weakness, thereby requiring a lower dose or an alternative therapeutic approach.

Stress Incontinence and Mixed Incontinence

Stress incontinence is leakage that coincides *instantaneously* with both the onset and cessation of a cough or other cause of increased abdominal pressure; nocturnal leakage is rare. Some women report both urge and stress incontinence, termed *mixed incontinence*. To plan treatment, it is useful to determine which component is the most bothersome. In men with sphincter damage following radical prostatectomy, leakage resembles the intermittent drip of a leaky faucet.

DIAGNOSIS

Older persons in particular should be screened for incontinence. In addition to a targeted clinical evaluation (Table 115-2),[9,10] a bladder diary can provide diagnostic clues and guide therapy (E-Fig. 115-1). For example, incontinence occurring only between 8 AM and noon may be caused by a morning loop diuretic. Incontinence that occurs at night in a demented man with heart failure, but not during a 4-hour nap in his wheelchair, is likely due to nocturnal diuresis associated with his heart failure and not to dementia, impaired mobility, or prostatic obstruction. A woman with volume-dependent stress incontinence may leak only on the way to void after a full night's sleep, when her bladder contains more than 400 mL—more than it ever does during her continent waking hours.

Because urinary retention is difficult to detect by examination and can affect diagnosis and therapy, the postvoid residual volume usually should be determined, except in a middle-aged woman who desires only behavioral therapy for a classic presentation of stress incontinence.[11,12] Urodynamic testing is generally recommended only when diagnostic certainty is required or before nonroutine surgery (not required prior to most surgery for uncomplicated stress incontinence) or if there is evidence of a serious underlying cause of the incontinence, such as a brain or spinal cord lesion, or hydronephrosis. Urodynamic evaluation comprises a battery of tests designed to assess the lower urinary tract during the filling and voiding phases of micturition. The selection among tests depends on the clinical setting and question to be answered; for instance, measuring detrusor pressure and urine flow during voiding can determine whether urethral obstruction is present, whereas monitoring bladder and urethral pressures during the filling phase and with coughing may be helpful for patients with an atypical presentation of mixed incontinence.

TABLE 115-2 CLINICAL EVALUATION OF URINARY INCONTINENCE

HISTORY
Symptom type (urge, stress, overflow, or mixed)
Incontinence frequency, severity, and duration
Pattern (diurnal, nocturnal or both; also, e.g., after taking medications)
Precipitants
Associated symptoms (straining to void, incomplete emptying, dysuria, hematuria, suprapubic/perineal discomfort or numbness)
Alteration in bowel habit/sexual function (because of proximity to the bladder and shared innervation)
Other relevant factors (cancer, acute illness, neurologic disease, pelvic or lower urinary tract surgery/radiation therapy
Medications, including nonprescription agents (see Table 115-1)
PHYSICAL EXAMINATION
General examination to identify and/or assess relevant medical conditions (e.g., heart failure, peripheral edema)
Brief assessment of cognitive and physical function (e.g., MiniCog, Get Up and Go [see Chapters 361 and 371])
If stress incontinence is suspected, determine whether leakage *coincides* with the onset *and* cessation of a single, forceful cough
Palpate for bladder distention after voiding
Pelvic examination to detect atrophic vaginitis, lichen sclerosis, mass, prolapse (if beyond the vagina, there is increased risk for urinary retention)
Rectal examination for skin irritation, resting tone and voluntary control of anal sphincter, prostate nodule; fecal impaction (*note:* prostate size correlates poorly with presence of urethral obstruction)
Neurologic examination, especially mental status and elemental examination, including sacral reflexes and perineal sensation
INITIAL INVESTIGATION
Bladder diary (see E-Fig. 115-1)
Metabolic survey (electrolytes, calcium, glucose, and urea nitrogen as appropriate)
Measure postvoid residual volume, by portable ultrasound if available
Urinalysis to detect sterile hematuria or infection; culture if new-onset or worsening incontinence
Renal ultrasound to detect hydronephrosis in men whose postvoid residual volume urine exceeds about 200 mL
Urine cytology for patients with hematuria, pain, or unexplained new-onset or worsening incontinence
Uroflowmetry for men in whom urethral obstruction is suspected
Cystoscopy for patients with hematuria, suspicion of lower urinary tract pathology (e.g., bladder fistula, stone, or tumor; urethral diverticulum), or need for lower urinary tract surgery

Adapted from Resnick NM, Yalla SV. Management of urinary incontinence in the elderly. *N Engl J Med.* 1985;313:800-805.

TREATMENT

Optimal therapy requires a multifactorial approach (Table 115-3), including treatment of any associated causes, underlying medical conditions, functional impairments, fluid intake, and the urinary tract abnormality itself.[13] Treatment of the precipitants alone may be sufficient to restore continence, even if there is coexisting urinary tract dysfunction. For example, a flare of hip arthritis in a woman with age-related detrusor overactivity may decrease mobility sufficiently to convert her urinary urgency into incontinence. Treatment of the arthritis, rather than the involuntary detrusor contractions, will not only restore continence but also lessen pain and improve mobility. Because of their frequency, reversibility, and association with morbidity beyond incontinence, any transient causes (see Table 115-1) should be addressed first.

Although pads and diapers have a role, they remain an adjunct to more specific therapy. Urinary catheters should rarely be used for chronic incontinence because of the high risk of urinary tract infection (Chapter 263).

Lifestyle Interventions

Lifestyle interventions include education, self-monitoring with a bladder diary, adjustment of fluid and caffeine intake, weight loss for overweight women with stress incontinence, smoking cessation, and use of aids (e.g., a bedside urinal).[A1] Phone-based apps also show promise for the self-management of urge and mixed incontinence.[A2] Helpful online resources are available for patients.[14–16]

Behavioral Therapy

Behavioral therapy[17] includes pelvic muscle exercises and bladder retraining (progressively increasing voiding intervals, strategies to cope with urgency).[A3] For each option, group education is an effective alternative to individual instruction.[A4]

For stress incontinence, pelvic muscle exercises are effective but less so than surgery,[A5] and combining the two does not enhance efficacy.[A6] Acupuncture[A7] and pessaries[18] can also be effective.

For urge incontinence, behavioral therapy is as effective as pharmacotherapy. However, combining the two is more effective than either alone[A8] because neither therapy generally abolishes involuntary bladder contractions.

For institutionalized patients who are cognitively impaired but can state their name and are partly mobile, regular daytime reminders to void ("prompted voiding") have proved effective for daytime incontinence. Wet checks and protective garments are appropriate for the others.[A9]

Pharmacotherapy

Currently approved drugs have not proved effective for stress incontinence or overflow incontinence. For urge incontinence, several bladder relaxants are modestly and equally effective (Table 115-4), including in vulnerable older patients.[A10] All anticholinergic agents can cause dry mouth, constipation, and visual blurring, with some variation among agents. Their use can also be associated with short- and long-term cognitive impairment, although this complication appears to be very uncommon.[19] Nevertheless, each may be well tolerated, even in cognitively impaired elderly patients, when they are prescribed properly and cognitive status is monitored. Patients who are taking a cholinesterase inhibitor, which can cause incontinence, have three options: delay intervention because the incontinence will often subside, reconsider the benefits of continued cholinesterase treatment, or consider adding a non-anticholinergic agent.

The choice among these drugs may also depend on other considerations. For instance, immediate-release oxybutynin has the quickest onset of action, thereby making it an inexpensive and effective choice for patients who need control at predictable times. Other drugs, although more expensive, can be used less often and can be better tolerated for daily use.

The β_3-adrenergic agonists mirabegron[A11] and vibegron have efficacy similar to the anticholinergic agents and may be preferable when there is concern for anticholinergic or cognitive adverse effects. If needed, mirabegron also may be combined with an anticholinergic for improved efficacy. Desmopressin should be avoided in older persons due to the risk of severe hyponatremia.

Ultimately, the choice of medication should depend on ease of use, cost, and avoidance of adverse effects in an individual patient. Regardless of the drug

Date	Time	Volume Voided (mL)	Are You Wet or Dry?	Approximate Volume of Incontinence	Comments
4/5	3:40 pm	240	Wet	Slight	
	6:05 pm	210	Dry		
	8:15 pm	150	Dry		Running water
	10:20 pm	150	Wet	15 mL	Bowel movement
	10:30 pm	30	Dry

	10:25 pm	130	Dry		

E-FIGURE 115-1. Sample bladder diary. Bladder diary of an incontinent 75-year-old man. Urodynamic evaluation excluded urethral obstruction and confirmed a diagnosis of detrusor hyperactivity with impaired contractility. Note the 24-hour urine output of nearly 3 liters due to the belief that drinking 10 glasses of fluid per day was "good for my health." (He did not mention this until queried about the voiding record.) Given the typical voided volume of 150 to 250 mL and a measured postvoid residual of 150 mL, excess fluid intake was overwhelming his usual bladder capacity of 400 mL (150 + 250 mL). Although involuntary bladder contractions were present, the easily reversible volume component of the problem, combined with the risk for precipitating urinary retention with an anticholinergic agent, prompted treatment with volume restriction alone. After daily urinary output dropped to 1500 mL, frequency abated, and incontinence resolved. (Adapted from DuBeau CE, Resnick NM. Evaluation of the causes and severity of geriatric incontinence: a critical appraisal. *Urol Clin North Am*. 1991;18:243-256.)

selected, the key is to begin with a low dose and increase it slowly, realizing that full benefit may not apparent be for 2 to 3 months and that adverse effects may offset the benefit. With such titration, urge incontinence can be controlled in about one third of patients and substantially improved in another one third. Success rates are lower in patients with moderate-severe dementia.

For urinary incontinence in the setting of atrophic vaginitis, a 3- to 12-month course of topical estrogen can be useful, although oral estrogen can worsen incontinence.[A12]

Surgical Procedures

Stress Incontinence

For women with stress incontinence or stress-predominant mixed incontinence, surgery has proved effective and relatively durable at all ages. Periurethral bulking injection can help frail women or those with mild stress incontinence, but it does not generally restore continence.[20] However, urethral sling and mid-urethral tape suspension procedures can cure most women for at least 5 years. For women with more complex stress incontinence and women who have adequate cognitive and functional capacity, an artificial sphincter can be moderately effective, although experience is still limited.

Urge Incontinence

For urge incontinence, surgical intervention, including neuromodulation,[21] tibial nerve stimulation,[22] and injections of onabotulinum toxin,[A13] are third-line agents. Limited available data suggest that their efficacy may be only modestly better than the efficacy of pharmacotherapy and that older patients may not fare as well as younger ones. Older patients treated with onabotulinum toxin also are more likely to develop urinary retention and urinary tract infections.

Issues Specific to Men

Apart from atrophic vaginitis, the transient causes of incontinence in men are the same as in women. However, owing to the frequency of prostate enlargement, urinary retention occurs more often in the setting of conditions that suppress detrusor contractility (e.g., fecal impaction) or use of drugs such as anticholinergics, α-adrenergic agonists, and opiates. Urge incontinence is equally common in men as in women, but it may be associated with an obstructive prostate. Therapeutic considerations for incontinence related to prostatic hypertrophy include α-adrenergic agonists and 5-α reductase inhibitors, as well as prostate surgery (see Table 115-3, Fig. 114-3, and Table 114-1). Antimuscarinics and mirabegron (both used in combination with an α-blocker) are also helpful. Botulinum toxin may be useful as well, but it appears to be less effective than in women.[A14] Stress incontinence is rare in men unless they have undergone radical (not transurethral) prostatectomy for carcinoma.[23] In such cases, anti-incontinence surgery, such as a male sling operation or creation of an artificial urinary sphincter, is moderately successful[A15] but is usually reserved for incontinence that is moderate to severe and persists for more than a year in men who otherwise have a good prognosis. As in women, overflow incontinence is uncommon but, when present, in men it is more likely due to obstruction.

PREVENTION

Data suggest that group- or community-based education and behavioral modification programs may be helpful in older women. Weight loss can reduce the risk for stress incontinence.[24]

TABLE 115-3 STEPWISE APPROACH TO TREATMENT OF URINARY INCONTINENCE*

CONDITION	CLINICAL TYPE OF INCONTINENCE†	TREATMENT
Detrusor overactivity with normal contractility	Urge	1. Bladder retraining or prompted voiding regimens. 2. ± Bladder relaxant medication if needed and not contraindicated (see Table 115-4). If treatment fails, consider posterior tibial neurostimulation, sacral neuromodulation, or intradetrusor injection of onabotulinumtoxinA. 3. Indwelling catheterization alone is often unhelpful because detrusor spasms often increase, leading to leakage around the catheter. 4. In selected cases, induce urinary retention pharmacologically and add intermittent or indwelling catheterization.‡
Detrusor hyperactivity with impaired contractility	Urge§	1. If bladder empties adequately, behavioral methods (as above) ± bladder relaxant medication (low doses; especially feasible if sphincter incompetence coexists). 2. If residual urine >150 mL, augmented voiding techniques¶ or intermittent catheterization (± bladder relaxant medication). If neither is feasible, undergarment or indwelling catheter.‡ 3. In selected cases, induce urinary retention pharmacologically and add intermittent or indwelling catheterization.‡
Stress incontinence	Stress	1. Conservative methods (weight loss if obese; treatment of cough or atrophic vaginitis; physical maneuvers to prevent leakage [e.g., tighten pelvic muscles before cough, cross legs]; occasionally, use of tampon or pessary is helpful). 2. If leakage threshold ≥150 mL identified, adjust fluid excretion and voiding intervals appropriately. 3. Pelvic muscle exercises ± biofeedback/weighted intravaginal cones; must continue indefinitely. 4. Surgery (sling, artificial sphincter, periurethral bulking injections).
Urethral obstruction (see Chapter 114)	Urge/overflow‖	1. Conservative methods (including adjustment of fluid excretion, bladder retraining/prompted voiding) if hydronephrosis, recurrent symptomatic UTI, and hematuria have been excluded. 2. α-Adrenergic antagonist (α_{1a} specific may be better tolerated in patients with orthostatic hypotension). 3. Also consider adding a bladder relaxant if detrusor overactivity coexists, postvoid residual volume is small, and surgery is not desired/feasible; *monitor postvoid residual volume!* 4. 5-α Reductase inhibitor, if not contraindicated and the patient either prefers it or is not a surgical candidate; clinical benefit takes months. 5. Surgery (incision, prostatectomy) is an effective alternative before or after these steps.
Underactive detrusor	Overflow	1. Decompress for at least several days (the larger the postvoid residual volume, the longer should be the decompression [up to a month]) and then perform a voiding trial. 2. Exclude urethral obstruction if this has not already been done. 3. If cannot void or if postvoid residual volume remains large, try augmented voiding techniques¶ ± α-adrenergic antagonist but only if some voiding possible; bethanechol *rarely* useful. 4. If fails or voiding is not possible, intermittent or indwelling catheterization.‡

*These treatments should be initiated only after adequate toilet access has been ensured, contributing conditions have been treated (e.g., atrophic vaginitis, UTI, fecal impaction, heart failure), fluid management has been optimized, and unnecessary or exacerbating medications have been addressed. For additional details, see text.

†*Urge:* leakage in the absence of stress maneuvers and urinary retention, usually preceded by *abrupt* onset or intensification of the need to void; stress: leakage that coincides instantaneously with stress maneuvers, in the absence of urinary retention or detrusor contraction; overflow: frequent leakage of small amounts associated with urinary retention.

‡UTI prophylaxis can be used for recurrent symptomatic UTIs but only if catheter is not indwelling.

§May also mimic stress or overflow incontinence.

‖Also can cause postvoid "dribbling" alone, which is treated conservatively (e.g., by sitting to void and allowing more time, "double voiding," and in men by gently "milking" the urethra after voiding).

¶Augmented voiding techniques include Credé (application of suprapubic pressure) and Valsalva (straining) maneuvers and double voiding. They should be performed only after voiding has begun.

UTI = urinary tract infection.

TABLE 115-4 BLADDER RELAXANT AGENTS FOR URGE INCONTINENCE

- Anticholinergic
  - Oxybutynin IR, 7.5-20 mg daily (2.5-5 mg three or four times daily; doses >2.5 mg four times daily can be problematic and rarely helpful); oxybutynin XL, 5-30 mg once daily; oxybutynin patch (3.9 mg/day) twice weekly; oxybutynin 10% gel (1 g topically once per day)
  - Tolterodine, 1-2 mg twice daily; tolterodine LA, 4 mg once daily
  - Darifenacin, 7.5-15 mg once daily
  - Solifenacin, 5-10 mg once daily
  - Trospium, 20 mg daily to twice daily; 60 mg (extended release) once daily
  - Fesoterodine, 4-8 mg once daily
- β_3-Adrenergic agonist
  - Mirabegron, 25-50 mg once daily
  - Vibegron 75 mg daily

PROGNOSIS

Incontinence is associated with sexual dysfunction and other adverse effects on quality of life.[25] Limited data suggest that incontinence progresses in about one third of patients and remits in about 10 to 15%, although it is unclear how much of the remission reflects intervention or improvement in functional or medical status.

116 CHRONIC KIDNEY DISEASE

ANDREW S. LEVEY AND MARK J. SARNAK

Chronic kidney disease represents a heterogeneous group of disorders that become increasingly common as the population ages. Diabetes (Chapter 210), hypertension (Chapter 64), and autoimmune glomerular diseases (Chapter 107) are the most common causes of chronic kidney disease worldwide, but systemic infections, drug toxicity, and environmental exposures are important causes in selected populations. Irrespective of the cause, many kidney diseases follow a progressive course and cause complications in virtually every organ system. In patients in whom the rate of disease progression is fast or life expectancy is long, the disease may culminate in kidney failure that leads to uremia and death.

DEFINITION

Chronic kidney disease is defined as the presence of either a marker of kidney damage, such as more than 30 mg/day of albuminuria, or a glomerular filtration rate less than 60 mL/min/1.73 m^2 for 3 or more months.[1] The threshold value for albuminuria reflects a more than three-fold elevation above the normal value of 5 to 10 mg/day, whereas the threshold glomerular filtration rate reflects a more than 50% reduction below the normal value of approximately 125 mL/min/1.73 m^2. Irrespective of age, both of these abnormalities are associated with an increased risk of progressive kidney disease, altered metabolism and excretion of many drugs by the kidney, complications, and death (E-Fig. 116-1).[2]

EPIDEMIOLOGY

The prevalence of chronic kidney disease in U.S. adults is approximately 11.5% (Fig. 116-1), including approximately 4.7% of the population that has increased albuminuria with a glomerular filtration rate greater than 60 mL/min/1.73 m^2 (stages G1 and G2) and 6.8% of the population that has a glomerular filtration rate less than 60 mL/min/1.73 m^2 (stages G3 to G5). The glomerular filtration rate declines by an average rate of approximately 1 mL/min/1.73 m^2 per year after about age 40 years, but with a wide range among individuals. The cause of the decline with age is not well understood, but the decline may be due to senescence, kidney disease, or both. Irrespective of cause, 25% of individuals in the United States have a glomerular filtration rate less than 60 mL/min/1.73 m^2 by age 70 years and older.

In the United States, an estimated 800,000 or so individuals, equivalent to about 0.25% of the population, have kidney failure (stage G5) and require kidney replacement therapy with dialysis or transplantation (Chapter 117), and this prevalence has been rising by approximately 20,000 per year due to the growth and aging of the population.[3] The age-adjusted incidence of the initiation of kidney replacement therapy has been declining, however, perhaps related to better and earlier management. Unfortunately, the rising prevalence of obesity may increase incidence of kidney failure in future years because of the earlier onset of diabetes and hypertension.

The worldwide prevalence of kidney disease in adults and children is estimated to be about 9%, or about 700 million people.[4] About 30% of chronic kidney disease is attributed to diabetes. The annual mortality from chronic kidney disease is about 1.2 million owing to kidney failure itself and 1.4 million owing to an increased incidence of cardiovascular disease, thereby representing about 4.6% of total mortality and making it the twelfth leading worldwide cause of death. The disability-adjusted life years lost vary widely among regions of the world (E-Fig. 116-2). The risk for chronic kidney disease is associated with increased susceptibility (e.g., old age, family history, history of acute kidney disease, member of ethnic or racial minority in the United States, reduced nephron mass because of low birthweight or a prior partial or complete nephrectomy), or with exposure to conditions that cause chronic kidney disease, such as diabetes and hypertension [Table 116-1]). Chronic kidney disease is more common in older, male, Black, and Hispanic individuals in the United States.[5]

116 CHRONIC KIDNEY DISEASE

ANDREW S. LEVEY AND MARK J. SARNAK

Chronic kidney disease represents a heterogeneous group of disorders that become increasingly common as the population ages. Diabetes (Chapter 210), hypertension (Chapter 64), and autoimmune glomerular diseases (Chapter 107) are the most common causes of chronic kidney disease worldwide, but systemic infections, drug toxicity, and environmental exposures are important causes in selected populations. Irrespective of the cause, many kidney diseases follow a progressive course and cause complications in virtually every organ system. In patients in whom the rate of disease progression is fast or life expectancy is long, the disease may culminate in kidney failure that leads to uremia and death.

DEFINITION

Chronic kidney disease is defined as the presence of either a marker of kidney damage, such as more than 30 mg/day of albuminuria, or a glomerular filtration rate less than 60 mL/min/1.73 m^2 for 3 or more months.[1] The threshold value for albuminuria reflects a more than three-fold elevation above the normal value of 5 to 10 mg/day, whereas the threshold glomerular filtration rate reflects a more than 50% reduction below the normal value of approximately 125 mL/min/1.73 m^2. Irrespective of age, both of these abnormalities are associated with an increased risk of progressive kidney disease, altered metabolism and excretion of many drugs by the kidney, complications, and death (E-Fig. 116-1).[2]

EPIDEMIOLOGY

The prevalence of chronic kidney disease in U.S. adults is approximately 11.5% (Fig. 116-1), including approximately 4.7% of the population that has increased albuminuria with a glomerular filtration rate greater than 60 mL/min/1.73 m^2 (stages G1 and G2) and 6.8% of the population that has a glomerular filtration rate less than 60 mL/min/1.73 m^2 (stages G3 to G5). The glomerular filtration rate declines by an average rate of approximately 1 mL/min/1.73 m^2 per year after about age 40 years, but with a wide range among individuals. The cause of the decline with age is not well understood, but the decline may be due to senescence, kidney disease, or both. Irrespective of cause, 25% of individuals in the United States have a glomerular filtration rate less than 60 mL/min/1.73 m^2 by age 70 years and older.

In the United States, an estimated 800,000 or so individuals, equivalent to about 0.25% of the population, have kidney failure (stage G5) and require kidney replacement therapy with dialysis or transplantation (Chapter 117), and this prevalence has been rising by approximately 20,000 per year due to the growth and aging of the population.[3] The age-adjusted incidence of the initiation of kidney replacement therapy has been declining, however, perhaps related to better and earlier management. Unfortunately, the rising prevalence of obesity may increase incidence of kidney failure in future years because of the earlier onset of diabetes and hypertension.

The worldwide prevalence of kidney disease in adults and children is estimated to be about 9%, or about 700 million people.[4] About 30% of chronic kidney disease is attributed to diabetes. The annual mortality from chronic kidney disease is about 1.2 million owing to kidney failure itself and 1.4 million owing to an increased incidence of cardiovascular disease, thereby representing about 4.6% of total mortality and making it the twelfth leading worldwide cause of death. The disability-adjusted life years lost vary widely among regions of the world (E-Fig. 116-2). The risk for chronic kidney disease is associated with increased susceptibility (e.g., old age, family history, history of acute kidney disease, member of ethnic or racial minority in the United States, reduced nephron mass because of low birthweight or a prior partial or complete nephrectomy), or with exposure to conditions that cause chronic kidney disease, such as diabetes and hypertension [Table 116-1]). Chronic kidney disease is more common in older, male, Black, and Hispanic individuals in the United States.[5]

ABSTRACT

Chronic kidney disease can be caused by a wide spectrum of kidney diseases, including diabetes, hypertension, autoimmune conditions, systemic infections, drug toxicity, and environmental exposure as well as by inherited diseases or obstructive uropathy. The signs (e.g., hypertension, fluid overload), symptoms (e.g., fatigue, loss of appetite), and laboratory findings (e.g., acidosis, hyperkalemia) of chronic kidney disease are principally related to the level of the glomerular filtration rate and the degree of albuminuria rather than to the underlying cause. Cause-specific treatments are often helpful, and treatments related to the level of glomerular filtration rate and the degree of albuminuria can slow the progression of disease, independent of its cause. In patients who have hypertension, whether it is the cause or a complication of chronic kidney disease, systolic blood pressure should be lowered to <130 mm Hg, and patients who have albuminuria should initially receive an angiotensin receptor blocker or angiotensin-converting enzyme inhibitor, with careful monitoring of their serum potassium level. Sodium glucose cotransporter-2 inhibitors can slow the rate of progression of chronic kidney disease and have become a cornerstone of therapy except in patients who have type 1 diabetes. In patients who have type 2 diabetes and albuminuria, glucagon-like peptide 1 agonists and mineralocorticoid receptor antagonists are additional options to slow the progression of chronic kidney disease. Dialysis and kidney transplantation are effective treatments for kidney failure when the complications cannot be controlled and begin to compromise quality of life or survival.

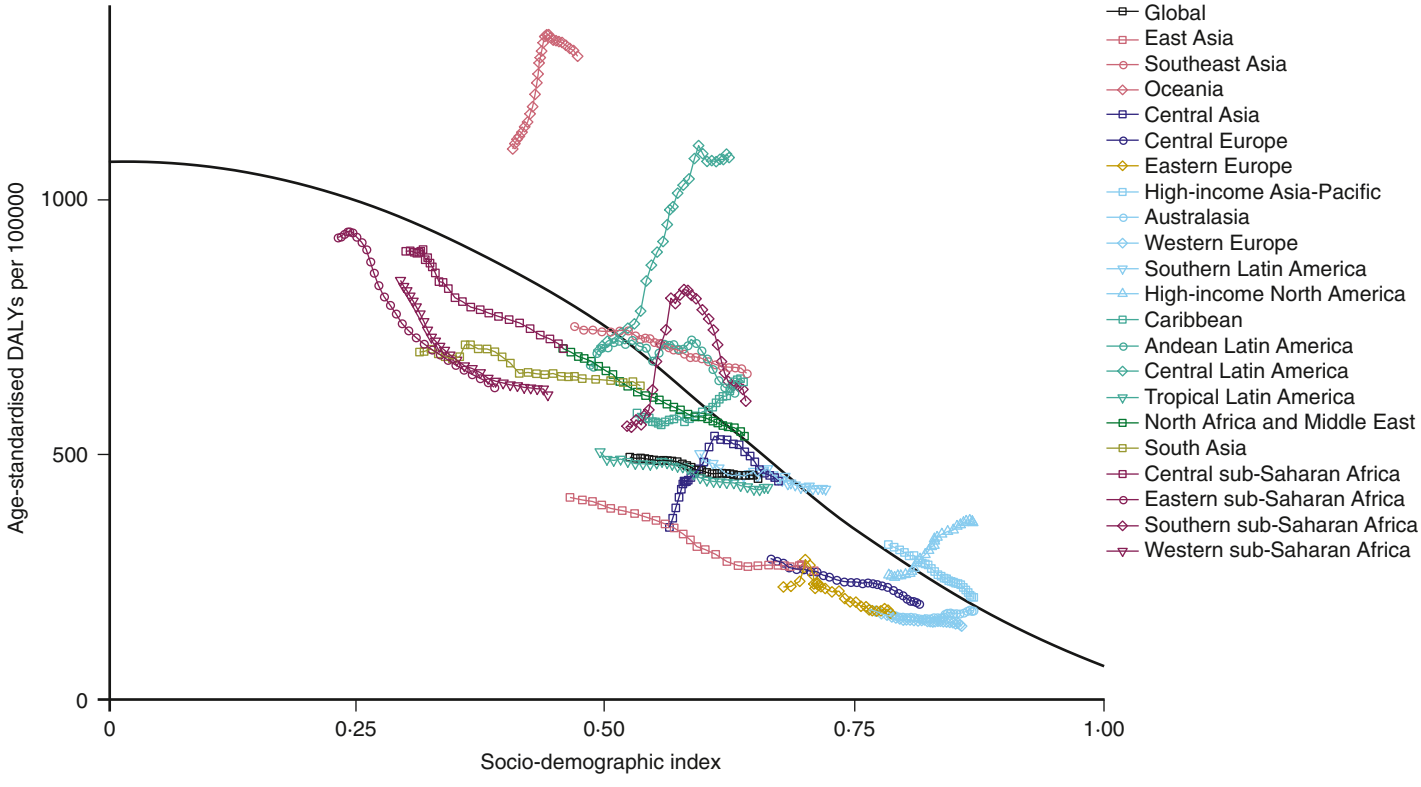
E-FIGURE 116-1. Conceptual model for chronic kidney disease. The diagram presents the continuum of development, progression, and complications of chronic kidney disease (CKD) and strategies to improve outcomes. Green represents stages of CKD; blue represents potential antecedents of CKD; purple represents consequences of CKD. *Horizontal arrows* represent the development, progression, and remission of CKD. *Arrows* pointing from left to right emphasize the progressive nature of CKD. *Dashed arrowheads* pointing from right to left signify that remission is less frequent than progression. *Diagonal arrows* represent complications, referring to conditions that occur more commonly in patients with vs. without CKD. Complications may also arise from adverse effects of interventions to prevent or treat the disease. CKD = chronic kidney disease; GFR = glomerular filtration rate. (From Levey AS. A decade after the KDOQI CKD guidelines. *Am J Kidney Dis*. 2012;60:683-685.)



E-FIGURE 116-2. Age-standardized rate of disability-adjusted life years for chronic kidney disease for 21 world regions according to the sociodemographic index, 1990–2017. *Solid black line* shows expected values for disability-adjusted life years across the spectrum of the sociodemographic index. DALY = disability-adjusted life-year (the sum of years of life lost to death and disability). (From Bikbov B, Purcell CA, Levey AS, et al. Global, regional, and national burden of chronic kidney disease, 1990-2017: a systematic analysis for the Global Burden of Disease Study 2017. *Lancet*. 2020;395:709-733.)

Stages of the Glomerular Filtration Rate (mL/min/1.73m^2)		Stages of Albuminuria (description and range)		
		A1	A2	A3
		normal to mildly increased	moderately increased	severely increased
		<30 mg/g <3 mg/mmol	30-299 mg/g 3-29 mg/mmol	≥300 mg/g ≥30 mg/mmol
	G1, normal or high, >90	56%	2%	0.4%
	G2, mildly decreased, 60-89	33%	2%	0.3%
	G3, mildly to moderately decreased, 45-59	4%	0.8%	0.2%
	G3b, moderately to severely decreased, 30-44	1.0%	0.4%	0.2%
	G4, severely decreased, 15-29	0.2%	0.1%	0.1%
	G5, kidney failure, <15	0%	0%	0.1%

FIGURE 116-1. Approximate percentage of the U.S. population by glomerular filtration rate and albuminuria. For population studies, chronic kidney disease is generally defined as albuminuria greater than 30 mg/day or a decreased glomerular filtration rate (<60 mL/min/1.73 m^2). The prevalence of chronic kidney disease in U.S. adults is 11.5%, which is the rounded sum of all shaded cells. Albuminuria stages A_2 and A_3 correspond to microalbuminuria and macroalbuminuria, respectively. Albuminuria stage A3 includes nephrotic-range albuminuria (greater than about 2000 mg/day). Albuminuria (in mg/day) equals albuminuria (in mg/g) if the urinary creatinine excretion equals 1.0 g/day. For albuminuria: 1.0 mg/g = 0.113 mg/mmol. GFR = glomerular filtration rate. Prognosis is color coded: white = low risk; yellow = moderately increased risk; orange = high risk; red = very high risk. (Modified from Kidney Disease: Improving Global Outcomes [KDIGO]. KDIGO 2012 clinical practice guideline for the evaluation and management of chronic kidney disease. *Kidney Int Suppl*. 2013;3:1-150 and based on data from the National Health and Nutrition Examination Survey [NHANES] 1999-2006.)

Causes of kidney disease are classified according to the site of pathologic findings (e.g., glomerular, tubulointerstitial, vascular, and cystic and congenital diseases that affect multiple sites), as well as the presence or absence of systemic disease affecting the kidney. Among older adults, diabetes and hypertension are the most common causes in Europe and North America, whereas congenital anomalies of the kidney and urinary tract (Chapter 113) and glomerular diseases (Chapter 107) are more common in children and young adults. Autoimmune glomerular diseases are also common in East Asia (Chapter 107). Chronic infections causing glomerular and interstitial diseases are more common in low- and middle-income nations. Tubulointerstitial diseases are known to be endemic in certain areas due to exposure to aristolochic acid, heavy metals, fine particulate matter, or extremes of heat and agricultural work (Chapter 108). An important risk factor in people of West African ancestry is inheritance of two of the G1 or G2 variants of *APOL1*, likely reflective of a selective advantage from resistance to *Trypanosoma brucei*,[6] which confers an approximately four-fold greater risk of kidney failure.

PATHOBIOLOGY

Irrespective of the initial mechanism, most kidney diseases progress through a final common pathway that culminates in pathologic features of glomerular, interstitial, and vascular sclerosis in which tubular atrophy coexists with glomerular and tubular hypertrophy and the formation of cysts. These pathologic changes result in a progressive increase in albuminuria and a decline in the glomerular filtration rate.

In health, proteinuria is minimal because of low permeability of the glomerular capillary wall to high-molecular-weight plasma proteins and the efficient receptor-mediated tubular reabsorption of filtered low-molecular-weight plasma proteins (Fig. 116-2).[7] The normal urine protein excretion rate and albumin excretion rate are generally less than 50 and 10 mg/day, respectively. Proteinuria can be classified by increased glomerular permeability to macromolecules (glomerular; Chapter 107), decreased tubular reabsorption of filtered proteins (tubular; Chapter 108) due to disorders of tubular epithelium; or increased filtered load of low-molecular-weight proteins, such as immunoglobulin light chains. Regardless of the cause, the presence of albumin and other macromolecules in glomerular filtrate may be associated with progressive tubular and interstitial damage, thereby contributing to the subsequent decline in glomerular filtration rate.

Large increases in albuminuria (greater than approximately 2.0 g/day, corresponding to proteinuria above approximately 3.5 g/day) can give rise to nephrotic syndrome (Chapter 107), with a decreased serum albumin level, edema, hypercholesterolemia, and hypercoagulability (Table 116-2). Loss of albumin in the urine lowers plasma oncotic pressure, thereby resulting in redistribution of plasma to the interstitial space, increased renal tubular reabsorption of sodium chloride and water, and retention of extracellular fluid (Chapter 107). Decreased oncotic pressure stimulates increased production of plasma proteins by the liver, including apolipoproteins, thereby leading to hyperlipidemia. The urinary loss of anticoagulant proteins (e.g., antithrombin,

TABLE 116-1 CAUSES OF CHRONIC KIDNEY DISEASE

	EXAMPLES OF SYSTEMIC DISEASES AFFECTING THE KIDNEY	EXAMPLES OF PRIMARY KIDNEY DISEASE (ABSENCE OF SYSTEMIC DISEASES AFFECTING THE KIDNEY)
Glomerular diseases (Chapter 107)	Diabetes (Chapter 210), obesity (Chapter 201), systemic autoimmune diseases (systemic lupus erythematosus [Chapter 245], antineutrophil cytoplasmic antibody–associated vasculitis, cryoglobulinemia, Henoch-Schonlein purpura [Chapter 249], Goodpasture syndrome), systemic infections (bacterial endocarditis or endovascular infection [Chapter 47], human immunodeficiency virus [Chapter 359], hepatitis B virus, hepatitis C virus [Chapter 135], schistosomiasis [Chapter 326]), drugs (vascular endothelial growth factor inhibitors, gold, penicillamine, pamidronate), neoplasia (light chain deposition disease, amyloidosis [Chapter 174])	Diffuse, focal, or crescentic proliferative glomerulonephritis (postinfectious, immunoglobulin A nephropathy, complement factor 3 glomerular nephritis, anti–glomerular basement membrane nephritis); focal and segmental glomerulosclerosis, membranous nephropathy, minimal change disease, inherited podocytopathies
Tubulointerstitial diseases (Chapter 108)	Systemic infections (*Legionella* [Chapter 290], leptospirosis, streptococci [Chapter 268]), autoimmune (acute interstitial nephritis, tubulointerstitial nephritis, and uveitis [Chapter 108], systemic lupus erythematosus [Chapter 245], Sjogren syndrome [Chapter 247], immunoglobulin G4 interstitial nephritis), sarcoidosis (Chapter 83), drugs (nonsteroidal anti-inflammatory drugs, iodinated contrast, calcineurin inhibitors, aminoglycoside antibiotics, β-lactam antibiotics, vancomycin, tenofovir, amphotericin, cis-platinum, ifosfamide), metabolic disorders (hyperuricemia due to tumor lysis, hypokalemia [Chapter 103], hypercalcemia [Chapter 227]), environmental toxins (heavy metals, aristolochic acid; Chapter 20), neoplasia (e.g., multiple myeloma; Chapter 173)	Urinary tract infections (bacteria, *Mycobacteria*, schistosomiasis), stones, obstruction, inherited tubulointerstitial diseases (autosomal dominant [medullary cystic disease], autosomal recessive [nephronophthisis])
Vascular diseases	Atherosclerosis (Chapter 65), hypertension (Chapter 64), ischemia (Chapter 110), cholesterol emboli (Chapter 66), thrombotic microangiopathy (hemolytic uremic syndrome [Chapter 158], thrombotic thrombocytopenic purpura [Chapter 158]), systemic sclerosis (Chapter 246)	Fibromuscular dysplasia, radiation
Cystic and congenital diseases	Polycystic kidney disease (Chapter 112), Alport syndrome, Fabry disease (Chapter 192)	Congenital anomalies of the kidney and urinary tract (CAKUT)

Genetic diseases are not considered separately because some diseases in each category are now recognized as having genetic determinants.
Adapted from Kidney Disease: Improving Global Outcomes (KDIGO). KDIGO 2012 clinical practice guideline for the evaluation and management of chronic kidney disease. *Kidney Int Suppl*. 2013;3:1-150.

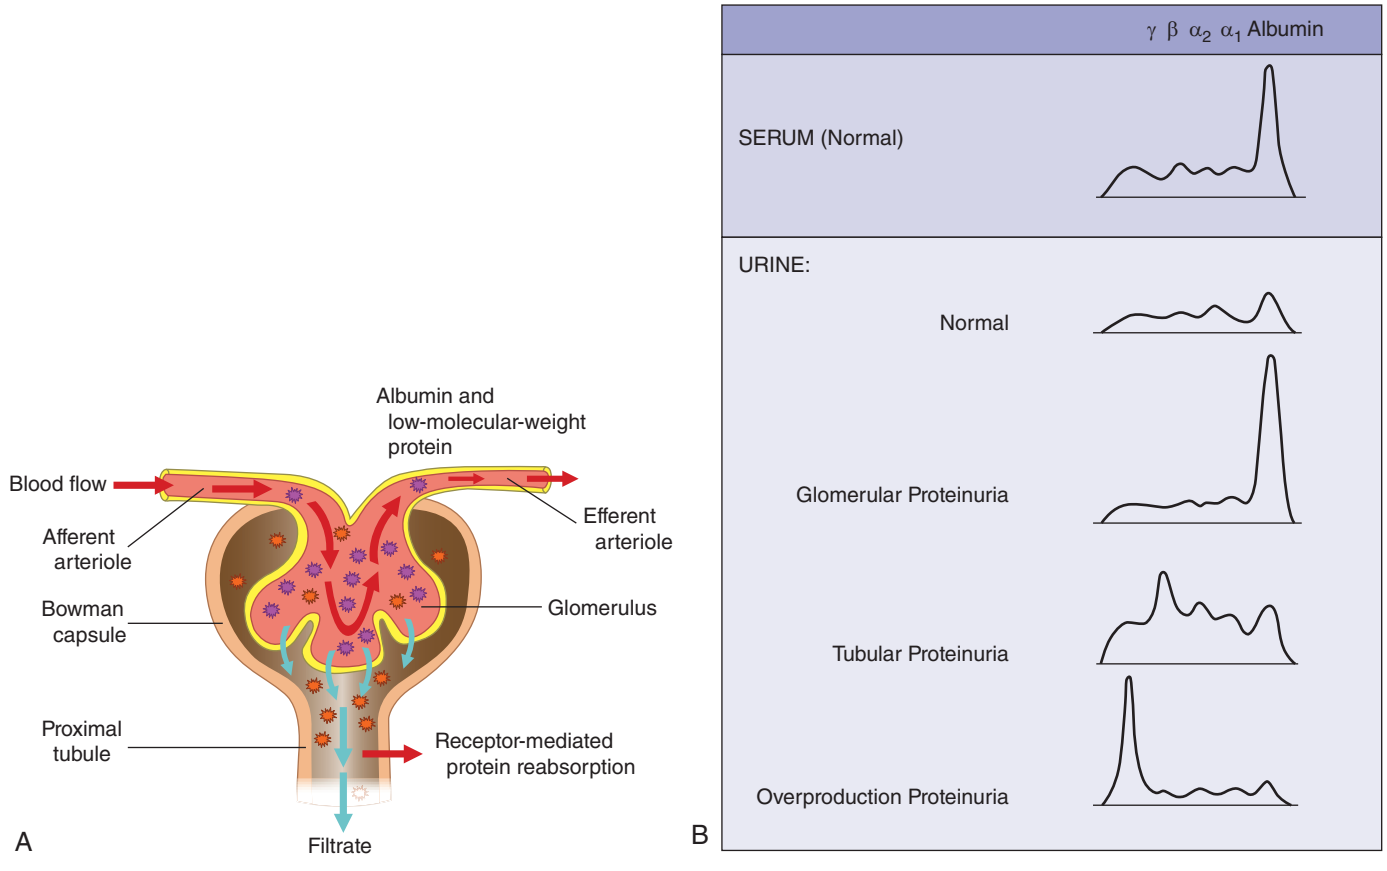


FIGURE 116-2. Pathophysiology of proteinuria. A, Glomerular filtration barrier to macromolecules (albumin) and tubular reabsorption of low-molecular-weight proteins. **B**, Normal serum protein electrophoresis and patterns of proteinuria. **A**, In health, proteinuria is minimal because of the low permeability of glomerular capillary wall to high-molecular-weight serum proteins, such as albumin (*purple symbols*, approximately 65,000 daltons) and gamma globulins (approximately 150,000 daltons), as well as the efficient receptor-mediated tubular reabsorption of filtered low-molecular-weight serum proteins, such as α-1, α-2, and β-globulins (e.g., β-2 microglobulin, cystatin C, β-trace protein, and immunoglobulin light chains; *orange symbols*, approximately 10,000 to 20,000 daltons). Other proteins in normal urine include proteins secreted by the tubule, such as uromodulin (the most abundant protein in normal urine and present in aggregates of up to several million daltons), and from the lower urinary and genital tracts. **B**, Normal serum protein electrophoresis showing separate peaks for albumin and globulins (α-1, α-2, β, and γ), according to molecular weight and charge (albumin is most anionic). Normal urine protein electrophoresis shows minimal amounts of all serum proteins. Glomerular proteinuria shows predominantly albumin; tubular proteinuria shows predominantly α-1, α-2, and β-globulins; and overproduction proteinuria shows light-chain immunoglobulins. These patterns can also be detected by measurement of urinary albumin and total protein, specific low-molecular-weight serum protein or light chains, and immunofixation. Philadelphia: Lippincott Williams & Wilkins; 2007:299-336.)

TABLE 116-2 CHRONIC KIDNEY DISEASE CLINICAL DISORDERS, MECHANISM, MANIFESTATIONS, AND MANAGEMENT (CLINICAL ACTION PLAN) BY GLOMERULAR FILTRATION RATE AND ALBUMINURIA STAGES

ALBUMINURIA STAGE	ALBUMIN EXCRETION RATE (mg/24 h) AND APPROXIMATELY EQUIVALENT ALBUMIN TO CREATININE RATIO (mg/g)*	DISORDER	MECHANISM	MANIFESTATIONS	MANAGEMENT (CLINICAL ACTION PLAN)*
A1	<30				Diagnose and treat the cause Treat comorbid conditions Evaluate for reversible CKD risk factors Start measures to slow CKD progression and reduce CVD risk (lifestyle and diet, blood pressure control, glycemic control in diabetes, lipid-lowering and antithrombotic therapy if indicated)
A2	30-299	Increased risk for GFR decline	Tubulointerstitial damage from uptake of filtered macromolecules	CKD progression	ACE inhibitors or angiotensin receptor blockers; SGLT2 inhibitors; mineralocorticoid-receptor antagonists and GLP1 agonists in diabetes
		Increased risk for CVD	Pro-inflammatory and prothrombotic state	Clinical CVD	
A3	≥300	Nephrotic syndrome if albumin to creatinine ratio above about 2000 or protein to creatinine ratio above about 3500	Low serum oncotic pressure; increased hepatic synthesis of lipoproteins; loss of serum anticoagulant proteins; kidney edema	Low serum albumin (<3.5 g/dL), edema, hyperlipidemia, DVT, acute GFR decline	Diuretics, statins, anticoagulants, albumin infusions as necessary for refractory edema or acute GFR decline

GFR STAGE	GFR (mL/min/1.73 m²)	DISORDER	MECHANISM	MANIFESTATIONS	MANAGEMENT (CLINICAL ACTION PLAN)*
G1	>90				Diagnose and treat the cause Treat comorbid conditions Evaluate for reversible CKD risk factors Start measures to slow CKD progression and reduce CVD risk (lifestyle and diet, blood pressure control, glycemic control in diabetes, lipid-lowering and antithrombotic therapy if indicated)
G2	60-89				Estimate progression
G3a†	45-59	Increased risk for GFR decline			Consider alkali therapy, dietary protein restriction
G3b†	30-44	Increased risk for CVD	CKD-related nontraditional CVD risk factors	Hypertension, heart failure, myocardial ischemia, stroke	Consider intensifying CVD risk factor management
		Drug toxicity	Decreased drug excretion	Increased serum drug concentrations, side effects, drug-drug interactions	Adjust medication dosages as indicated
		Metabolic bone disease, vascular and soft tissue calcification	Decreased active vitamin D_3, increased PTH and fibroblast growth factor 23	High serum phosphorus, normal or low serum calcium, increased bone reabsorption (osteitis fibrosa cystica), decreased bone formation (osteomalacia)	Dietary phosphate restriction, phosphate-binding agents, calcitriol, calcimimetics
		Anemia	Decreased erythropoietin, increased hepcidin, relative iron deficiency, shortened red blood cell survival	Low hemoglobin, normal MCV, low reticulocyte count	Iron, erythropoietin-stimulating agents, hypoxia inducible factor stabilizers, red blood cell transfusions
		Malnutrition	Decreased protein and energy intake	Weight loss, low serum albumin	Referral to registered dietitian nutritionist, appropriate protein intake
		Metabolic acidosis, hyperkalemia	Decreased renin and aldosterone (in some patients), decreased acid secretion, decreased potassium secretion	Low serum bicarbonate, high or normal serum anion gap, high serum potassium	Alkali therapy, dietary potassium restriction, potassium-binding agents
		Sexual and reproductive disorders	Increased prolactin	Amenorrhea, menorrhagia, impotence, oligospermia, galactorrhea	
G4	15-29			Many of the disorders noted earlier (for example, hypertension, 75%; anemia, 30%; hyperphosphatemia, 20%)	Prepare for kidney replacement therapy (transplantation and/or dialysis) or comprehensive conservative treatment

TABLE 116-2 CHRONIC KIDNEY DISEASE CLINICAL DISORDERS, MECHANISM, MANIFESTATIONS, AND MANAGEMENT (CLINICAL ACTION PLAN) BY GLOMERULAR FILTRATION RATE AND ALBUMINURIA STAGES—cont'd

GFR STAGE	GFR (mL/min/1.73 m²)	DISORDER	MECHANISM	MANIFESTATIONS	MANAGEMENT (CLINICAL ACTION PLAN)*
G5	<15	Symptoms of uremia	Retention of toxic solutes	Fatigue, anorexia, nausea, vomiting, peripheral neuropathy, pruritus, serositis (pericardial and pleural effusions), encephalopathy, increased risk for infections, coagulopathy with gastrointestinal bleeding More of the disorders noted earlier (for example, hypertension, 75%; anemia, 50%; hyperphosphatemia, 30%)	If symptoms of uremia are present, start kidney replacement therapy or comprehensive conservative treatment Treat symptoms

*Clinical action plan is cumulative, meaning that the plan for later stages (lower GFR and higher albuminuria) includes the plan from earlier stages (higher GFR and lower albuminuria).
†There is wide variability in the level of GFR at which clinical manifestations occur. Manifestations can be detected by laboratory testing at stages G3a to G3b. Treatment is often deferred until stages G3b to G4.
ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin II receptor blocker; CKD = chronic kidney disease; CVD = cardiovascular disease; DVT = deep vein thrombosis; GFR = glomerular filtration rate; GLP1 = glucagon-like peptide 1; MCV = mean corpuscular volume; MRA = mineralocorticoid receptor antagonist; PTH = parathyroid hormone; SGLT2 = sodium-glucose transport protein 2.

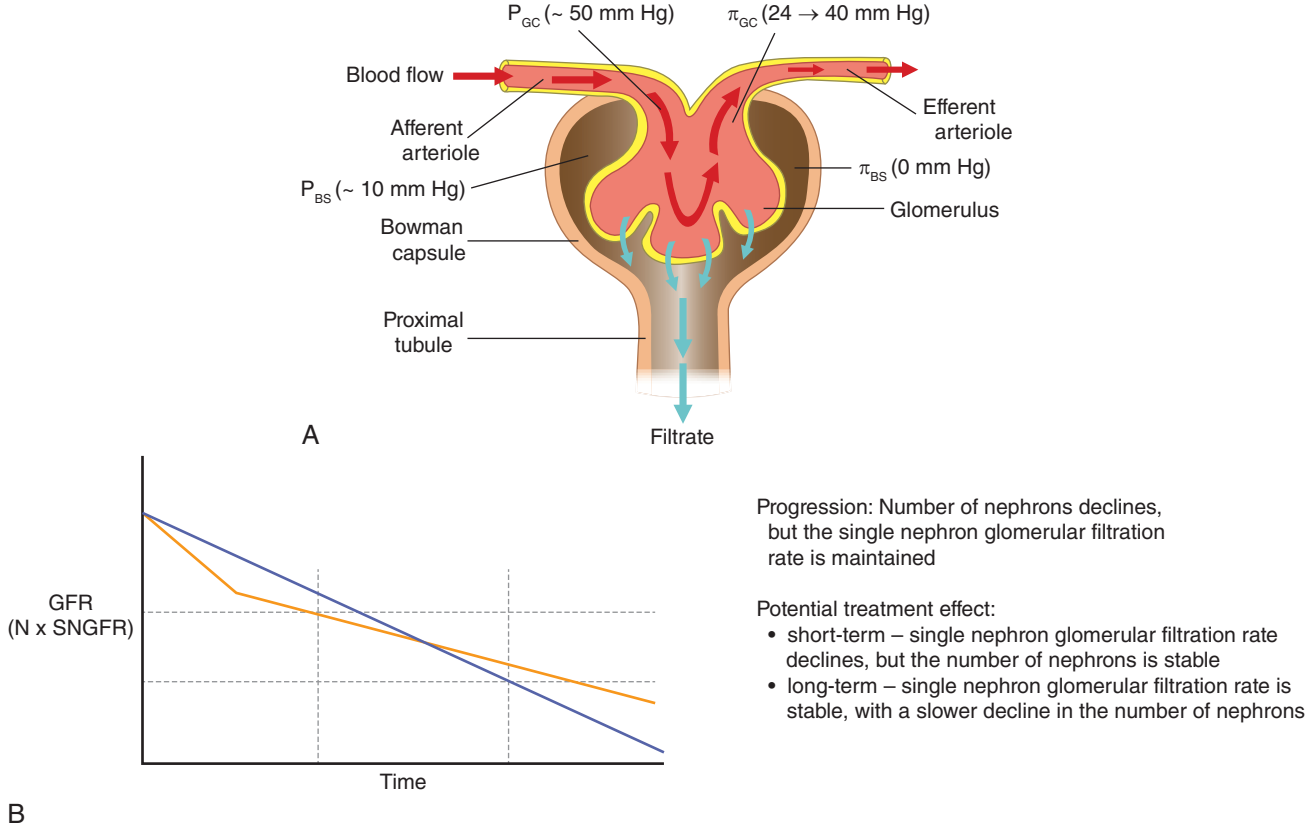

FIGURE 116-3. Pathophysiology of decreased glomerular filtration rate. A, Hemodynamic determinants of the single-nephron glomerular filtration rate. **B,** Mechanism of interventions to slow glomerular filtration rate decline. **A,** In health, a high glomerular filtration rate reflects a high filtration pressure gradient across the glomerular capillary wall (the difference between the hydrostatic pressure gradient [the hydrostatic pressure in the glomerular capsule (P_{GC}) compared with the pressure in Bowman space (P_{BS})] and oncotic pressure gradients [the oncotic pressure in the glomerular capillary (π_{GC}) compared with the oncotic pressure in Bowman space (π_{BS})]) and the high ultrafiltration coefficient of the glomerular capillary wall (K_f, the product of surface area times hydraulic permeability). **B,** Glomerular filtration rate is the product of the number of nephrons times the average single nephron glomerular filtration rate. A decline in glomerular filtration reflects a loss of nephrons. Some therapies for chronic kidney disease reduce the single-nephron glomerular filtration rate but slow the loss of nephrons, thereby initially lowering the glomerular filtration rate (short-term effect) but subsequently slowing the rate of decline of glomerular filtration (long-term effect). GFR = glomerular filtration rate; SNGFR = single nephron GFR.

proteins S and C) and increased liver production of clotting factors and other procoagulant proteins results in hypercoagulability that can manifest as renal vein or deep vein thrombosis.[8] Decreased plasma volume and interstitial edema in the kidney may cause acute kidney injury. Smaller increases in albuminuria (30 to 2000 mg/day, A2 to A3, subnephrotic range) may parallel endothelial damage in other organs and be associated with pro-inflammatory or prothrombotic signals that increase the risk of cardiovascular disease and other complications of chronic kidney disease.

In health, the normal glomerular filtration rate is approximately 125 mL/min/1.73 m² in young adults owing to a high filtration pressure gradient (the difference between hydrostatic and oncotic pressure gradients) across the glomerular capillary wall and its high ultrafiltration coefficient (the product of surface area times hydraulic permeability) (Fig. 116-3). In principle, the glomerular filtration rate is the product of the nephron number (approximately 1 million per kidney) times the mean single-nephron glomerular filtration rate. A decreased glomerular filtration rate is often caused by a decreased number of nephrons and increased nephron glomerular filtration rate per remnant

nephron (single nephron hyperfiltration). This hyperfiltration is caused by the combined effect of glomerular hypertrophy and increased filtration pressure from decreased glomerular capillary resistance, with greater reduction in afferent than efferent resistance. These changes may be considered adaptive because the increase in the single nephron glomerular filtration rate enables continued excretion of solutes despite a decreased number of nephrons, but it is also maladaptive because the increased pressure may damage remnant nephrons, thereby leading to progressive loss of nephrons and a further decline in the glomerular filtration rate. The number of nephrons may also be reduced in premature and low-birthweight infants, thereby leading to subsequent higher risk for the development of chronic kidney disease.[9] Numerous other mechanisms, with or without hyperfiltration and proteinuria, may contribute to the progression of kidney disease.

Therapies targeted to the glomerular adaptations can lower filtration pressure either by increasing afferent resistance or by decreasing efferent resistance and inducing an initially faster glomerular filtration rate decline (short-term or acute effect) followed by a subsequent slowing in the rate of decline in glomerular filtration (long-term or chronic effect), presumably by slowing of the loss of nephrons (Fig. 116-3B). Albuminuria is also generally reduced by such therapies.

The uremic syndrome, which occurs at a glomerular filtration rate below 15 mL/min/1.73m^2 (stage G5, kidney failure), is characterized by retention of solutes that are normally excreted by the kidney (e.g., urea, creatinine, phosphorus, hydrogen ion, potassium, sodium, chloride, unmeasured anions, low-molecular-weight proteins, lipids, and carbohydrates; see Table 116-2). The increased concentration of retained solutes can be directly toxic to cells, such as cells of the neuromuscular and immune systems. In addition, the retention of solutes may also stimulate regulatory systems to try to maintain their net excretion by decreasing their reabsorption or increasing their secretion. However, these tubular adaptations may be maladaptive because they have adverse consequences in other organ systems. For example, parathyroid hormone (PTH) is increased in response to the retention of phosphate; the result is reabsorption of bone and the potential for tertiary hyperparathyroidism if the hyperparathyroidism becomes autonomous (Chapter 227). The kidney's endocrine and metabolic functions also tend to decline in parallel with decreased excretory function; examples include decreased production of erythropoietin and 1,25-dihydroxycholecalciferol (activated vitamin D_3), as well as decreased urinary production of ammonia.

With smaller decreases in glomerular filtration rate, the retention of solutes is less marked but still may cause complications (see Table 116-2). For example, most patients with chronic kidney disease have hypertension, often with onset at stages G1 to G2, due to a combination of increased extracellular fluid volume from the retention of sodium chloride and increased systemic vascular resistance from a deficiency in nitric oxide and a failure to suppress the sympathetic nervous system and the renin-angiotensin system.

Increased PTH and deficiency of active vitamin D_3 are among the earliest complications of decreased glomerular filtration rate, generally occurring at stage G3a. The metabolic bone disease of chronic kidney disease includes renal osteodystrophy as well as vascular and soft tissue calcification. Renal osteodystrophy is characterized by a combination of bone lesions from increased secretion of PTH (osteitis fibrosa cystica) and a deficiency of active vitamin D_3 (osteomalacia).

The anemia of chronic kidney disease (Chapter 144) is hypoproliferative and normochromic, largely due to a deficiency in erythropoietin, the accumulation of hepcidin, and relative iron deficiency. However, the survival of red cells is also diminished. Anemia generally first appears at stage G3a to G3b but is usually mild (hemoglobin >10 g/dL) until stage G4.

Muscle and fat wasting is primarily due to decreased intake of protein and energy owing to anorexia, although gastrointestinal symptoms (nausea, vomiting, and diarrhea) may contribute at stage G5. Micronutrient deficiencies may also occur. Other causes of muscle and fat wasting may include the accumulation of leptin, ghrelin deficiency, inflammation, and metabolic acidosis. Malnutrition may also be a side effect of dietary restrictions.

Metabolic acidosis (Chapter 104) in chronic kidney disease is caused by retention of hydrogen ion owing to decreased tubular secretion. The most common cause (uremic acidosis) is the decreased production of ammonia owing to decreased nephron mass at stages G3b to G5. A concomitant elevation in the anion gap occurs at stage G4 to G5 owing to the reduced filtration of unmeasured anions. Nevertheless, an acid urine pH is preserved, and the serum bicarbonate level usually stabilizes between 12 and 18 mEq/L because of buffering of retained hydrogen ions in bone. Causes of metabolic acidosis in chronic kidney disease at stage G1 to G2 include impaired acidification (e.g., distal renal tubular acidosis, nonacid urinary pH , usually with hypokalemia), impaired bicarbonate reabsorption (proximal renal tubular acidosis, alkaline urine pH during the generation phase but acid urine pH in the steady-state phase, usually with hypokalemia), and hyporeninemic hypoaldosteronism (type 4 renal tubular acidosis, acid urine pH, usually with hyperkalemia).

Hyperkalemia (Chapter 103), which generally begins at stages G3b to G4, is usually caused by the retention of potassium owing to a combination of excessive dietary intake, decreased filtered load, and decreased tubular secretion. Potassium retention directly stimulates the secretion of aldosterone by the adrenal zona glomerulosa, thereby leading to increased tubular secretion of potassium. The inhibition of the renin-angiotensin system leads to impaired secretion of aldosterone and to type 4 renal tubular acidosis with resulting hyperkalemia. Causes of hyperkalemia without potassium retention include a transcellular shift of potassium from intracellular to extracellular fluid (for example, due to metabolic acidosis, hyperglycemia, or β-adrenergic blockade) or cell lysis.

As the glomerular filtration rate falls, prolactin is retained. Elevated prolactin levels contribute to disturbances in the hypothalamic-pituitary axis and can cause sexual and reproductive disorders at stage G3b to G4. The toxicity of numerous retained solutes leads to peripheral neuropathy, uremic encephalopathy, and an increased risk of infections at stage G5.

Chronic kidney disease is a risk factor for cardiovascular disease, including atherosclerosis (e.g., coronary ischemia and myocardial infarction, cerebral ischemia and stroke, and aortic and peripheral vascular disease), left ventricular hypertrophy, and heart failure. In addition to the increased prevalence of traditional risk factors (e.g., older age, male sex, diabetes, hypertension, hyperlipidemia, obesity, smoking, and physical inactivity) in patients with chronic kidney disease, chronic kidney disease itself also appears to be a risk factor for left ventricular hypertrophy and cardiovascular disease, due in part to increased levels of fibroblast growth factor 23 as well as to pro-inflammatory and prothrombotic states.

CLINICAL MANIFESTATIONS

Clinical manifestations depend on the degree of albuminuria and the severity of the reduction in the glomerular filtration rate (see Table 116-2).[10] Chronic kidney disease is usually silent in its early stages. The earliest manifestation may be the new onset or worsening of hypertension, abnormalities on a urinalysis, electrolyte or acid-base abnormalities, or the development of edema. Often symptoms are nonspecific, such as fatigue or lassitude.

Albuminuria generally indicates glomerular damage and is the earliest marker of kidney damage in conditions such as diabetes, hypertension, and obesity. Subnephrotic-range albuminuria (30 to 2000 mg/day, stages A2 to A3) has few clinical manifestations but is associated with increased risk of cardiovascular disease, anemia, infections, and cognitive impairment. Nephrotic syndrome can cause severe edema, deep vein thrombosis or pulmonary embolism, or acute kidney injury.

A decreased glomerular filtration rate may lead to the accumulation of drugs that are excreted by the kidney, with an increased risk for side effects owing to toxicity and drug-drug interactions. Side effects can also occur due to increased renal toxicity of radiographic contrast agents that contain iodine and the systemic toxicity of gadolinium (Chapter 246). Superimposed acute kidney injury (Chapter 106) is common due to side effects of drugs used to treat chronic kidney disease, cardiovascular disease, and other frequently occurring comorbid conditions.

Many clinical manifestations of decreased glomerular filtration rate may occur at stages G3b to G4. Renal osteodystrophy may cause pathologic fractures and soft tissue masses. Hyperphosphatemia may elevate the calcium-phosphate concentration product in excess of its solubility in extracellular fluid, causing soft tissue and vascular calcification, leading to noncompliant large arteries, left ventricular hypertrophy, heart failure, and, rarely, necrosis of skin and underlying soft tissue owing to ischemia (calciphylaxis). Anemia may cause weakness and contribute to heart failure. Muscle and fat wasting may cause weight loss, often superimposed on preexisting obesity. At stage G3b, the serum anion gap may be in the normal range (normal anion gap metabolic acidosis). At stage G4 to G5, the serum anion gap is usually increased due to retention of inorganic anions (phosphates and sulfates), and high anion gap metabolic acidosis appears. Consequences of chronic metabolic acidosis in chronic kidney disease include osteopenia due to dissolution of calcium salts, as well as muscle wasting and faster progression of kidney disease. Mild hyperkalemia (serum potassium 5.0 to 5.5 mEq/L; Chapter 103) is common, especially in patients treated with drugs that inhibit the renin-angiotensin-aldosterone system. Moderate hyperkalemia (serum potassium 5.5 to 6.5 mEq/L) is more common at stage G3b, and severe hyperkalemia (serum

potassium >6.5 mEq/L) is seen with more advanced chronic kidney disease. Sexual and reproductive disorders may include amenorrhea, menorrhagia, impotence, oligospermia, or galactorrhea.

Kidney failure (glomerular filtration rate <15 mL/min 1.73 m^2, stage G5) can give rise to signs of uremia. The uremic syndrome includes hypertension, extracellular fluid overload, metabolic bone disease, anemia, malnutrition, peripheral neuropathy, pruritus, gastrointestinal symptoms, pericarditis (Chapter 62), encephalopathy, and an increased risk for infections.

DIAGNOSIS

Patients with possible chronic kidney disease should be evaluated systematically (Table 116-3) to define whether they meet the diagnostic criteria (Table 116-4), based on the degree of their albuminuria (>30 mg/day), the decline in their glomerular filtration rate (<60 mL/min 1.73 m^2), and the chronicity of these changes (3 or more months) (Table 116-5). In patients who are determined to have chronic kidney disease, the disease should be classified according to its severity, based on the degree of albuminuria and the glomerular filtration rate (see Fig. 116-1 and see Table 116-2), as well as on its cause (see Table 116-1).

TABLE 116-3 GUIDE FOR THE DETECTION, EVALUATION, AND MANAGEMENT OF CHRONIC KIDNEY DISEASE

1. **Recognition of increased risk of chronic kidney disease**	• Increased susceptibility to chronic kidney disease • Exposure to conditions that cause chronic kidney disease
2. **Testing for chronic kidney disease**	• Measure serum creatinine to estimate glomerular filtration rate • Measure urinary albumin • Assess other markers of kidney damage that are specific to the risk (urine sediment, imaging abnormalities, renal tubular syndromes, kidney biopsy) • Perform confirmatory tests (if indicated)
3. **Detection of chronic kidney disease**	• Duration >3 months (documented or inferred) • Markers of kidney damage • Glomerular filtration rate <60 mL/min per 1.73 m^2 (estimated or measured)
4. **Evaluation of clinical diagnosis for implementation of cause-specific therapy**	• Diabetic kidney disease (type 1 or 2) • Nondiabetic kidney disease (glomerular disease other than diabetic glomerulosclerosis, vascular diseases, tubulointerstitial diseases, cystic or congenital diseases) • Kidney disease in kidney transplant recipients
5. **Assessment of stage for implementation of stage-based cause-independent therapy**	• Albuminuria stages • Glomerular filtration rate stages
6. **Prognosis (risk assessment with detection, evaluation, and management tailored to patient's risk)**	• Predictive instruments using level of albuminuria and glomerular filtration rate plus other factors specific for the outcome (kidney failure, kidney disease progression, acute kidney injury, chronic kidney disease, cardiovascular disease and other complications, mortality)

Modified from Levey AS, Coresh J. Chronic kidney disease. *Lancet*. 2012;379:165-180.

TABLE 116-4 CRITERIA FOR CHRONIC KIDNEY DISEASE (ANY OF THE FOLLOWING PRESENT FOR >3 MONTHS)

Markers of kidney damage (one or more)	Albuminuria (albumin excretion rate ≥30 mg/24 hr; albumin to creatinine ratio ≥30 mg/g; albumin to creatinine ratio stages A2-A3) Urine sediment abnormalities Imaging abnormalities Electrolyte and other abnormalities due to tubular disorders Pathologic abnormalities History of kidney transplantation
Decreased GFR	Glomerular filtration rate <60 mL/min/1.73 m^2 (glomerular filtration rate stages G3a-G5)

From Kidney Disease: Improving Global Outcomes (KDIGO). KDIGO 2012 clinical practice guideline for the evaluation and management of chronic kidney disease. *Kidney Int Suppl*. 2013;3:1-150.

Evaluation of Duration

Evaluation of duration of the kidney disease distinguishes chronic kidney disease (>3 months) from acute kidney injury (Chapter 106).[11] The duration can be documented either by review of past medical records or inferred from specific findings. For example, oliguria or a decreased glomerular filtration rate in the setting of acute illness suggests acute kidney injury. Small kidneys on imaging studies or chronic illness signifies chronic kidney disease. Many kidney diseases can cause either acute or chronic disease, but acute tubular necrosis, the most common cause of acute kidney injury, does not have a chronic phase, and diabetic kidney disease, the most common cause of chronic kidney disease, does not have an acute phase.

Evaluation of Markers of Kidney Damage

Albuminuria signifies increased glomerular permeability, and a large quantity of albuminuria generally signifies a glomerular disease. The albumin excretion rate in a timed urine sample is the gold standard for assessing albuminuria, but an albumin to creatinine ratio in an untimed "spot" urine sample is recommended as the initial test because of its specificity and convenience.[12] As a rough guide, an albumin excretion rate of less than 30 mg/day corresponds approximately to a protein excretion rate of less than 150 mg/day and a dipstick protein reading of negative to trace positive. An albumin excretion rate of greater than 300 mg/day corresponds approximately to a protein excretion rate greater than 500 mg/day and a dipstick that is 1+ positive or greater. Renal tubular disorders may cause abnormalities of serum and urine electrolytes as well as urine pH, glucose, amino acids, and low-molecular-weight proteins in the absence of other markers of kidney damage or a decreased glomerular filtration rate. The evaluation of these disorders usually requires referral to specialists.

Evaluation of the urine sediment can be helpful to determine whether hematuria or pyuria reflect kidney damage (Chapter 101). Dysmorphic red blood cells (RBCs) indicate a glomerular disease (Chapter 107), RBC casts suggest a proliferative glomerulonephritis (Chapter 107), and white blood cell casts suggest pyelonephritis (Chapter 263) or tubulointerstitial nephritis (Chapter 108). Oval fat bodies and fatty casts are found in diseases with proteinuria. Renal tubular epithelial cells and casts may be seen in any parenchymal kidney disease; in the absence of hematuria and proteinuria, such cells may indicate acute tubular necrosis.

Ultrasound is generally the first imaging modality because it is noninvasive, does not require contrast, and has high sensitivity for detecting hydronephrosis, cortical scarring, masses (Chapters 182 and 186), stones (Chapter 111), polycystic kidney disease (Chapter 112), and large or small kidneys. CT and MRI with contrast or diagnostic angiography may be necessary for further delineation of the kidney structures, and percutaneous antegrade or cystoscopic retrograde procedures may be necessary to evaluate the renal collecting system.

Pathologic abnormalities are the gold standard for kidney damage, but biopsy of the kidney is an invasive procedure that is generally reserved for evaluation of markers of kidney damage or decreased glomerular filtration rate when knowledge of the pathologic findings will affect treatment. The main complication of percutaneous biopsy is bleeding, which occurs more frequently in patients who have hypertension, a lower glomerular filtration rate, and biopsy of native as compared with transplanted kidneys.

Evaluation of the Glomerular Filtration Rate

Approximately 90% of clinical laboratories in the United States report an estimated glomerular filtration rate (eGFR) whenever a serum creatinine is measured. Equations to estimate the eGFR use serum concentrations of creatinine and cystatin (Table 116-6), which are endogenous filtration markers that vary inversely with the glomerular filtration rate, plus demographic variables (e.g., with age, with or without sex, and without race), which serve as surrogates for factors other than the glomerular filtration rate that influence their serum concentrations.[13,14] Factors other than glomerular filtration rate that influence the serum creatinine concentration include its generation by muscle and diet, tubular secretion, and extrarenal elimination by intestinal bacteria. Unfortunately, the eGFR lacks precision; in populations with no systematic bias, only 80 to 90% of eGFR calculations are within 30% of the measured glomerular filtration rate. Systematic underestimation of the measured glomerular filtration rate can be observed in individuals who have a large muscle mass, who eat large amounts of meat, who take creatine supplements, or who are treated with medications that inhibit the tubular secretion of creatinine (e.g., trimethoprim, fenofibrate,

TABLE 116-5 EVALUATION OF CHRONIC KIDNEY DISEASE

Duration >3 mo on the basis of documentation or inference. Duration is necessary to distinguish chronic kidney disease from acute kidney injury

- Clinical assessment can indicate duration
  - Review of previous laboratory data
  - Acute illness or oliguria suggests acute kidney injury
  - Chronic illness or small kidneys indicate chronic kidney disease
- Documentation of duration is not usually available in epidemiologic studies

Kidney damage as defined by structural abnormalities or functional abnormalities other than decreased glomerular filtration rate. Markers of kidney damage may suggest cause of disease

Albuminuria as a marker of kidney damage. Increased glomerular permeability, urine albumin to creatinine ratio >30 mg/g

- The normal urinary albumin to creatinine ratio in young adults is ≤10 mg/g. Urine albumin to creatinine ratio stages 10-29, 30-300, and >300 mg are high-normal, high, and very high, respectively
- Threshold value of 30 mg/g roughly corresponds to urine dipstick values of trace or 1+, dependent on urine concentration
- High urinary albumin to creatinine ratio can be confirmed by urine albumin excretion in a timed urine collection

Abnormalities in urinary sediment as markers of kidney damage

- Dysmorphic red blood cells in glomerular disease
- Red blood cell casts in proliferative glomerulonephritis
- White blood cell casts in pyelonephritis or interstitial nephritis
- Oval fat bodies or fatty casts in diseases with proteinuria
- Granular casts and renal tubular epithelial cells in many parenchymal diseases (nonspecific)

Imaging abnormalities as markers of kidney damage (ultrasound, computed tomography, and magnetic resonance imaging with or without contrast, isotope scans, angiography)

- Hydronephrosis due to obstruction
- Cortical scarring due to infarcts, pyelonephritis, or vesicoureteral reflux
- Polycystic kidney disease
- Kidney stones
- Renal artery stenosis
- Renal masses or enlarged kidneys due to infiltrative diseases
- Small and echogenic kidneys (common in late stages of chronic kidney disease because of many parenchymal diseases)

Renal tubular syndromes as markers of kidney damage

- Renal tubular acidosis
- Nephrogenic diabetes insipidus
- Bartter and Gittelman syndromes
- Fanconi syndrome
- Cystinuria
- Familial hypomagnesemia with hypercalciuria and nephrocalcinosis

Pathologic abnormalities as markers of kidney damage

- Glomerular diseases
- Vascular diseases
- Tubulointerstitial diseases
- Cystic diseases
- Congenital diseases

Glomerular filtration rate (GFR) <60 mL/min per 1.73 m^2

- Glomerular filtration rate is the best overall index of kidney function in health and disease
- Normal glomerular filtration rate in young adults is about 125 mL/min per 1.73 m^2; glomerular filtration rate <15 mL/min per 1.73 m^2 is defined as kidney failure
- Glomerular filtration rate may be assessed by measurement of clearances of exogenous filtration markers (measured glomerular filtration rate) or estimated from serum concentrations of endogenous filtration markers (estimated glomerular filtration rate)
- Estimated glomerular filtration rate using serum creatinine is the first step in glomerular filtration rate evaluation
  - Non–glomerular filtration rate determinants of serum creatinine include generation by muscle or diet, tubular secretion, and extrarenal elimination by gastrointestinal tract bacterial creatininase
  - In populations with acute illness or chronic comorbid illness, estimated glomerular filtration rate from creatinine may have systematic error (bias) compared to measured glomerular filtration rate
  - In populations in which estimated glomerular filtration rate from creatinine does not have bias, estimated glomerular filtration rate from creatinine lacks precision: only 80-90% of estimated glomerular filtration rates are within 30% of measured glomerular filtration rate
- Confirmatory tests for decreased estimated glomerular filtration rate from creatinine include estimated glomerular filtration rate using serum cystatin C or the combination of serum creatinine and cystatin C; measured creatinine clearance; or measured glomerular filtration rate using inulin, iothalamate, iohexol, ethylene-diamine tetracetic acid, or diethylene triamine pentaacetic acid

Cause of chronic kidney disease. Classification of cause is based on

- Site of documented or presumed pathologic abnormalities
- Presence or absence of systemic disease affecting the kidneys

Modified from Levey AS, Coresh J. Chronic kidney disease. *Lancet*. 2012;379:165-180.

ritonavir, cobicistat, dolutegravir, and other antiviral agents) or inhibit bacterial creatininase (broad-spectrum antibiotics). In contrast, systematic overestimation of the measured glomerular filtration rate can be observed in individuals who have muscle wasting, eat a vegetarian or low-protein diet, or have large losses of creatinine-containing extravascular fluid, such as when pleural or peritoneal effusions are continuously drained and replaced with intravenous fluids. Cystatin C is an alternative filtration marker that is recommended as a confirmatory test to estimate the glomerular filtration rate. Serum cystatin C is not affected by muscle mass, diet, or tubular secretion, but it is affected by smoking, obesity, inflammation, thyroid hormones, and glucorticosteroids, independent of glomerular filtration rate. The estimation of glomerular filtration rate by cystatin C is not more accurate than a

TABLE 116-6 EQUATIONS FOR ESTIMATING THE GLOMERULAR FILTRATION RATE

Using the serum creatinine level only $142 \times \min(Scr/k,1)^{\alpha} \times \max(Scr/k,1)^{-1.200} \times 0.9938^{age} \times 1.012$ [if female] where Scr is serum creatinine, k is 0.7 for females and 0.9 males, α is −0.241 for females and −0.302 for males, min indicates the minimum of Scr/k or 1, max indicates the maximum of Scr/k or 1
Using the serum cystatin level only $133 \times \min(Scys/0.8,1)^{-0.499} \times \max(Scys/0.8,1)^{-1.328} \times 9962^{age} \times 0.932$ [if female] where Scys is serum cystatin C
Using both the serum creatinine and serum cystatin level $135 \times \min(Scr/k,1)^{\alpha} \times \max(Scr/k,1)^{-0.544} \times \min(Scys/0.8,1)^{-0.323} \times \max(Scys/0.8,1)^{-0.778} \times 0.9961^{age} \times 0.963$ [if female] where Scr is serum creatinine, Scys is serum cystatin C, k is 0.7 for females and 0.9 males, α is −0.219 for females and −0.144 for males, min indicates the minimum of Scr/k or 1, max indicates the maximum of Scr/k or 1

From National Kidney Foundation calculator: https://kidney.org/professionals/kdoqi/gfr_calculator.

glomerular filtration rate estimated by creatinine, but together they are more accurate than either alone.

Evaluation of Cause

For evaluation of cause, the classification can be simplified into diabetic (Chapter 109) versus nondiabetic diseases of native kidneys and diseases in kidney transplant recipients (Chapter 117). In general, further diagnostic testing should be guided by the likelihood of detecting a treatable disease (Chapter 100).

Diabetic kidney disease is the most common cause of kidney disease in adults in high-income nations, and the clinical features of diabetic glomerulosclerosis can be easily recognized without specialized diagnostic tests (Chapter 109). Slowly worsening albuminuria, hypertension, and a progressive decline in glomerular filtration rate are typical, whereas hematuria, pyuria, and imaging abnormalities are usually absent.

Among the nondiabetic kidney diseases, hypertensive nephrosclerosis (Chapter 64) is the most common. It has no distinct markers, but increased albuminuria can occur before or after the onset of a decreased glomerular filtration rate. Hypertensive retinopathy (Fig. 391-24) and left ventricular hypertrophy are common, whereas hematuria, pyuria, and imaging abnormalities are typically absent. However, hypertension is a common complication of other kidney diseases, and an abnormal urine sediment or a family history of early onset of kidney disease suggests another primary cause of the kidney disease. Many cases of presumed hypertensive nephrosclerosis in individuals of West African descent may be associated with *APOL1* pathogenic variants (Chapter 107).

TREATMENT

General Principles

Management, which is based on the cause of chronic kidney disease and its stage, should begin as soon as the disease is detected. Cause-specific therapy that is directed at factors that cause chronic kidney disease may induce remission and slow progression. Stage-based therapies, which are directed by the level of albuminuria and the glomerular filtration rate, aim to slow the progression and prevent complications of chronic kidney disease, irrespective of the cause (see Table 116-2). Stage-based recommendations are cumulative, so recommendations for late stages include recommendations for early stages. Although many common problems can be managed with existing guidelines by non-nephrologists, specialty nephrology referral is recommended for patients with an uncertain diagnosis, an albumin to creatinine ratio greater than 300 mg/g (stage A3), a glomerular filtration rate less than 30 mL/min/1.73 m^2 (stage G4 to G5), or complications that are difficult to manage.

Cause-Specific Treatment for Chronic Kidney Disease

Glycemic control (Chapter 210) can retard the development of diabetic glomerulosclerosis, and blood pressure control (Chapter 64) can retard the development of hypertensive nephrosclerosis. However, no specific treatment can reverse either disease. For patients who have diabetic kidney disease, the recommended HbA_{1c} target is similar as for patients who have diabetes without kidney disease, although less strict targets may be appropriate for patients with comorbid conditions. Specific treatments (see Table 116-1) are available for many other causes of nondiabetic kidney disease, including glomerular diseases (Chapter 107) and the withdrawal of exposure to toxic drugs (Chapter 106).

Stage-Based Treatment Independent of Cause

Therapies to slow the progression of chronic kidney disease and reduce cardiovascular risk in patients with chronic kidney disease are the mainstays of treatment for most patients. Patients must avoid drugs that are toxic to the kidneys and reduce the dosage of drugs that are excreted by the kidney

Lifestyle and Diet Recommendations

As in the general population, a healthy eating pattern, physical activity, and tobacco cessation are recommended to reduce the risk of cardiovascular disease. A healthy eating pattern accounts for all foods and beverages within an appropriate calorie level and limits saturated fats and trans fats, added sugars, and sodium. A Mediterranean-type diet (Fig. 13-1) may improve lipid profiles, and a DASH-sodium diet (Table 13-4) may lower blood pressure and reduce the production of acid.[15] Dietary sodium restriction (<2.0 g/day) is recommended for patients who have hypertension. The recommended dietary allowance for protein for the general population is approximately 0.8 g/kg/day, which is far below the average protein intake in high-income nations. Some guidelines recommend a dietary protein intake of 0.6 to 0.8 g/kg/day at stage G3 to G5 because of its favorable effect on ameliorating solute retention and the potential to slow the progression of chronic kidney disease. Maintenance of a total energy intake of 25 to 35 kcal/kg/day while consuming a low-protein diet is recommended to avoid protein-calorie malnutrition. Involvement of a registered dietitian nutritionist is essential.

Blood Pressure Control

A systolic blood pressure less than 130 mm Hg is key, and a systolic blood pressure less than 120 mm Hg (using standardized office-based measurements) is recommended by some guidelines.[16] Caution is advised because a lower blood pressure goal may initially be associated with an increased risk of reducing the glomerular filtration rate, especially in older patients with comorbid conditions. Renin-angiotensin-aldosterone system inhibition with an ACE inhibitor or an angiotensin receptor blocker (Tables 64-7 and 64-9) is recommended for patients with albuminuria with or without diabetes to reduce albuminuria and slow the decline in the glomerular filtration rate,[A1] with diuretics[A2] and calcium channel antagonists as additional agents and calcium channel antagonists as the third agent (Chapter 64). Nonsteroidal mineralocorticoid receptor antagonists (e.g., finerenone 20 mg once daily if the glomerular filtration rate is greater than 60 mL/min/1.73m^2 and 10 mg once daily if it is 25 to 59 mL/mm/1.73m^2) are also effective in patients with diabetes and albuminuria.[A3,A4]

Sodium Glucose Transport Protein 2 (SGLT2) Inhibition and Glucagon-like Peptide 1 Agonists

SGLT2 inhibitors reduce sodium glucose cotransport in the proximal tubule, thereby resulting in natriuresis, weight loss, and lower blood pressure. Treatment with these medications[17] reduces albuminuria, slows the decline of the glomerular filtration rate, and reduces the risk for kidney failure and cardiovascular disease in patients who have albuminuria with diabetic (Chapter 109) or nondiabetic kidney disease.[A5–A7] These agents (e.g., canagliflozin 100 mg daily, dapagliflozin 5 mg daily, and empagliflozin 10 mg daily) recommended for patients with albuminuria who have type 2 diabetes (Chapter 109) or who do not have diabetes, but they are not approved for use in patients who have type 1 diabetes. Glucagon-like peptide-1 agonists also reduce albuminuria and slow the decline in glomerular filtration rate in patients with type 2 diabetes and albuminuria.[18]

Lipid-Lowering Therapy and Antithrombotic Agents

Patients with chronic kidney disease are at increased risk of cardiovascular disease (Chapter 40). A healthy diet (Chapters 13 and 201), statins (Chapter 190), and other therapies are recommended to reduce low-density lipoprotein (LDL) cholesterol levels and thereby reduce this risk.[19] When clinically indicated, antithrombotic agents appear to have similar efficacy as in patients who do not have chronic kidney disease; however, the risk of hemorrhagic side effects is higher in patients with chronic kidney disease, and the dose of antithrombotic agents often must be adjusted (Chapter 70). In contrast to their cardiovascular benefit, neither lipid-lowering therapy nor antithrombotic agents appear to have a beneficial effect on the progression of the kidney disease itself.

Treatment of Complications of Albuminuria

Diuretics are generally needed to control edema due to nephrotic syndrome (Chapter 107). In refractory cases, albumin infusion can be administered at the same time.[20] ACE inhibitors and angiotensin receptor blockers (Table 64-7) are useful to reduce albuminuria, but they may cause hypotension and hyperkalemia. Anticoagulants can be used to prevent or treat deep vein thrombosis (Chapter 68) and renal vein thrombosis (Chapter 110).

Treatment of Complications of a Decreased Glomerular Filtration Rate

Exogenous alkali can prevent and treat metabolic acidosis due to chronic kidney disease. It also can slow the decline in the glomerular filtration rate in patients with or without metabolic acidosis and in diabetic and nondiabetic kidney disease.[A8] A reasonable starting dose is sodium bicarbonate at 650 mg twice daily, titrated to a target serum bicarbonate of approximately 22 to 24 mEq/L.

Extracellular fluid volume retention may be a potential risk of therapy with sodium bicarbonate.

Mild hyperkalemia (potassium level 5 to 5.5 mEq/L) generally requires no treatment other than education to avoid foods with large concentrations of potassium. Levels higher than 5.5 mEq/L generally require treatment[21] (Chapter 103). Urgent therapy for higher levels may include calcium gluconate to prevent cardiac arrhythmias; insulin, glucose, and bicarbonate to shift potassium from extracellular to intracellular fluid; loop diuretics, potassium-binding agents, and dialysis to remove potassium from the body; and treatment of reversible causes of hyperkalemia. If there are no reversible disorders, prevention includes dietary potassium restriction (<2 g/day) and potassium-binding agents (Chapter 103).

Metabolic bone disease is treated with phosphate-binding agents to maintain a normal serum phosphorus level (Chapter 105) and with activated vitamin D_3 (e.g., calcitriol starting at 0.25 μg to 0.5 μg orally every day or every other day depending on the glomerular filtration rate and the PTH level) or its analogues. In dialysis patients, calcimimetics (e.g., cinacalcet starting at 30 mg orally daily) should be used to suppress PTH. Subtotal parathyroidectomy is required in refractory cases of tertiary hyperparathyroidism (Chapter 207).

Treatment of symptomatic anemia includes iron repletion if indicated, erythropoiesis-stimulating agents, and red cell transfusions. To stimulate erythropoiesis, erythropoiesis-stimulating agents (e.g., darbepoetin alpha starting at 0.45 μg/kg every 4 weeks) are generally begun when the hemoglobin level is less than 9 g/dL in patients who have symptoms of anemia, who are likely to need red cell transfusions, and in whom the goal is to reduce the risk of alloimmunization or other transfusion-related risks (Chapter 162). Erythropoiesis-stimulating agents are associated with an increased risk of deep vein thrombosis and cardiovascular disease, so they are generally reserved for patients with stages G4 to G5 chronic kidney disease and are used to raise the hemoglobin level only to 10 to 11 g/dL because higher levels are associated with more cardiovascular complications. Hypoxia-inducible factor-stabilizing agents also are effective for raising the hemoglobin level[A9,A10] but are not currently approved in the United States for patients who are not being treated by dialysis because of safety concerns.

Kidney Replacement Therapy and End-of-Life Care

Kidney failure (glomerular filtration rate <15 mL/min/1.73 m^2), which is the end stage of chronic kidney disease, is treated for as long as possible with comprehensive conservative care, which is management of clinical disorders and symptoms of uremia to maintain quality of life without dialysis. When such care is no longer adequate for controlling symptoms and signs, kidney replacement therapy (Chapter 117) is required. Dialysis is effective in resolving the most severe symptoms and signs, but it is associated with many complications and often does not result in full resolution of symptoms and signs. Since both quality of life and survival are limited with dialysis, especially for older patients, kidney transplantation is preferred, whenever possible, to resolve symptoms and extend life. Unfortunately, it is not available to all patients.

End-of-life care (Chapter 3) refers to maintaining comfort at the end of life in patients treated by transplantation, dialysis, or comprehensive conservative care. A shared decision model is recommended for implementation of these modalities of therapy, and planning should begin well in advance of the onset of uremic symptoms.

PREVENTION

Primary prevention of chronic kidney disease refers to the prevention and treatment of risk factors for chronic kidney disease, including diabetes, hypertension, cardiovascular disease, and other associated systemic disorders, as well as reducing exposure to drugs and environmental toxins that cause kidney disease. Adoption of public health guidelines for a healthy lifestyle and diet can lower the prevalence of hypertension, diabetes, obesity, and cardiovascular disease. Secondary prevention to slow the progression of kidney disease relies upon early detection, such as evaluating albuminuria to assess kidney damage and the serum creatinine level to estimate the glomerular filtration rate, in patients who have hypertension, diabetes, cardiovascular disease, and other systemic diseases associated with an increased risk for chronic kidney disease.[22] Failure to assess markers of kidney damage delays the detection of chronic kidney disease and the ability to implement measures to slow its progression. Detection of albuminuria or other markers of kidney damage enables implementation of measures to slow progression before glomerular filtration rate declines, thereby potentially increasing the interval until the onset of kidney failure (E-Fig. 116-3). Tertiary prevention in chronic kidney disease refers to kidney replacement therapy for kidney failure to prevent complications and death.

PROGNOSIS

The prognosis in chronic kidney disease depends primarily on the cause of disease, the level of albuminuria and glomerular filtration rate, and the availability of treatment. Kidney disease often progresses even after the diseases that initially caused it are no longer active. Explanations include systemic hypertension, proteinuria, increased glomerular capillary pressure with increased glomerular filtration, and accumulation of nephrotoxins.

Risk stratification is an important consideration for the detection, evaluation, and management of chronic kidney disease. The Kidney Failure Risk Equation (https://ckdpcrisk.org/kidneyfailurerisk/) predicts the 2-year and 5-year risk of kidney failure with replacement therapy in people with glomerular filtration rate less than 60 mL/min/1.73 m^2 using four variables (age, sex, glomerular filtration rate, and albumin to creatinine ratio) or eight variables (the same four variables plus serum albumin, bicarbonate, calcium, and phosphorus). The Timing of Clinical Outcomes in CKD with Severely Decreased GFR instrument (https://ckdpcrisk.org/lowgfrevents/) predicts the 2-year and 4-year risk of kidney failure with replacement therapy, cardiovascular disease, and death in people with glomerular filtration rate less than 30 mL/min/1.73 m^2 from 10 variables (age, sex, race, glomerular filtration rate, albumin to creatinine ratio, systolic blood pressure, body mass index, presence or absence of diabetes, history of smoking, and history of cardiovascular disease).[23]

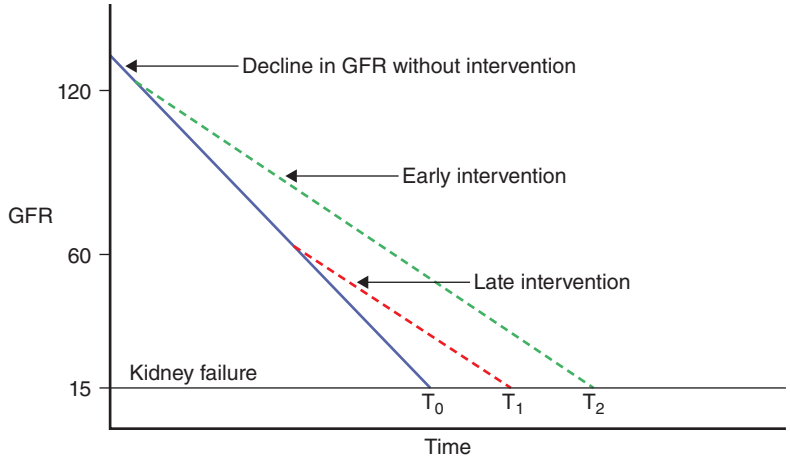
117 TREATMENT OF IRREVERSIBLE RENAL FAILURE

DAVID COHEN AND ANTHONY MICHAEL VALERI

Chronic kidney disease (Chapter 116) tends to progress over time as glomerular capillary hypertension leads to glomerular hyperfiltration, which in turn precipitates progressive injury, glomerulosclerosis, tubulointerstitial fibrosis, and progressive loss of nephrons, regardless of the original insult. Irreversible and advanced end-stage renal disease requires renal replacement therapy, which can be broadly categorized as hemodialysis, peritoneal dialysis, and renal transplantation. In the United States, about 800,000 people receive some form of renal replacement therapy; approximately 480,000 people receive in-center hemodialysis, 16,000 people receive home hemodialysis, 65,000 people are on peritoneal dialysis, and 245,000 have a functioning kidney transplant. Approximately 180,000 people develop end-stage renal disease every year.[1]

Renal replacement therapy must be initiated when fluid and electrolyte derangements, particularly hyperkalemia, acidosis, or volume overload, can



E-FIGURE 116-3. Beneficial effect of early vs. late intervention for CKD. Plot shows GFR decline vs. time since onset of CKD in the absence of intervention (blue line), after late intervention (red line), and after early intervention (green line). T_0 represents the interval from onset of CKD until onset of kidney failure (stage G5, 15 mL/min/1.73 m^2) in the absence of treatment. T_1 represents the interval until onset of kidney failure if treatment is initiated when decreased GFR is detected (G3a, <60 mL/min/1.73 m^2). T_2 represents the interval until onset of kidney failure if treatment is initiated before GFR declines when markers of kidney damage are detected (G1, >90 mL/m/min/1.73 m^2). The intervals from T_0 to T_2 and T_1 represent the benefit of early vs. late intervention, respectively. CKD = chronic kidney disease; GFR = glomerular filtration rate.

Extracellular fluid volume retention may be a potential risk of therapy with sodium bicarbonate.

Mild hyperkalemia (potassium level 5 to 5.5 mEq/L) generally requires no treatment other than education to avoid foods with large concentrations of potassium. Levels higher than 5.5 mEq/L generally require treatment[21] (Chapter 103). Urgent therapy for higher levels may include calcium gluconate to prevent cardiac arrhythmias; insulin, glucose, and bicarbonate to shift potassium from extracellular to intracellular fluid; loop diuretics, potassium-binding agents, and dialysis to remove potassium from the body; and treatment of reversible causes of hyperkalemia. If there are no reversible disorders, prevention includes dietary potassium restriction (<2 g/day) and potassium-binding agents (Chapter 103).

Metabolic bone disease is treated with phosphate-binding agents to maintain a normal serum phosphorus level (Chapter 105) and with activated vitamin D_3 (e.g., calcitriol starting at 0.25 μg to 0.5 μg orally every day or every other day depending on the glomerular filtration rate and the PTH level) or its analogues. In dialysis patients, calcimimetics (e.g., cinacalcet starting at 30 mg orally daily) should be used to suppress PTH. Subtotal parathyroidectomy is required in refractory cases of tertiary hyperparathyroidism (Chapter 207).

Treatment of symptomatic anemia includes iron repletion if indicated, erythropoiesis-stimulating agents, and red cell transfusions. To stimulate erythropoiesis, erythropoiesis-stimulating agents (e.g., darbepoetin alpha starting at 0.45 μg/kg every 4 weeks) are generally begun when the hemoglobin level is less than 9 g/dL in patients who have symptoms of anemia, who are likely to need red cell transfusions, and in whom the goal is to reduce the risk of alloimmunization or other transfusion-related risks (Chapter 162). Erythropoiesis-stimulating agents are associated with an increased risk of deep vein thrombosis and cardiovascular disease, so they are generally reserved for patients with stages G4 to G5 chronic kidney disease and are used to raise the hemoglobin level only to 10 to 11 g/dL because higher levels are associated with more cardiovascular complications. Hypoxia-inducible factor-stabilizing agents also are effective for raising the hemoglobin level[A9,A10] but are not currently approved in the United States for patients who are not being treated by dialysis because of safety concerns.

Kidney Replacement Therapy and End-of-Life Care

Kidney failure (glomerular filtration rate <15 mL/min/1.73 m^2), which is the end stage of chronic kidney disease, is treated for as long as possible with comprehensive conservative care, which is management of clinical disorders and symptoms of uremia to maintain quality of life without dialysis. When such care is no longer adequate for controlling symptoms and signs, kidney replacement therapy (Chapter 117) is required. Dialysis is effective in resolving the most severe symptoms and signs, but it is associated with many complications and often does not result in full resolution of symptoms and signs. Since both quality of life and survival are limited with dialysis, especially for older patients, kidney transplantation is preferred, whenever possible, to resolve symptoms and extend life. Unfortunately, it is not available to all patients.

End-of-life care (Chapter 3) refers to maintaining comfort at the end of life in patients treated by transplantation, dialysis, or comprehensive conservative care. A shared decision model is recommended for implementation of these modalities of therapy, and planning should begin well in advance of the onset of uremic symptoms.

PREVENTION

Primary prevention of chronic kidney disease refers to the prevention and treatment of risk factors for chronic kidney disease, including diabetes, hypertension, cardiovascular disease, and other associated systemic disorders, as well as reducing exposure to drugs and environmental toxins that cause kidney disease. Adoption of public health guidelines for a healthy lifestyle and diet can lower the prevalence of hypertension, diabetes, obesity, and cardiovascular disease. Secondary prevention to slow the progression of kidney disease relies upon early detection, such as evaluating albuminuria to assess kidney damage and the serum creatinine level to estimate the glomerular filtration rate, in patients who have hypertension, diabetes, cardiovascular disease, and other systemic diseases associated with an increased risk for chronic kidney disease.[22] Failure to assess markers of kidney damage delays the detection of chronic kidney disease and the ability to implement measures to slow its progression. Detection of albuminuria or other markers of kidney damage enables implementation of measures to slow progression before glomerular filtration rate declines, thereby potentially increasing the interval until the onset of kidney failure (E-Fig. 116-3). Tertiary prevention in chronic kidney disease refers to kidney replacement therapy for kidney failure to prevent complications and death.

PROGNOSIS

The prognosis in chronic kidney disease depends primarily on the cause of disease, the level of albuminuria and glomerular filtration rate, and the availability of treatment. Kidney disease often progresses even after the diseases that initially caused it are no longer active. Explanations include systemic hypertension, proteinuria, increased glomerular capillary pressure with increased glomerular filtration, and accumulation of nephrotoxins.

Risk stratification is an important consideration for the detection, evaluation, and management of chronic kidney disease. The Kidney Failure Risk Equation (https://ckdpcrisk.org/kidneyfailurerisk/) predicts the 2-year and 5-year risk of kidney failure with replacement therapy in people with glomerular filtration rate less than 60 mL/min/1.73 m^2 using four variables (age, sex, glomerular filtration rate, and albumin to creatinine ratio) or eight variables (the same four variables plus serum albumin, bicarbonate, calcium, and phosphorus). The Timing of Clinical Outcomes in CKD with Severely Decreased GFR instrument (https://ckdpcrisk.org/lowgfrevents/) predicts the 2-year and 4-year risk of kidney failure with replacement therapy, cardiovascular disease, and death in people with glomerular filtration rate less than 30 mL/min/1.73 m^2 from 10 variables (age, sex, race, glomerular filtration rate, albumin to creatinine ratio, systolic blood pressure, body mass index, presence or absence of diabetes, history of smoking, and history of cardiovascular disease).[23]

117 TREATMENT OF IRREVERSIBLE RENAL FAILURE

DAVID COHEN AND ANTHONY MICHAEL VALERI

Chronic kidney disease (Chapter 116) tends to progress over time as glomerular capillary hypertension leads to glomerular hyperfiltration, which in turn precipitates progressive injury, glomerulosclerosis, tubulointerstitial fibrosis, and progressive loss of nephrons, regardless of the original insult. Irreversible and advanced end-stage renal disease requires renal replacement therapy, which can be broadly categorized as hemodialysis, peritoneal dialysis, and renal transplantation. In the United States, about 800,000 people receive some form of renal replacement therapy; approximately 480,000 people receive in-center hemodialysis, 16,000 people receive home hemodialysis, 65,000 people are on peritoneal dialysis, and 245,000 have a functioning kidney transplant. Approximately 180,000 people develop end-stage renal disease every year.[1]

Renal replacement therapy must be initiated when fluid and electrolyte derangements, particularly hyperkalemia, acidosis, or volume overload, can

ABSTRACT

When conservative medical management is no longer adequate to manage patients with advanced kidney disease, renal replacement therapy becomes the only option. Treatments include dialysis and renal transplantation. In the United States, approximately 800,000 patients are currently receiving renal replacement therapy. Hemodialysis involves the flow of blood from the patient to the dialyzer, where diffusion of solutes along their concentration gradient and bulk convection of plasma water across a semipermeable membrane correct many of the acid-base and electrolyte abnormalities in the blood. The cleaned blood is then returned to the patient. Peritoneal dialysis involves the instillation of dialysis fluid into the patients' peritoneal cavity via an indwelling catheter. This technique relies upon diffusion and convection of solutes across the peritoneal membrane from the patient's blood into the peritoneal dialysis fluid, which is then drained via the peritoneal dialysis catheter. Renal transplantation, which involves surgically implanting a single kidney from a living or deceased donor, allows more complete correction of these problems and results in improved long-term survival compared with either form of dialysis. However, renal transplantation requires long-term immunosuppressive therapy to prevent rejection, with its attendant increased risk of infection and malignancy. Not all patients are medically suitable for renal transplant, and there remains a substantial shortage of available kidneys (approximately 90,000 patients on the waiting list and only about 25,000 transplants performed annually from about 19,000 deceased donors and about 6000 live donors). Although short-term success rates of kidney transplant are excellent, long-term results remain disappointing.

no longer be adequately controlled with dietary modifications and medications (Chapter 116) or if uremic symptoms, such as anorexia, nausea, vomiting, gastritis pericarditis, or encephalopathy, develop (Table 117-1). Renal replacement therapy typically is required when the estimated glomerular filtration rate (eGFR) is below 10 mL/minute, although it may be needed at an eGFR of 10 to 15 mL/minute when comorbid conditions, particularly heart failure, make medical management even more challenging and difficult. In one small randomized trial of critically ill patients with stage 2 acute kidney injury (defined as a serum creatinine level ≥2 times baseline or urinary output <0.5 mL/kg/hour for ≥12 hours and a plasma neutrophil gelatinase-associated lipocalin level >150 ng/mL), early initiation of renal replacement therapy reduced 90-day mortality compared with delayed initiation.[A1] However, larger randomized trials of intensive care unit patients with stage 3 acute kidney injury showed no reduction in mortality, and patients whose dialysis was delayed tended to have earlier diuresis, fewer adverse events, and a shorter duration of renal replacement therapy.[A2,A3] The routine initiation of dialysis (creatinine level 7.5 mg/dL) is no better than standard dialysis beginning at a creatinine level of approximately 10 mg/dL.[A4] Furthermore, intensive dialytic renal support therapy is no better than standard dialytic therapy, and intermittent hemodialysis and continuous renal replacement therapy lead to similar clinical outcomes in acute renal failure. It also is important to verify that the prescribed dialysis is received and that standardized measures are achieved. Some patients—especially patients in an increased catabolic state, trauma patients, and patients receiving glucocorticoids—may require dialysis more than three times per week to achieve adequate therapy. Neither furosemide nor low-dose dopamine improves outcome, even though low-dose dopamine may temporarily improve metrics of renal physiology.

Hemodialysis relies on diffusion across a semipermeable artificial membrane, whereas peritoneal dialysis brings the blood and the dialysate solution in contact across a natural biologic membrane. The diffusion of solutes along their respective concentration gradients across a semipermeable membrane removes nitrogenous waste products and corrects imbalances of potassium, calcium, magnesium, phosphorus, and acid. In addition, plasma water filters across the membrane and, by convection, drags solutes across the membrane in approximately the same concentration as in the plasma water. The electrolyte concentrations in the dialysate solution are not necessarily physiologic but are intentionally varied with respect to their potassium, calcium, magnesium, and bicarbonate concentrations to favor correction of the plasma toward a more normal physiologic state. For example, a typical dialysate solution might use a potassium concentration of 2 mEq/L and a bicarbonate concentration of 35 mEq/L to enable correction of hyperkalemia and uremic metabolic acidosis. Convection across the dialysis membrane is driven by either a hydrostatic pressure gradient applied across the membrane (hemodialysis) or an oncotic pressure gradient using high-dextrose concentrations or a large, poorly absorbed carbohydrate polymer in the dialysate solution (peritoneal dialysis) for the removal and filtration of excess salt and water from the body.

DIALYSIS

HEMODIALYSIS

Conventional hemodialysis is typically provided at an outpatient dialysis unit where patients are treated three times per week for 3 or 4 hours per session. The measures used for determining the adequacy of treatment are based on urea clearance (as a surrogate marker molecule for the generation and clearance of small-molecular-weight nitrogenous waste products, <500 daltons). The simplest measure is the urea reduction ratio, which is the percentage fall in the blood urea nitrogen level with each dialysis session, with a goal of 65% or greater, or a single pool normalized urea clearance based on the single pool variable volume urea kinetic model *(spKt/V)* of 1.2 or greater on a thrice-weekly dialysis schedule. More precise measurements can fine-tune the dialysis in an individual patient. A more intensive protocol for increased urea clearance with a 40% increase in the *spKt/V* from 1.32 to 1.53 on a thrice-weekly schedule does not improve survival, perhaps because it increases the likelihood of hypotension during dialysis. More frequent hemodialysis, whether as in-center hemodialysis or nocturnal home hemodialysis six times per week, improves outcomes such as kidney-specific measures of quality of life, blood pressure, regression of left ventricular hypertrophy, and serum phosphorus levels, but it did not reduce mortality at 12 months, although longer follow-up (median of 3.6 years) showed a 46% reduction in mortality.[A5]

Patients on hemodialysis are exposed to a large volume of dialysate solution (typically 36 to 48 L/hour during dialysis) and must be protected against even small quantities of impurities, such as trace minerals, bacteria, and bacterial endotoxins, in the dialysis solution. To this end, dialysate solutions are prepared from concentrates diluted with water prepared by reverse osmosis systems or deionizer tanks to remove undesired trace cations and anions and then filtered through small micron-sized pore filters to remove bacteria and their byproducts. Exposure to low levels of bacteria and bacterial byproducts may contribute to the chronic inflammation seen in some patients on hemodialysis.

In critically ill patients who are hemodynamically unstable, one alternative is continuous venovenous hemofiltration, which requires central venous access (double-lumen catheter) and blood flows between 150 and 300 mL/minute. Plasma water under pressure passes across one side of a highly permeable membrane, thereby allowing both water and solutes up to about 60 kD to be removed. In contrast to hemodialysis, urea, creatinine, and phosphate are cleared at similar rates (convective clearance) during hemofiltration, but with improved clearance of larger molecular weight solute ("middle molecules"). The filtrate is discarded, and the fluid lost is partially replaced with a solution containing the major crystalloid components of the plasma at physiologic levels. However, there is no evidence from randomized trials that continuous venovenous hemofiltration offers a survival advantage compared with intermittent hemodialysis in patients with acute renal failure.

New modes of hemodialysis, used predominantly outside the United States, have sought to take advantage of convection to increase the clearance of middle molecules by using high-flux dialysis membranes and ultrafiltration rates of more than 20 L of fluid per dialysis session. In a large randomized trial, this approach, termed high-efficiency postdilution online hemofiltration, reduced all-cause mortality by 30%.

Uremic toxins are classified as low molecular weight (<500 daltons), middle molecular weight (500-60,000) protein-derived metabolites/solutes, and protein-bound solutes. Conventional hemodialysis is most efficient at the removal of low-molecular-weight uremic solutes (<500 daltons). One method to increase the removal of larger-molecular-weight uremic solutes ("middle molecules" in the 500 to 5000 dalton range) is by extending the time on dialysis to permit greater diffusion of these molecules across the dialysis membrane. However, the benefits of this approach remain unclear. Another method of increasing the clearance of middle-molecular-weight uremic solutes is by the use of membranes with larger pore sizes (referred to as medium cutoff dialyzers), which are able to achieve clearances comparable to or, for molecules at the higher end of this range, superior to hemodiafiltration with standard dialyzers. The concern, however, is the filtration and loss of albumin and the long-term implications in terms of overall nutritional status.[A6–A8]

The most common complications during hemodialysis are vascular access problems, hypotension, muscle cramps, nausea, vomiting, headache, and chest pain. Excessive fluid removal is the most frequent cause of hypotension, but persistent hypotension may be caused by sepsis (Chapter 94), myocardial ischemia (Chapter 57), pericardial tamponade (Chapter 62), arrhythmias (Chapters 49 to 53), and active bleeding. A rare complication is an air embolus (Chapter 68), which is manifested with agitation, cough, dyspnea, and chest pain. The patient should be given 100% oxygen and positioned with the left side down (Duran position) in Trendelenburg, or flat and supine, in an attempt to trap air in the right ventricle.

TABLE 117-1 INDICATIONS FOR DIALYSIS IN CHRONIC KIDNEY DISEASE

Uremic encephalopathy or neuropathy
Pericarditis or pleuritis
Bleeding attributable to uremia
Fluid overload refractory to diuretics
Hypertension poorly responsive to medication
Persistent hyperkalemia, metabolic acidosis, hypercalcemia, hypocalcemia, or hyperphosphatemia refractory to medical therapy
Malnutrition or weight loss
Persistent nausea and vomiting

PERITONEAL DIALYSIS

Peritoneal dialysis,[2] which is an alternative mode of renal replacement therapy, is usually performed at home by the patient or the patient's family. A peritoneal dialysis catheter is implanted through a surgically created tunnel in the abdominal wall and inserted into the peritoneal cavity. The catheter's tip in the pelvis is used to instill a dialysis solution into the peritoneal cavity and then to drain the solution from it. Peritoneal dialysis uses the peritoneal

membrane, which consists of the visceral peritoneum, the interstitial tissues, and the mesenteric capillaries, as the filter across which the diffusion of solutes and convection of plasma water occur. Different forms include continuous ambulatory peritoneal dialysis, which is typically performed with 1.5- to 3-L exchanges of peritoneal dialysis solution instilled in the abdomen through a Tenckhoff catheter four times per day; automated peritoneal dialysis, which is performed with a cycler machine at night cycling 1.5 to 3 L of peritoneal dialysis fluid into and out of the abdomen four or five times overnight; and continuous cyclic peritoneal dialysis, a hybrid of continuous ambulatory peritoneal dialysis and automated peritoneal dialysis that uses cycler therapy at night combined with one or two manual exchanges during the day. *Kt/V* urea is the total volume clearance of urea (*Kt*) normalized to the urea space, *V*, which is approximately equal to total body water. For patients who are treated with peritoneal dialysis, residual renal function is often important for ensuring adequate clearance of uremic toxins. For such patients, residual renal function is measured periodically by a 24-hour urine collection. Then the amount of clearance of urea is also measured from the fluid drained from the patient's abdominal cavity after a dialysate exchange to be sure that total urea clearance, from the dialysate plus residual renal function, meets the minimal clearance that is recommended for the patient.

Clearance of small solutes is a key predictor of survival in patients undergoing peritoneal dialysis, and residual renal function also plays a critical role. Current guidelines advocate a minimal target *Kt/V* urea of at least 1.7 per week. Every effort should be made to maintain residual renal function as long as possible by avoiding nephrotoxins such as nonsteroidal anti-inflammatory drugs, iodinated contrast agents, and aminoglycosides. As residual renal function diminishes over time, the peritoneal dialysis prescription needs to be adjusted accordingly.

MEDICAL ISSUES

Renal replacement therapy is concerned not only with adequate dialytic clearance of nitrogenous waste products, the restoration of acid-base and electrolyte balance, and the control of salt and water balance but also with preserving adequate access sites for dialysis, nutrition, and the management of anemia, bone diseases, and cardiovascular risk.

Access Issues

The optimal dialysis access for hemodialysis is a native vein arteriovenous fistula, which can be created by the surgical anastomosis of the radial artery to the cephalic vein or of the brachial artery to either the brachiocephalic or the basilic vein. If a patient's veins are inadequate, a synthetic graft can be placed between the radial, brachial, or axillary artery and the brachiocephalic, basilic, or axillary vein as an alternative. Most commonly, these grafts are made from a synthetic polymer, expanded polytetrafluoroethylene. Less frequently, urgent temporary access can be obtained with a dual-lumen central venous dialysis catheter that is inserted into the internal jugular (preferable) or subclavian vein (right preferred to left). Dialysis access requires periodic Doppler monitoring to detect stenoses that can lead to reduced or even inadequate blood flow, thereby resulting in inadequate urea clearance and, if untreated, thrombosis. These stenoses can be treated by percutaneous transluminal angioplasty, with drug-coated balloons preferable to standard angioplasty,[A9] although stenting is sometimes required to maintain adequate luminal patency.

Nutrition

Adequate nutrition is important for optimizing outcome with renal replacement therapy, and rates of hospitalization are reduced when patients ingest at least 1 g/kg/day of protein. Another marker of nutritional status is the serum albumin level, which generally serves as a reasonable predictor of outcomes with renal replacement therapy.

Anemia

Anemia in end-stage renal disease is due to the reduced production of erythropoietin by the diseased kidneys, a shortened half-life of red blood cells, and the potential loss of red blood cells in the extracorporeal dialysis circuit and the gastrointestinal tract (related to intermittent anticoagulation for the hemodialysis procedure). Erythropoietic stimulating agents should aim to avoid transfusion by maintaining the hemoglobin level generally above 9 g/dL but not higher than 11 g/dL because higher levels are associated with more cardiovascular complications. Patients who have relative or absolute iron deficiency, as evidenced by a transferrin saturation below 20 to 25% or a serum ferritin level below 200, are often relatively resistant to erythropoietic stimulating agents and can benefit from the concurrent administration of a 1-g course (during 8 to 10 dialysis sessions) of intravenous iron (iron sucrose, ferric gluconate, ferumoxytol, or ferric carboxymaltose).[A10]

Unlike the original class of erythropoietic stimulating agents, which were erythropoietin or modified forms of it, a new class of agents (e.g., roxadustat, vadadustat, and daprodustat) inhibits the metabolism and degradation of the α subunit of hypoxia-inducible factor.[A11–A13] This factor stimulates the production of erythropoietin from the kidney and liver and also enhances the mobilization and utilization of iron from stores in the reticuloendothelial system by suppressing the production of hepcidin in the liver. Daprodustat is the first of these drugs to be approved by the U.S. Food and Drug Administration for the treatment of anemia in end-stage renal disease patients on dialysis.

Metabolic Bone Disease

Metabolic bone disease and phosphorus imbalance are common in end-stage renal disease. Clinical manifestations of renal osteodystrophy (Chapter 116) can range from adynamic bone disease to osteomalacia (Chapter 226) to secondary hyperparathyroidism (Chapter 227) and osteitis fibrosa cystica. The goals of therapy are to achieve a serum phosphorus level within or close to the normal physiologic range, typically about 2.5 to 5.5 g/dL; a corrected calcium (0.8 × [4 − Serum albumin level] + Serum calcium level])–phosphorus product less than 55; and an intact parathyroid hormone level within two to nine times the upper limit of normal.[3] Management includes the restriction of dietary phosphate to 750 to 1000 mg/day of elemental phosphorus; the use of phosphate binders (calcium carbonate or acetate, sevelamer carbonate, lanthanum carbonate, or potentially other cationic agents, magnesium or ferric ion) with meals to bind phosphate in the intestines and to reduce its absorption; the use of activated forms of vitamin D (e.g., calcitriol [0.5 to 4 μg IV or 0.5 to 1 μg PO], paricalcitol [1 to 15 μg IV or PO], or doxercalciferol [1 to 6 μg IV or 5 to 20 μg PO] at each hemodialysis session) to stimulate the parathyroid cells to suppress parathyroid hormone secretion; and cinacalcet (30 to 180 mg daily) to reduce secondary hyperparathyroidism significantly by nearly 70%, even though it does not provide a survival benefit over activated vitamin D therapy alone. Etelcalcetide, which is an intravenous calcimimetic, that is, administered during dialysis sessions, appears to be an equally effective alternative to daily oral cinacalcet.[A14]

Hyperphosphatemia can also lead to pruritus, which occurs in about 50% of patients. If moderate-to-severe pruritus persists, however, intravenous difelikefalin (0.5 μg/kg three times per week) can significantly reduce itching and improve itch-related quality of life.[A15] Reducing the serum phosphorus level is the key treatment.

Cardiovascular Disease

Cardiovascular disease is the leading cause of morbidity and mortality in patients on dialysis. The mainstay of blood pressure control in renal replacement therapy is to achieve the lowest tolerated postdialysis weight to facilitate blood pressure control and enhance the body's sensitivity to antihypertensive agents. The general approach to antihypertensive medication therapy is similar to the approach for other patients, with the exception that diuretics are not helpful (see Tables 64-7 and 64-9). The ideal or goal interdialytic blood pressure for the patient with end-stage renal disease is probably 125 to 145 mm Hg systolic.

Dialysis-dependent chronic kidney disease is an indicator for the same type of aspirin therapy and β-adrenergic blockade used in survivors of a myocardial infarction (Chapters 57 and 58). Statin therapy (Chapter 190) is often recommended, but statins are not of proven benefit for reducing major cardiovascular events or overall mortality in dialysis patients despite clinically relevant reductions in low-density lipoprotein cholesterol levels. The addition of spironolactone (25 mg daily) can reduce the risk of a cardiovascular or cerebrovascular event by about 50%. Control of diabetes (Chapter 210) is important, but mortality in hemodialysis patients is not increased until the hemoglobin A_{1c} level is 8.5% or higher. In patients with chronic kidney disease and stable moderate or severe coronary disease, an initial invasive coronary strategy is no better than a conservative guideline-based strategy.[A16,A17]

Amyloidosis

Dialysis-associated amyloidosis (Chapter 174), typically seen in patients who have been on dialysis for more than 10 to 12 years, is caused by the deposition of end-products of β_2-microglobulin catabolism as amyloid fibrils. The clinical syndrome includes carpal tunnel syndrome (Chapter 388), arthropathy, and autonomic neuropathy (Chapter 386).

Infection

Infection is the second leading cause of morbidity and mortality in dialysis patients. For example, patients on hemodialysis account for about 8% of all patients who develop bacterial endocarditis (Chapter 61), with *S. aureus* and enterococcal endocarditis being equally common.[4]

In hemodialysis, vascular access sites are the primary sources of bacteria and account for about 75% of all cases of bacteremia. In a patient with possible catheter-related bacteremia, blood culture specimens should be obtained both from the catheter and from a peripheral vein. Most vascular access infections are caused by staphylococcal organisms (Chapter 267) and should be treated empirically with vancomycin (15 to 20 mg/kg or approximately 1 g) at the end of each dialysis session, adjusted to blood levels, unless another organism is cultured. In patients with systemic sepsis (Chapter 94) with hemodynamic instability, the line should be pulled promptly and reinserted only after blood cultures are negative for at least 48 hours and the patient has defervesced. Interim dialysis can use an alternative access site, such as a temporary nontunneled catheter. A prolonged course of antibiotic therapy (4 to 8 weeks) is recommended for bacteremia or fungemia that persists after the catheter is removed or in patients with evidence of endocarditis (Chapter 61), septic arthritis (Chapter 251), osteomyelitis (Chapter 251), epidural abscess (Chapter 381), or other metastatic infection.

With peritoneal dialysis, infection is the most frequent reason that the catheter must be removed and therapy discontinued. Infection is suspected by erythema, tenderness, induration, or purulent or bloody drainage. Peritonitis must be suspected in patients with abdominal pain and cloudy dialysate; the physical examination usually shows abdominal tenderness, often with rebound. The peritoneal fluid white blood cell count is typically above 100/μL with a predominance of neutrophils, although lymphocytes may predominate with fungal or mycobacterial infections. Polymicrobial infections should raise the possibility of a perforated diverticulum (Chapter 128), ruptured appendix (Chapter 128), ischemic bowel (Chapter 129), incarcerated hernia (Chapter 128), pancreatitis (Chapter 130), or gynecologic conditions (Chapters 184, and 219) and should prompt an emergent abdominal computed tomography scan. *Staphylococcus epidermidis* (Chapter 267) is the most common cause of peritonitis, but *Pseudomonas* species (Chapter 282) account for 5 to 8% of cases. Recommended initial empirical treatment is intraperitoneal, unless there is evidence of bacteremia or hematogenous spread of the infection. Options include vancomycin (15 to 30 mg/kg in one exchange every 5 to 7 days as guided by serum levels) or a cephalosporin (e.g., cefazolin, 15 to 20 mg/kg in one exchange daily) together with intravenous or intraperitoneal administration of a third-generation cephalosporin with antipseudomonal activity (e.g., ceftazidime, 1 to 1.5 g in one exchange daily) or gentamicin (0.6 mg/kg in one exchange daily) for at least 2 weeks.

Staphylococcus aureus (Chapter 267) is the most common organism for exit site and tunnel infections. Treatment options include empirical oral penicillinase-resistant penicillins (e.g., dicloxacillin, 250 to 500 mg twice daily), fluoroquinolones (e.g., ciprofloxacin, 250 mg twice daily or 500 mg daily), trimethoprim-sulfamethoxazole (e.g., 80 mg/400 mg twice daily or 160 mg/800 mg daily), and cephalosporins (e.g., cephalexin, 500 mg two to three times per day). Vancomycin should be avoided as first-line therapy except for methicillin-resistant *S. aureus*. Mupirocin nasal ointment applied to the exit site twice daily for 5 days every 4 weeks significantly reduces the incidence of *S. aureus* exit site infections.

PROGNOSIS

The prognosis of patients with end-stage renal disease on chronic dialysis depends on their age and other comorbid conditions, especially diabetes. On average, the 5-year survival rate is about 40 to 50% and is similar for hemodialysis and peritoneal dialysis. Survival rates are markedly lower than for the age-matched U.S. population (Table 117-2). The leading cause of death is arrhythmic cardiac arrest, but about 15% of deaths are related to withdrawal of dialysis.

RENAL TRANSPLANTATION

For appropriate patients, renal transplantation continues to be the best treatment for advanced chronic kidney disease. The success of renal transplantation has increased dramatically during the past several decades owing to improved surgical technique, improved medical care, and safer and more effective immunosuppressive medications. Although transplant recipients do not have a normal life expectancy, current 5-year survival rates are nearly twice as high as for similar patients who remain on dialysis or on the transplant waiting list. Several long-held axioms have been proved false, most notably the need for long-term steroid therapy, the impossibility of transplantation in the face of antidonor human leukocyte antigen (HLA) antibodies (positive crossmatch), the inability to transplant ABO-incompatible donor-recipient pairs, and the inability to create long-term tolerance. Despite this remarkable progress, the number of patients on the waiting list far exceeds the number of available kidneys, and the long-term survival rates for kidneys and patients remain disappointing.

EPIDEMIOLOGY

Over 26,000 total renal transplants, including combined kidney-pancreas, kidney-liver, and kidney-heart, are performed annually in the United States. The most common disease leading to renal transplantation is diabetic nephrosclerosis (Chapter 109), followed by hypertensive nephrosclerosis (Chapter 110) and other forms of glomerulonephritis (Chapter 107). Kidney transplant recipients vary in age from infants to older than 80 years, with the majority being between 35 and 64 years of age. About 65% of the kidneys transplanted

85+	2.4	2.1			3.8	3.3

*For patients age 75+ years.

Table shows the expected remaining lifetime, in years, for the 2020 prevalent end-stage renal population and the general U.S. population. The table illustrates the markedly foreshortened projected lifespan for patients with end-stage renal disease relative to those without. In individuals aged 40-44 years, for example, there is a >25-year projected lifespan difference between men receiving dialysis (expectancy 9.4 years) and men in the general population (expectancy 35.3 years); the difference was >30 years for women receiving dialysis.

Data Source: USRDS ESRD database. 2022 Annual Data Report, End Stage Renal Disease Chapter 6, Table 6-1, https://usrds-adr.niddk.nih.gov/2022, and National Vital Statistics Report Volume 71, 2022. United States Life Tables 2020, Tables 2,3.

in the United States are from deceased donors, with the other 35% from living donors, who include both living genetically related family members and genetically unrelated donors, most often spouses or friends. The number of deceased kidney donors has increased in recent years, in part due to the opioid epidemic, whereas the number of living donors has remained relatively constant, as has the number of patients on the active transplant waitlist. Currently, the number of patients on the active waitlist is three times larger than the supply of kidneys; and, as a result, the median waiting time for a patient listed for kidney transplantation exceeds 4 years. Fewer than 50% of candidates on the waitlist are transplanted within 5 years of listing, and approximately one third either die or are removed from the waitlist without having received a transplant. Due to improved survival and reduced costs of kidney transplantation compared with dialysis, the U.S, government has recently taken initiatives to encourage increased rates of transplantation for patients with end-stage renal disease.[5]

Renal Transplant Success Rates

For deceased donor kidney transplants, the overall 1-year success rate is approximately 93%, and the 10-year success rate is approximately 50%. For recipients of live donor kidney transplants, the overall 1-year success rate is more than 97%, and the 10-year success rate is 65%.

KIDNEY DONATION

Potential *living kidney donors* undergo a thorough evaluation to ensure that age-adjusted renal function is normal, that the surgical risk of donor nephrectomy is acceptably low, and that there are no medical conditions that would increase the risk of future renal disease in the donor. In addition, all donors are screened for transmissible infections or malignant neoplasms.

Potential donors must be capable of understanding the risks and benefits of live kidney donation, cannot be coerced into donating, and cannot condition the donation on the receipt of money or other valuable goods. Federal law prohibits the buying and selling of organs. Although recent data suggest that live kidney donors have a 3.5- to 5.3-fold higher risk for developing end-stage renal disease compared with healthy non-donors during the 10 years after donation, the absolute risk remains less than 1%.[6] Gestational hypertension or preeclampsia also is more likely in kidney donors than in matched nondonors.

Potential recipients who have a willing and medically and psychosocially suitable live donor, but who either have preformed antidonor HLA antibodies or are blood group incompatible with their potential donor, can receive successful transplants by desensitization protocols that involve intravenous immune globulin and plasmapheresis to reduce the level of antidonor HLA antibodies or isoagglutinins. Despite remarkable short-term success, the high incidence of antibody-mediated rejection has made long-term success rates somewhat disappointing, at about 60 to 70% at 5 years. However, data indicate that patients who receive kidney transplants from HLA-incompatible live donors still realize a substantial survival benefit compared with similar patients who wait for compatible transplants from deceased donors or who remain on the waitlist. An increasingly popular alternative to desensitization is kidney-paired donation. In this scenario, two recipients, each with an incompatible live donor who is compatible with the other recipient, exchange donors, thereby creating two immunologically compatible donor-recipient pairs. Over 1000 annual paired donation transplants in the United States now account for approximately 15% of all living-donor transplants. In some situations, more complicated exchanges may involve multiple donor-recipient pairs.

The majority of deceased donors are brain dead, as a result of head trauma (Chapter 368), cerebrovascular catastrophe (Chapter 377), or anoxia (Chapter 50), but continue to maintain a normal circulation. The Uniform Anatomical Gift Act of 1968 and subsequent revisions equate brain death with death (Chapter 2) and permit organ donation after a declaration of brain death, provided there is consent from the family of the deceased. Events surrounding brain death and organ procurement may result in acute kidney injury, and renal biopsies are frequently performed before implantation to assess kidney quality and potential longevity.

The shortage of available donor organs continues to plague the field of clinical transplantation. Attempts to increase the number of donor organs have included the use of lower quality kidneys, such as kidneys from older donors or donors with a history of diabetes mellitus or hypertension. Deceased donor kidneys are now rated on a continuous grading system—the Kidney Donor Profile Index (KDPI). Characteristics used to calculate the KDPI include the donor's age, height and weight, serum creatinine, history of hypertension, history of diabetes, hepatitis C status, whether the donation was after a cardiac death, and the cause of death. Lower KDPI values—higher quality kidneys—are associated with a lower inherent estimated risk of kidney failure (longer anticipated function after transplantation), whereas transplantation of kidneys with higher KDPI values will result in shorter estimated allograft survival times. This prognosis allows for better informed decision making on the part of both patients and physicians. Developing algorithms to facilitate the optimal use of suboptimal kidneys will continue to be a challenge. Protocols have also been developed to allow organ recovery from deceased donors after cessation of cardiac function (donation after cardiac death [DCD] donors). These kidneys function as well as those recovered by traditional donation after brain death.

Initiatives to increase the deceased donor pool include kidney transplantation from a human immunodeficiency virus (HIV)-positive donor to an HIV-infected recipient. With the availability of curative treatment for hepatitis C (Chapter 135), infected donor kidneys can now be used for hepatitis C-negative recipients, who then receive antiviral therapy immediately after transplantation.[7,8]

WHO IS A CANDIDATE FOR RENAL TRANSPLANTATION?

All patients with advanced chronic kidney disease must be informed about the option of transplantation. Candidates must undergo an age and gender appropriate comprehensive medical and psychosocial evaluation to determine their suitability. The major elements of the evaluation include an assessment of cardiovascular risk,[9,10] urologic suitability, cancer screening, risk of infection, and overall frailty. Because cardiovascular disease is common in end-stage renal disease patients, cardiovascular testing is often undertaken in patients older than 50 years and in patients with a history of diabetes (Chapter 401). In general, contraindications to transplant include active uncontrolled infection, cancer not amenable to treatment, advanced untreatable cardiac disease, cirrhosis, advanced chronic lung disease, inability to follow the post-transplant medical regimen owing to psychosocial reasons, and poor perioperative risk. For otherwise suitable patients with advanced liver, lung, cardiac disease, combined liver-kidney, lung-kidney, or heart-kidney transplantation may be an appropriate option. Despite consensus guidelines, the criteria for listing a candidate for transplant vary among transplant centers.[11]

ALLOCATION

The national systems in the U.S. (the United Network for Organ Sharing) and in virtually every country oversee the distribution of deceased donor kidneys. Given the imbalance between demand and supply, this allocation system attempts to balance equity and utility. Some prioritization is given to patients who are likely to have the best allograft survival, but all suitable candidates have a chance to receive a kidney.

The national system for the allocation of deceased donor organs in the United States is divided into 58 donor service areas, each with an organ procurement organization responsible for procuring and allocating deceased donor organs. The distribution of these organs is first local, then regional, and finally national if no local compatible recipient exists. Waiting time for active listing can begin from the date a patient first starts dialysis, or when their eGFR is <20 mL/minute. The current allocation system largely prioritizes waitlisted candidates with longest waiting time as first in line for the next available compatible kidney within their blood group. Each waitlisted patient receives an Estimated Post-Transplant Survival (EPTS) score based on four factors: time on dialysis, current diagnosis of diabetes, prior solid organ transplants, and age. Patients with low EPTS scores (longer predicted post-transplant survival) are prioritized to receive donor organs with longer anticipated function, beginning the practice of longevity matching in kidney allocation. Special consideration is given to children who are waitlisted prior to age 18 years, patients with high levels of anti-HLA antibodies (for whom compatible donors are difficult to find), patients receiving combined (heart-kidney, liver-kidney, or lung-kidney) transplants, and patients for whom a potential donor has a high degree of HLA matching.[12]

IMMUNOSUPPRESSION

Notwithstanding several reports of successful medication-free long-term renal allograft survival in small numbers of carefully selected patients undergoing complicated conditioning regimens, long-term immunosuppression remains obligatory in virtually all patients to achieve long-term renal allograft survival. The principal drivers of the immune response to an organ allograft and the principal obstacle to organ acceptance are the HLA antigens (Chapter 38). HLA-identical siblings enjoy the best long-term survival rates, and increasing degrees of HLA antigen *mis*match continue to be associated with inferior long-term outcomes (Chapter 38).

Immunosuppressive treatment can be divided into three phases: induction, maintenance, and antirejection (Table 117-3). Induction immunosuppression consists of antilymphocyte antibodies given within the first week immediately after transplantation. Maintenance immunosuppression refers to those medications given daily as long as the allograft is functioning. Antirejection therapy is given to treat episodes of acute or chronic rejection.

For about two thirds of patients, the standard maintenance therapy for the long-term prevention of renal allograft rejection is a three-drug regimen: a calcineurin inhibitor, a purine synthesis inhibitor, and a corticosteroid—tacrolimus, mycophenolate, and prednisone. In the approximately one third of patients with a low-to-moderate risk of rejection, corticosteroids can be safely withdrawn within the first week after transplantation,[A18] and a dual-therapy regimen of mycophenolate and tacrolimus is continued. Outcomes appear to be similar with either regimen. In a randomized trial, however, substituting belatacept (a costimulation blocker) for cyclosporine reduced the 7-year risk of death from graft failure more than 40% and resulted in significantly improved allograft function without an increase in any adverse events, despite a higher number of early acute rejection episodes.[A19]

Induction therapy consists of polyclonal or monoclonal antilymphocyte antibodies administered in the first week after transplantation. Approximately 80% of kidney transplant recipients are in centers that administer induction therapy, the majority with rabbit-derived polyclonal antilymphocyte serum (usually 6 mg/kg total dose) and the others with either basiliximab (20 mg, day 0 and day 4) or alemtuzumab (30-mg single dose). The goals of induction therapy include a reduction in the number of acute rejection episodes in the first several weeks or months after transplantation, a long-term reduction in the overall number of acute rejection episodes, and a resulting improvement in long-term success rates. The addition of cell-based biologic products (regulatory T cells, dendritic cells, or macrophages) is an experimental approach under investigation, with the goal of permitting a reduction in long-term immunosuppression, without any compromise in results (Chapter 38).[13]

REJECTION AND ITS TREATMENT

Despite the availability of more effective and safer immunosuppressive medications, rejection remains an ever-present threat, and a significant proportion of allograft failures are ultimately caused by immune-mediated injury. Classically, there are three types of rejection: hyperacute, acute, and chronic. Histological definitions of acute and chronic rejection are based on criteria (Banff Classification) established and periodically updated by a working group of pathologists and clinicians. Most recently, the category of chronic T-cell mediated rejection has been recognized, and criteria for its diagnosis have been outlined.[14]

Hyperacute rejection occurs when a kidney is transplanted into a recipient who is presensitized to the donor. The recipient's circulating preformed antidonor antibodies may target HLA antigens, blood group (ABO) antigens, or endothelial cell antigens expressed on the donor kidney. The result is immediate endothelial injury and irreversible thrombosis of the transplant. Because of the prescreening of all donor-recipient pairs for the presence of such antidonor antibodies, hyperacute rejection occurs in less than 1% of all renal transplants.

Acute rejection is characterized clinically by an increase in the serum creatinine level over days to weeks, often in the absence of symptoms. On pathologic examination, acute rejection is most frequently "cellular" and characterized by T-lymphocyte infiltration of the tubules, interstitium, and of the vascular structures in more severe rejection. Acute rejection now occurs in only 10 to 15% of transplant patients during the first post-transplantation year and about another 10% in the second year. The majority of acute rejections occur in the first 3 to 6 months after transplantation and are clinically mild, treatable, and reversible. Other causes of allograft dysfunction (e.g., hemodynamic factors such as hypotension and volume depletion, urinary tract obstruction, drug-induced nephrotoxicity, and BK polyomavirus nephropathy) must be excluded. Percutaneous biopsy of the allograft is required to establish the diagnosis with certainty, to determine the type and severity of the rejection, and to guide therapeutic decisions. Acute cellular rejection should be treated immediately, either with high-dose intravenous corticosteroid therapy for milder forms or with polyclonal antilymphocyte sera for steroid-resistant or more severe acute rejection episodes. Such treatment is usually effective at resolving the episode.

Between 10 and 20% of patients have acute antibody-mediated rejection injury, due either to preformed antidonor antibodies or to the development of de novo donor specific antibodies. A hallmark of acute antibody-mediated rejection is the deposition of C4d, a metabolite of a complement component C4, in the peritubular capillaries, accompanied by inflammatory cells in the peritubular capillaries. This antibody-mediated rejection may occur alone or in combination with cellular rejection. Early antibody-mediated rejection is much more common in patients with a prior history of exposure to alloantigen through transfusion, pregnancy, or prior transplantation. The development of sensitive reagents for detection of circulating antidonor antibodies has greatly facilitated the diagnosis of antibody-mediated rejection. Treatment is more problematic, and patients frequently receive plasmapheresis to remove antidonor antibodies, high dose corticosteroids, and/or polyclonal antilymphocyte globulin, as well as various regimens of intravenous immune globulin. Although

TABLE 117-3 IMMUNOSUPPRESSIVE MEDICATIONS USED IN RENAL TRANSPLANTATION

CLASS	DRUGS	HOW USED	MECHANISM OF ACTION	MAJOR ADVERSE EFFECTS
Steroids	Prednisone, methylprednisolone	Induction, maintenance, antirejection	Multiple sites, anti-inflammatory; inhibit production of multiple cytokines	Poor wound healing, weight gain, diabetes, acne, hypertension, cushingoid appearance
Calcineurin inhibitors	Tacrolimus and cyclosporine	Maintenance	Inhibit calcineurin, prevent interleukin-2 production	Nephrotoxicity, hypertension, diabetes mellitus
Purine synthesis inhibitors	Azathioprine	Maintenance	Metabolized to 6-mercaptopurine	Anemia, leukopenia, thrombocytopenia
	Mycophenolic acid	Maintenance	Inhibits purine synthesis by the inhibition of inosine monophosphate dehydrogenase, specific for the purine de novo pathway on which lymphocytes depend	Anemia, leukopenia, thrombocytopenia; teratogenic
mTOR inhibitors	Sirolimus, everolimus	Maintenance	Inhibit mTOR (mammalian target of rapamycin), block lymphocyte response to growth factors	Poor wound healing, proteinuria, hyperlipidemia
Costimulation blockade	Belatacept	Maintenance	Human recombinant fusion protein combining the extracellular portion of cytotoxic T lymphocyte–associated antigen-4 (CTLA-4) with the Fc fragment of human IgG; this binds to the CTLA-4 receptor, preventing engagement of CTLA-4 on the T cell, preventing costimulation	Central nervous system post-transplantation lymphoproliferative disease
T cell–depleting antibodies	Thymoglobulin	Induction, antirejection	Rabbit-derived polyclonal antilymphocyte serum (multiple targets)	Infusion reaction, leukopenia, thrombocytopenia
	Alemtuzumab	Induction	Anti-CDS2	
Anti-IL2R monoclonal antibodies	Basiliximab	Induction	Block interleukin-2 receptor (IL2R)	Rare infusion reaction

Ig = immunoglobulin.

this treatment is often effective in reversing acute antibody-mediated rejection, successful elimination of antidonor antibody and prevention of alloantibody resynthesis are much more difficult. Chronic antibody-mediated rejection frequently follows an episode of acute antibody-mediated rejection.

Chronic rejection is characterized by a slow decline in allograft function, generally during a period of months to years, and frequently accompanied by proteinuria. Although it can occur in the absence of documented episodes of acute rejection and after many years of stable allograft function, early acute rejection is a major risk factor for later chronic rejection and allograft failure. The development of donor-specific anti-HLA antibodies appears to be a strong risk factor for subsequent allograft failure. Antibodies targeting non-HLA loci are also likely to play an important role.[15,16] Anti-HLA antibodies are detectable in a high percentage of cases of chronic allograft dysfunction.[17] Biopsy may show evidence of T cell–induced injury, antibody-induced injury with deposits of C4d, transplant glomerulopathy, or a combination of these findings. In many patients with long-term deterioration of allograft function, however, the only findings are interstitial fibrosis and tubular atrophy, often accompanied by arteriolar hyalinosis, without clear-cut evidence as to the cause. Unfortunately, no treatment has been proved to be effective for chronic T cell or chronic antibody-mediated rejection, which are common causes of long-term allograft failure.

OTHER COMPLICATIONS OF RENAL TRANSPLANTATION

Immunosuppression in renal transplant recipients is associated with a number of adverse effects, the most important of which are infection, malignant neoplasia, and nephrotoxicity.

Infection

Infections occurring in the first few weeks after transplantation are generally nosocomial (Chapter 260), donor derived, present in the recipient at the time of transplantation, or a result of complications of the surgical procedure, such as wound, catheter-associated, or urinary tract infections (Chapter 263) (Fig. 117-1). Next is a period of 5 to 6 months during which opportunistic infection or reactivation of latent infection, such as cytomegalovirus (CMV) infection (Chapter 347) or Epstein-Barr virus (EBV) infection (Chapter 348), is most likely to occur. Later in the course, when the doses of immunosuppressive medication are decreased, community-acquired infections are most common. This timeline is partly a function of infection prophylaxis, given to all renal transplant recipients to minimize infectious complications during periods of highest risk, including perioperative antibiotics to prevent wound and urinary tract infection (Chapter 263), trimethoprim-sulfamethoxazole to prevent *Pneumocystis jiroveci* pneumonia (Chapter 313), oral nystatin or clotrimazole to prevent oral candidiasis (Chapter 310), and oral valganciclovir (see Table 328-4) to prevent CMV disease (Chapter 347). Urinary tract infections (Chapter 263) are the most frequent bacterial infections that lead to hospitalizations in kidney transplant recipients, and the most common organism is *Escherichia coli*.

Up to 30% of patients develop active infection with the BK polyomavirus (Chapter 341), which is trophic for the urinary epithelia. In 5 to 10% of patients, this infection leads to tubulitis and interstitial nephritis, which may result in significant allograft injury. Histologically, BK polyomavirus nephritis is often difficult to distinguish from acute rejection without the use of a special SV40 stain that identifies the large T antigen of BK virus. Approximately 80 to 90% of the general population has serologic evidence of exposure to BK polyomavirus, so infection in the renal transplant recipient may be due to reactivation, superinfection, or primary infection. Interestingly, BK nephropathy is very rare in equally immunosuppressed recipients of other organ transplants. The most important noninvasive indicator of possible BK viral nephropathy is BK viremia, which can be documented in about 10 to 20% of renal transplant recipients. It is presently estimated that 5 to 10% of all renal transplant recipients develop BK virus–induced nephritis and allograft dysfunction, which leads to allograft failure in about half of these patients. Monitoring for BK viremia or virurla is strongly recommended, especially in the first year post-transplant. BK viremia and BK viral nephropathy should be treated initially with a reduction in immunosuppression. No effective antiviral therapy exists for patients who do not respond to lowered immunosuppression.

CMV infection (Chapter 347) continues to be a major cause of morbidity in renal transplant recipients. CMV is widely distributed in the general population, with seroprevalence rates from 40 to 90%, so infections may be due to reactivation, superinfection, or primary infection. CMV disease may be limited to fever and malaise, but frequently causes significant morbidity and even mortality after infecting the gastrointestinal tract, lungs, or liver. Most transplant centers use oral valganciclovir (see Table 328-4) for CMV prophylaxis for 7 months or more after transplantation for all patients at risk, especially seronegative

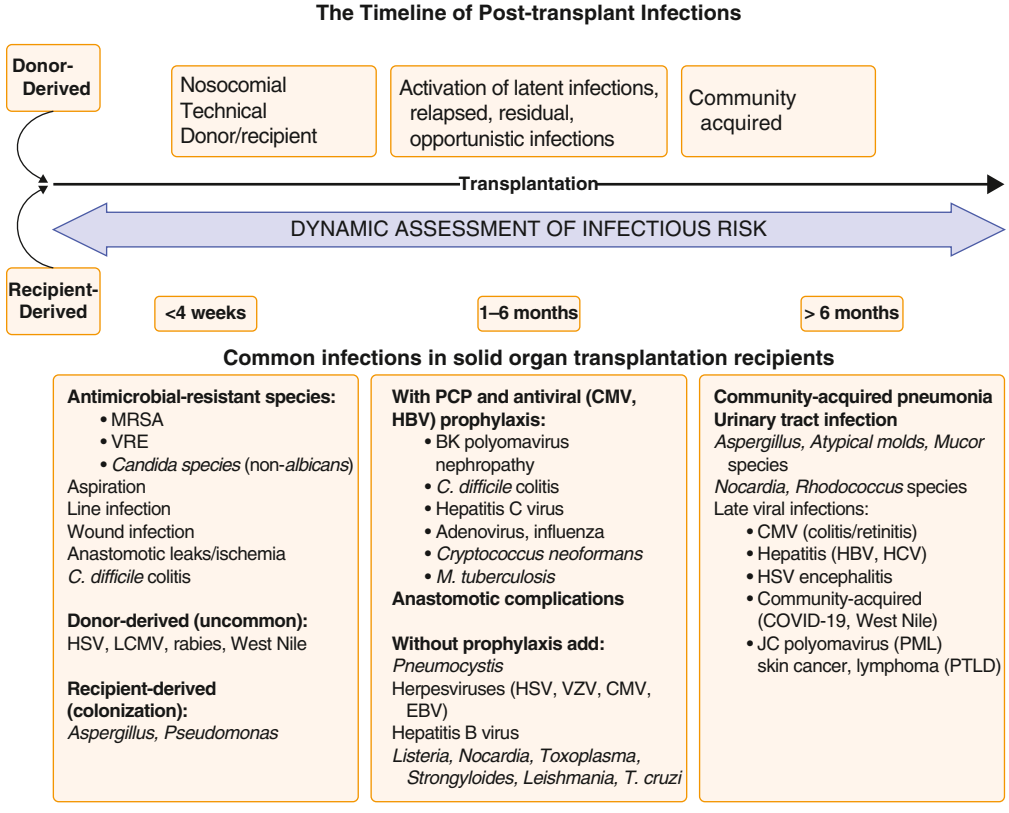

FIGURE 117-1. Timeline of post-transplantation infections. CMV = cytomegalovirus; COVID-19 = coronavirus disease 2019; EBV = Epstein-Barr virus; HBV = hepatitis B virus; HCV = hepatitis C virus; HSV = herpes simplex virus; LCMV = lymphocytic choriomeningitis virus; MRSA = methicillin-resistant *Staphylococcus aureus;* PCP = *Pneumocystis* pneumonia; PML = progressive multifocal leukoencephalopathy; PTLD = post-transplantation lymphoproliferative disease; VRE = vancomycin-resistant enterococci; VZV = varicella-zoster virus. (From Fishman JA. Introduction: infection in solid organ transplant recipients. *Am J Transplant*. 2009;9[Suppl 4]:S3-S6.)

recipients who receive transplants from seropositive donors. Another alternative is frequent post-transplantation monitoring, with treatment reserved for patients who develop viremia. Regardless of the initial strategy, approximately 10% of patients have later viral activation and require additional treatment. Antiviral therapy (Chapters 328) is usually highly effective.

EBV infection (Chapter 348) also may represent a primary infection, reactivation, or superinfection. EBV may cause a mononucleosis-like syndrome, but the more serious concern in renal transplant patients is a form of lymphoma termed post-transplantation lymphoproliferative disease (Chapters 171 and 348).

Renal transplant patients who are infected with severe acute respiratory syndrome coronavirus-2 have a higher mortality (15 to 30%) than the general population.[18] There is no agreed-upon protocol for the safe reduction of immunosuppression that will protect the allograft while mitigating the course of the infection. Vaccination against coronavirus disease 2019 (COVID-19) appears effective and protective against severe disease, albeit less so than in the non-immunosuppressed population.[19]

Malignant Neoplasia

Renal transplant patients develop some malignant neoplasms at higher rates than in the general population.[20] These malignancies include post-transplantation lymphoproliferative disorder related to EBV, Kaposi sarcoma (Chapter 359) caused by human herpesvirus 8 (Chapter 345), and cervical (Chapter 184) and anal (Chapter 131) carcinomas caused by human papillomavirus (Chapter 344). Post-transplantation lymphoproliferative disease most commonly involves the renal allograft, but it may involve any organ, including the gastrointestinal tract, lung, and central nervous system. Treatment usually involves a reduction in immunosuppression and chemotherapy (Chapter 171). Long-term patient survival rates approach 75%.

The relative risks of many common solid carcinomas are also elevated about two-fold, but with the exception of nonmelanoma skin cancers, the absolute risks remain low. Lifetime risk of nonmelanoma skin cancers (Chapter 188) may be as high as 70%. Annual skin screening and the attentive use of ultraviolet-blocking skin creams are strongly recommended. Otherwise, transplant recipients should follow the same standard screening guidelines as the general population for breast (Chapter 183), colon (Chapter 179), prostate (Chapter 186), and lung (Chapter 177) cancer. Whether immunosuppression should be reduced in patients who develop malignant neoplasms other than post-transplantation lymphoproliferative disease is unknown.

Calcineurin Inhibitor–Induced Nephrotoxicity

Calcineurin inhibitors (cyclosporine and tacrolimus; Chapter 28), which are arguably the most effective antirejection medications used in kidney transplantation, ironically cause a chronic, usually mild and stable, impairment of GFR in virtually all patients who receive them. Superimposed, acute reversible cyclosporine or tacrolimus nephrotoxicity may occur in patients who experience sudden elevations in drug blood levels. These acute episodes usually resolve when the dose of cyclosporine or tacrolimus is reduced. Of greater concern is long-term, irreversible calcineurin inhibitor–induced nephrotoxicity, which can cause allograft failure. This diagnosis is often difficult to make because there are few if any absolutely specific histologic biopsy findings. As a result, careful monitoring of blood calcineurin inhibitor levels is essential to avoid supratherapeutic levels (risking nephrotoxicity and infection) or subtherapeutic levels (risking rejection).

New-Onset Diabetes

By 36 months after transplantation, 30 to 40% of patients develop glucose intolerance or frank diabetes, which may be caused by corticosteroids, tacrolimus, and, to a lesser extent, cyclosporine. Treatment is as for diabetes in the general population (Chapter 210), with appropriate adjustment in the dose of insulin and oral agents for renal function. Patients who develop diabetes have poorer outcomes, including higher rates of cardiovascular events, graft failure, and death. Sodium glucose cotransporter 2 (SGLT2) inhibitors may be safe and appropriate treatment options for transplant patients, perhaps even for patients without diabetes mellitus.[A20]

MANAGEMENT OF THE PATIENT AFTER RENAL TRANSPLANTATION

In the initial few months after transplantation, patients are generally seen weekly. The interval then typically expands to once monthly for the remainder of the first year and every 2 to 6 months thereafter. Routine testing includes measurement of blood pressure, renal function, calcineurin inhibitor blood levels, lipid levels, glucose levels, BK polyomavirus assays, and proteinuria. Polymerase chain reaction analysis for CMV or EBV is indicated in selected patients. Monitoring for metabolic bone disease is also recommended, by parathyroid hormone and vitamin D levels as well as by bone densitometry. Influenza and pneumococcal vaccinations are strongly recommended for renal transplant recipients, but live vaccines are contraindicated (Chapter 15).

PROGNOSIS

Five-year kidney allograft survival is approximately 90% for recipients of living donor kidneys and 75% for recipients of deceased donor kidneys. Ten-year survival rates are approximately 70% and 45 to 50%, respectively.[21] Allograft failure with return to dialysis or retransplantation accounts for about 50% of long-term allograft failures.[22] Progressive loss of function in the long-term renal allograft is most commonly the result of chronic rejection but also may be due to nonimmunologic causes, such as calcineurin inhibitor nephrotoxicity, hypertension, diabetes, or recurrent glomerular disease (Table 117-4). A standardized evaluation (Table 117-5) can help establish the cause.

The importance of immunologic (or alloantigen-dependent) factors is illustrated by the fact that death-censored living donor transplants between HLA-identical siblings have a 94% 10-year graft survival, compared with 81% for parental or other less well-matched living donor kidneys and 40 to 50% overall for cadaveric kidney recipients.[23] Deceased donor kidneys with zero or one HLA-A, B, or DR mismatches have a higher success rate (close to 65% at 10 years) than do deceased donor kidneys with two or more antigen mismatches, which have 15 to 30% lower absolute survival rates.

Factors unrelated to anti-allograft immunity are also associated with reduced long-term success rates. These include hypertension, a kidney from an older (>50 years) donor, hyperlipidemia, diabetes mellitus, calcineurin inhibitor nephrotoxicity, recurrent glomerular disease, and a maladaptive response to hemodynamic injury, which is caused by elevated glomerular flow and pressure. Chronic calcineurin inhibitor toxicity leads to end-stage renal disease in at least 5 to 10% of recipients of nonrenal transplants and is likely to have at least a comparable long-term impact in renal transplant patients. Virtually all primary glomerular diseases (Chapter 107), including focal segmental glomerulosclerosis, membranous nephropathy, membranoproliferative glomerulonephritis, and immunoglobulin A (IgA) nephropathy, can recur after transplantation. Recurrent glomerulonephritis is a common cause of proteinuria and nephrotic syndrome after transplantation and may be responsible for up to 10% of all graft failures. For example, graft failure is significantly higher in patients with membranoproliferative glomerulonephritis, focal segmental glomerulosclerosis, membranous nephropathy, and IgA nephropathy compared with adult polycystic kidney disease. Renal biopsy is required to establish the diagnosis in a long-term renal allograft with deteriorating function or proteinuria and to distinguish immune-related from non–immune-related causes. Whether noninvasive biomarkers of actual or impending allograft injury (e.g., circulating donor-derived cell-free DNA or gene expression panels in peripheral blood or urine) will substitute for renal biopsy, in at least some

TABLE 117-4 COMMON CAUSES OF RENAL ALLOGRAFT DYSFUNCTION

Volume depletion: Nausea, vomiting, diarrhea, poor fluid intake, hemorrhage
Medication induced: Diuretics, antihypertensive medications, nonsteroidal anti-inflammatory drugs, calcineurin inhibitors, angiotensin-converting enzyme inhibitors
Urinary tract obstruction: Bladder outlet obstruction, ureteral obstruction
Transplant renal artery stenosis
Infection: Bacteremia, urinary tract infection
Rejection: Cell mediated, antibody mediated

TABLE 117-5 EVALUATION OF RENAL ALLOGRAFT DYSFUNCTION

History: Fluid intake and loss, medication changes, fever
Physical examination: Blood pressure, pulse rate, temperature, weight, edema, allograft tenderness or swelling
Laboratory tests: Serum creatinine level, BK virus detection by polymerase chain reaction analysis of urine or blood, calcineurin inhibitor levels, antidonor antibody testing, urine protein analysis, urine and blood cultures
Doppler ultrasound to assess for possible urinary tract obstruction or transplant renal artery stenosis
Renal biopsy

situations, is an area of active investigation. In the other 50% of failures, a patient dies with a functioning allograft. The most common cause of death in these patients is cardiovascular, due to the high prevalence of diabetes, hypertension, and hyperlipidemia, as well as the high burden of preexisting cardiovascular disease in transplant candidates. Although there are no specific guidelines for the prevention, monitoring, or management of cardiovascular disease after renal transplantation, standard risk factor reduction guidelines are generally considered applicable, including the use of statins (Chapter 190), and antihypertensive medications, to meet blood pressure targets (Chapter 64). The other leading causes of long-term death in renal transplant recipients are infection, sepsis, and malignant disease, all of which are complications of long-term immunosuppression.

118 APPROACH TO THE PATIENT WITH GASTROINTESTINAL DISEASE

KENNETH R. MCQUAID

The luminal gastrointestinal (GI) tract (esophagus, stomach, duodenum, small and large intestine, and anus) and pancreas are responsible for digestion, for the absorption of nutrients and fluids, and for the temporary storage and excretion of undigested waste. The GI tract has an epithelial lining with an enormous surface area that provides nutrient absorption and serves as a barrier to microorganisms. In addition, the GI tract has a large innate and adaptive immune system that interfaces with luminal food antigens, host proteins, commensal and pathogenic bacteria, and parasites and must decide which antigens to tolerate and which require immune activation.[1] The GI tract also contains an extensive enteric endocrine system that regulates food intake, weight control, and glucose homeostasis as well as secretions from the stomach, intestine, and pancreas. Finally, it has an enteric nervous system that is integrated with the autonomic and central nervous systems to control gastric emptying, intestinal motility, and defecation.[2]

Numerous diseases within and outside the GI tract may alter normal function by causing structural damage (erosion, ulceration, perforation, stenosis, or obstruction), bleeding, inflammation, abnormal absorption or secretion of nutrients and electrolytes, or abnormal motility. Despite its anatomic and physiologic complexity, the GI system has only a limited repertoire of symptoms and signs to express conditions that may be either serious or clinically insignificant: abdominal pain, heartburn, regurgitation, dysphagia, odynophagia, dyspepsia, nausea and vomiting, gas and bloating, weight loss, diarrhea, constipation, overt or occult GI tract bleeding, and incontinence.

GENERAL APPROACH TO PATIENTS WITH GASTROINTESTINAL SIGNS AND SYMPTOMS

An appropriate history and physical evaluation usually can narrow the differential diagnosis of GI complaints. A specific diagnosis can almost always be established thereafter by the judicious use of laboratory, endoscopic, or imaging studies (Table 118-1). Not surprisingly, the site of the abdominal pain has a significant correlation with the organ involved.[3]

CLINICAL HISTORY

The clinician should elicit the nature of the complaint, including its acuity, severity, location, radiation, duration, pattern (steady vs. colicky; abrupt vs. gradual onset), and relationship to food, meals, and bowel movements. Symptoms that arise from the GI tract are almost always improved or worsened by eating or by bowel movements. For symptoms of recent onset, it is important to elicit recent dietary intake, a medication history, potential exposure to enteric infections, coronavirus disease 2019 (COVID-19), or sexually transmitted infections (Chapter 264), and recent travel. It is also useful to establish whether there are signs or symptoms that suggest a systemic illness, including fever, weight loss, arthralgias, fatigue, weakness, and rash.

Most nonsurgical GI diseases are manifested with mild to moderate symptoms that develop gradually and do not require immediate attention. Acute symptoms that require urgent assessment are severe abdominal pain and overt GI bleeding (Chapter 121) that is manifested by hematemesis, melena, or large-volume hematochezia. Severe or dramatic abdominal pain that develops acutely during minutes to hours requires urgent evaluation to determine whether surgical intervention is required. Severe vomiting or diarrhea with signs of dehydration also warrants urgent attention.

Mild to moderate chronic or intermittent symptoms that have been present for a long period can be evaluated in a deliberate fashion. A substantial proportion of chronic GI complaints has no obvious organic or biochemical basis and ultimately is classified as *functional* GI disorders (Chapter 123). Complaints that have been ongoing for years rarely are attributable to readily remedied structural disorders. In patients with chronic GI symptoms, it is important to elicit and to address the current reason for seeking evaluation, which may include concern for underlying serious illness (especially cancer), a change in the character or severity of symptoms, life stressors, and depression. Asking the patient what he or she thinks or fears may provide insights into the proportion of the complaint attributable to these amplifying issues, regardless of whether the problem is functional or structural in origin.

A dietary history (Chapter 198) should be obtained. For acute symptoms of nausea, vomiting, diarrhea, or abdominal pain, intake during the previous 24 to 48 hours should be reviewed for clues to a food-borne illness, including possible exposure to a contaminated food or water source and similar symptoms in other people (Chapter 262). Possible exposure to COVID-19 during the previous 10 days should be assessed.[4] For chronic or intermittent complaints, a recall of meals and types of foods eaten during the previous 1 to 2 days provides insight into eating habits and the amounts and types of fruits and vegetables, whole grains, fiber, protein, fat, and dairy products ingested. A relationship between specific foods and symptoms may be found. For example, dairy products (lactose intolerance), whole grains, legumes or cruciferous vegetables, or fatty meals (malabsorption) may cause pain, flatulence, or diarrhea, and a low-fiber diet may cause chronic constipation. Recent and long-term changes in body weight should be elicited. Involuntary loss of more than 5% of body weight during the prior 12 months is worrisome for serious disease and significant malnutrition (Chapter 197).

The number and consistency of bowel movements should be elicited, and any change in bowel habits must be explored. Signs of acute GI bleeding (melena or hematochezia) or inflammatory colitis (blood, mucus, or pus) should be elicited. Improvement in symptoms after passage of flatus or a bowel movement suggests a disorder of the colon or anorectum.

PAST MEDICAL HISTORY

The past medical history should be reviewed for conditions that may cause acute or chronic GI symptoms, including endocrine disorders such as diabetes (Chapter 210) and thyroid dysfunction (Chapter 207), cardiovascular diseases such as heart failure (Chapter 45) and peripheral vascular disease (Chapter 65), chronic liver disease and portal hypertension (Chapter 139), neurologic conditions such as Parkinson disease (Chapter 378) and neuromuscular disorders (Chapter 366), and rheumatologic and collagen vascular disorders (Chapter 236). In addition to their impact on GI tract function, the severity of these conditions must be considered in weighing the risks of diagnostic studies, especially endoscopy. Patients with symptomatic or advanced respiratory insufficiency (Chapter 90), sleep apnea (Chapter 374), valvular heart disease (Chapter 60), coronary artery disease (Chapter 39), heart failure (Chapter 45), cirrhosis (Chapter 139), cerebrovascular disease (Chapter 375), neuromuscular disease (Chapter 390), or dementia (Chapter 371) have an increased risk of sedation-related complications during endoscopy.

A list of prescription and nonprescription medications, vitamins, minerals, and other nutritional supplements should be obtained, paying particular attention to any that were recently initiated or changed. Herbal supplements (Chapter 30) are commonly used but are seldom reported without direct questioning. Medications are potential causes of odynophagia, dyspepsia, nausea or vomiting, abdominal pain, diarrhea, and constipation. The use of antiplatelet agents and anticoagulants should be determined. The risks of stopping versus continuing these medications must be weighed in patients who have acute or chronic GI bleeding or in whom a therapeutic procedure is to be performed.

SOCIAL HISTORY

The patient's personal relationships, employment history, quality of life, alcohol intake (Chapter 364), and smoking (Chapter 363) history should be determined. It can be very informative to observe both verbal and nonverbal interactions between the patient and a partner or caregiver during an interview. Alcohol may cause heartburn, dyspepsia, nausea, diarrhea, or chronic liver disease. Many patients are reluctant to disclose the full extent of their alcohol intake on direct questioning; therefore, in addition to asking how often they imbibe (days/week and drinks/day), it may be revealing to inquire about their preferred beverage and how it is purchased (location, volume, and frequency). Cigarette smoking is associated with an increased risk of heartburn, peptic ulcer disease, Crohn disease, and GI malignant neoplasms.

Clinicians should inquire about the degree to which GI symptoms are disrupting a patient's life. GI illness may affect dietary and bowel habits, sleep, and sense of vitality. Concerns about dietary intolerances, inability to eat, inability to have comfortable bowel movements, uncontrolled diarrhea or gas, fecal urgency, or fecal incontinence may affect a patient's social life, personal and sexual relationships, employment, and sense of optimism.

The social history should also be reviewed for recent stressors that may precipitate or exacerbate GI symptoms, including marital or interpersonal

ABSTRACT

Diseases within and outside the gastrointestinal (GI) tract alter physiologic function by causing structural damage, bleeding, inflammation, nutrient malabsorption, or dysmotility. GI conditions manifest with a limited number of symptoms and signs, including abdominal pain, heartburn, dysphagia, dyspepsia, nausea, vomiting, gas and bloating, weight loss, diarrhea, constipation, incontinence, and acute or chronic bleeding. A specific diagnosis can be established in most patients after a targeted history, physical examination, and laboratory testing, as well as appropriate radiographic and endoscopic imaging. The clinical history should focus on the acuity, severity, location, duration, and pattern of symptoms, as well as their relationship with meals and bowel movements. The past medical history should elicit endocrine, cardiovascular, and neuromuscular disorders, including medications that may cause symptoms or increase the risk of diagnostic studies (including endoscopy). The social history should explore factors that may contribute to symptoms and determine the impact of GI symptoms on the patient's quality of life. The physical examination should assess for signs of weight loss, malnutrition, and pulmonary, cardiovascular, or neuropsychiatric conditions that may cause GI disease or increase the risk of endoscopic evaluation. The abdominal examination includes inspection, percussion, and light and deep palpation to detect hernias, distention, abdominal tenderness, peritoneal irritation, an enlarged liver or spleen, abdominal masses, and ascites. Routine blood tests include a complete blood count, liver tests, and serum chemistries. Stool examination sometimes is obtained for occult blood and infectious agents. Further evaluation with radiologic imaging (commonly abdominal ultrasound, computed tomography, or magnetic resonance imaging) and endoscopy (commonly upper endoscopy or colonoscopy) is guided by the suspected underlying disorder.

discord, personal or family illness, bereavement, financial pressures, job loss, and change in employment. To elicit such information, it may be helpful to tell patients that stress worsens many conditions and to inquire whether they believe stress may be contributing to their problem.

For elderly, disabled, or marginally housed patients, it is important to elicit how they obtain and prepare their meals and how they access toilet facilities. For patients undergoing GI procedures, it is important to determine whether they have mental, physical, or social barriers that would make it difficult to comply with preprocedural instructions (including bowel preparation) and whether they have an able-bodied adult who can accompany them to the procedure and observe them at home, if necessary, afterward.

FAMILY HISTORY

The family history should be reviewed for GI disorders with a heritable component, especially celiac disease (Chapter 126), inflammatory bowel diseases (Chapter 127), and neoplasms of the GI, gynecologic, and genitourinary tracts.

PHYSICAL EXAMINATION

Nonabdominal Examination

The nonabdominal examination should assess nutritional status (Chapter 198) and any signs of systemic conditions that may cause GI symptoms or that must be considered in weighing the risks and benefits of further testing, especially endoscopy. Vital signs should be obtained in all patients. Low-grade fever (<100.5° F) is common in inflammatory conditions, including gastroenteritis, inflammatory bowel disease, appendicitis, cholecystitis, and diverticulitis. High fever (>102° F) suggests sepsis, pelvic or intra-abdominal infections (e.g., cholangitis, pelvic inflammatory disease, pyelonephritis), or peritonitis. Hemodynamic instability (hypotension or tachycardia) suggests intravascular depletion due to poor oral intake, acute GI or intra-abdominal bleeding, severe diarrhea, or peritonitis. A body mass index of less than 18 suggests malnourishment.

A general survey should be performed to assess for signs of weight loss (fat and muscle wasting), malnutrition (dry or thin skin, hair loss, edema, anasarca), and vitamin deficiencies (pellagra, scurvy). Skin lesions may provide clues to systemic conditions such as liver disease (jaundice, spider telangiectasias, palmar erythema), inflammatory bowel disease (erythema nodosum, pyoderma gangrenosum), celiac disease (dermatitis herpetiformis), vasculitis, and rare GI malignant neoplasms, polyposis syndromes, and pancreatic endocrine tumors (Chapters 178, 179, and 213). An oral examination looks for mucocutaneous candidiasis (which may reflect immunosuppression), ulcerations (which may reflect inflammatory bowel disease, vasculitis, viral infection, or vitamin deficiencies), and glossitis or angular cheilitis (which may reflect vitamin deficiencies). With the exception of supraclavicular lymph nodes, peripheral lymph nodes are uninvolved with GI diseases but should be examined when systemic infection or advanced malignant disease is suspected (Chapter 154). Examination of the lungs and cardiovascular system should focus on evidence of conditions that might increase the risk of moderate sedation in the event that endoscopy is required (respiratory insufficiency, heart failure) and of conditions that increase the risk of intestinal ischemia (atrial fibrillation, valvular heart disease, peripheral vascular disease) (Chapter 129). The extremities should be evaluated for edema and peripheral pulses. Finally, a brief neurologic assessment should be performed to screen for intracranial mass lesions or other neurologic disorders that may be manifested with GI symptoms.

Abdominal Examination

The abdominal examination begins with a visual inspection of the abdomen and inguinal region for scars (due to prior surgeries or trauma), asymmetry (suggesting a mass or organomegaly), distention (due to obesity, ascites, or intestinal ileus or obstruction), prominent periumbilical veins (suggesting portal hypertension), or hernias (umbilical, ventral, inguinal). The examination proceeds with auscultation followed by percussion, and it ends with light and deep palpation.

In patients *without* abdominal pain, auscultation of bowel sounds to assess intestinal motility has limited usefulness and may be omitted. Percussion may be performed before or in conjunction with light and deep palpation. Initial cursory light percussion across the upper, mid, and lower abdomen is useful to denote areas of dullness and tympany as well as to elicit unanticipated areas of pain or tenderness before palpation. More extensive percussion provides limited but useful information about the size of the liver and spleen, gastric or intestinal distention, bladder distention, and ascites (Chapters 132 and 139). Gentle, light palpation promotes abdominal relaxation and allows the detection of muscle resistance (guarding), abdominal tenderness, and superficial masses of the abdominal wall or abdomen. Deeper palpation of the abdominal organs (liver, spleen, kidneys, aorta) and abdominal cavity may detect enlargement or abnormal masses. Superficial or deep masses should be assessed for size, location, mobility, content (solid, liquid, or air), and the presence or absence of tenderness. The consistency of a patient's response to palpation with and without distraction is particularly useful in those with suspected chronic functional abdominal discomfort. Superficial masses include hernias, lymph nodes, subcutaneous abscesses, lipomas, and hematomas. Neoplasms (liver, gallbladder, pancreas, stomach, intestine, kidney), abscesses (appendicitis, diverticulitis, Crohn disease), or aortic aneurysms may represent deep abdominal masses.

Examination of the right upper quadrant should assess the liver size, contour, texture, and tenderness. Liver size is crudely estimated by percussion of the upper and lower borders of liver dullness in the midclavicular line. Liver contour and tenderness are best assessed during held inspiration by deep palpation along the costal margin. Examination of the left upper quadrant is useful to detect splenomegaly (Chapter 154), although a normal-sized or even an enlarged spleen often cannot be detected. Percussion in the left upper quadrant near the tenth rib (posterior to the midaxillary line) may detect splenic dullness that is distinct from gastric or colonic tympany. The tip of an enlarged spleen may be palpated during inspiration if the examiner supports the left costal margin with the left hand while palpating below the costal margin with the right hand. Ascites should be suspected in a patient with a protuberant abdomen and bulging flanks. To screen for ascites, percussion of the flanks should be performed to assess the level of dullness. If the level of flank dullness appears to be increased, the most sensitive test for ascites is to check for "shifting" dullness when the patient rolls from the supine to the lateral position.

Digital Rectal and Pelvic Examinations

The digital rectal examination is intrusive and uncomfortable and should be performed only when necessary, such as in patients with perianal or rectal symptoms, incontinence, difficult defecation, suspected inflammatory bowel disease, and acute abdominal pain. The digital examination, with or without fecal occult blood testing, is not a useful screening test for colorectal cancer (Chapter 179). However, in patients with acute or chronic GI bleeding (Chapter 121), it is a rapid means of assessing the stool for color and occult blood. The perianal area should be visually inspected for rashes, soilage (suggesting incontinence or fistula), fistulas, fissures, skin tags, external hemorrhoids, and prolapsed internal hemorrhoids (Chapter 131). After gentle digital insertion, the anal canal should be assessed for resting tone and voluntary squeeze. The distal rectal vault should be swept circumferentially to palpate for mass lesions, tenderness, or fluctuance.

LABORATORY STUDIES

Blood Tests

Blood tests routinely obtained in the evaluation of patients with GI symptoms include a complete blood count, liver tests (Chapter 133), serum chemistries, and, in selected cases, pancreatic enzymes and markers of inflammation. GI causes of anemia include acute or chronic GI blood loss, inflammatory bowel disease, nutrient malabsorption (folate, iron, or vitamin B_{12}), and chronic liver disease. Microcytosis suggests iron deficiency due to chronic GI blood loss or malabsorption. Macrocytosis may be attributable to folate or B_{12} malabsorption, medications (e.g., immunomodulators used for inflammatory bowel disease), or chronic liver disease. An elevated platelet count suggests chronic inflammation (e.g., inflammatory bowel disease) or GI blood loss with compensatory marrow production. A low platelet count may be attributable to portal hypertension with splenic sequestration. Low serum albumin may be caused by chronic GI disorders that result in weight loss, nutrient malabsorption, chronic inflammation, loss of protein across abnormal GI mucosa (i.e., protein-losing enteropathy), or decreased hepatic synthesis (e.g., chronic liver disease). Abnormal liver test results may be due to acute or chronic liver diseases, disorders of the pancreas or biliary tract, and medications (Chapter 133). Serum amylase and lipase are obtained to screen for pancreatitis (Chapter 130) in patients with acute abdominal pain. Increased levels of inflammatory markers, such as an elevated erythrocyte sedimentation rate and C-reactive protein, are nonspecific but useful in the management of patients with inflammatory bowel disease (Chapter 127).

Serum ferritin reflects total body iron and may be decreased in patients with chronic GI blood loss or intestinal malabsorption (e.g., celiac disease). Deficiencies in the fat-soluble vitamins (A, D, E, K) (Chapter 126) may reflect disorders of malabsorption that result in steatorrhea. The serum international

TABLE 118-1 APPROACH TO COMMON GASTROINTESTINAL SYMPTOMS AND SIGNS

	ABDOMINAL PAIN	GI BLEEDING	DIARRHEA	STEATORRHEA	CONSTIPATION
History (ascertain the following)	Duration: acute vs. chronic Onset: sudden vs. 1-2 hr vs. gradual Character: visceral (vague or dull, steady or cramping, diffuse) or parietal (severe, well localized, worse with movement) Location: upper, middle, or lower; radiation Associated symptoms: vomiting, hematemesis, diarrhea, hematochezia, melena, constipation, obstipation, jaundice Previous episodes Other diseases	Acute vs. chronic (duration); intermittent vs. continuous; quantity; hematemesis, melena, or hematochezia; associated pain and location; symptoms of anemia (e.g., dyspnea, chest pain, lightheadedness); medication use (especially aspirin, NSAIDs, anticoagulants); previous episodes; risk factors for chronic liver disease (alcohol, hepatitis)	Acute (<2 wk) vs. chronic (duration); fever, weight loss, or abdominal pain; stool character: number per 24 hr, watery or bloody, large vs. small volume, change in volume with eating, greasy; dietary history (especially lactose); history of IBD, pancreatic disease, intestinal surgery, DM; recent change in medications or antibiotic use; community outbreak or similar symptoms in family members; potential exposure to contaminated food; elderly immunosuppressed host; risk of HIV or sexually transmitted disease; COVID-19 exposure	Duration; weight loss; stool number, consistency (greasy), presence of blood; abdominal pain; flatulence; history of excessive alcohol, chronic liver disease, pancreatitis, intestinal dysmotility, surgery, DM; history of easy bruising, night blindness, bone pain, osteoporosis, dermatitis herpetiformis	Acute vs. chronic (duration); age; number of stools per week; difficulty with defecation (straining, incomplete evacuation, digital manipulation); bloating or discomfort; blood on stools, weight loss; dietary fiber and fluid intake; chronic illness (DM, neuromuscular, endocrine); abdominal surgeries; medications, impaired mobility
Physical findings (evaluate for the following)	Fever, HR, BP Appearance: calm, restless, motionless Inspect: skin, distention, hernias Bowel sounds: present, absent, roaring Percussion and palpation: organomegaly, mass (abscess), focal tenderness, guarding Peritoneal signs: sharp pain with cough, shaking, percussion, light palpation	HR, BP, orthostatic findings; abdominal pain present or absent; signs of chronic liver disease and portal hypertension (which may indicate varices); jaundice, spider angiomas, hepatosplenomegaly; ascites; examine nasogastric aspirate for blood ("coffee grounds" vs. bright red); examine stool for blood (Hemoccult) and color (melena, maroon, or bright red)	HR, BP, orthostatic findings; fever; wasting; presence of abdominal tenderness or mass; perianal disease; extraintestinal symptoms of IBD (e.g., oral ulcers, arthritis, erythema nodosum)	Wasting, presence or absence of abdominal mass or tenderness; rash (vitamin deficiencies) or excessive bruising (vitamin K deficiency); jaundice or signs of chronic liver disease	Assess mobility and chronic medical conditions; abdominal distention; palpable stool within bowel in left lower quadrant; rectal examination—impacted stool, anal fissure, rectal prolapse, pelvic floor descent with straining, rectocele
Laboratory tests	CBC, BUN, Cr, glucose, amylase, lipase, liver tests (ALT, AST, bilirubin, alkaline phosphatase), albumin, INR, U/A, urine β-HCG; nasal swab for COVID-19	CBC, BUN, Cr, liver tests, INR, type and cross	CBC, BUN, Cr, glucose, electrolytes, liver tests, albumin, C-reactive protein Selected cases: consider serum chromogranin A, VIP, calcitonin, gastrin, glucagon, urinary 5-HIAA; stool for culture, ova, parasites or multiplex PCR tests; nasal swab for COVID-19; consider fecal weight, fat, elastase, calprotectin, electrolytes, laxative screen	CBC, glucose, liver tests, albumin, electrolytes, celiac disease antibody (IgA anti-tTG or EMA or IgG DGP, if IgA deficiency); assessment of vitamin and mineral absorption (A, D) and INR (K is fat soluble), folate, iron, calcium, phosphate, B_{12}; stool for fecal elastase and qualitative fat; stool for quantitative fecal fat; breath test for bacterial overgrowth	CBC, Chem-7, calcium, magnesium, phosphate, TFTs; selected patients with severe constipation may undergo anal manometry with balloon expulsion,
Endoscopy	EGD, colonoscopy	EGD, colonoscopy, enteroscopy, wireless capsule study	Colonoscopy (including ileal inspection) with biopsies; EGD with duodenal biopsies; wireless capsule study	EGD with duodenal biopsies	Colonoscopy if recent change in bowel habits
Imaging	CT scan or ultrasound; MR or CT enterography; angiography	CT angiography, angiography	Small bowel enterography: CT, MRI, (Crohn disease); somatostatin receptor scintigraphy	CT of the abdomen (pancreatic calcifications; biliary dilation)	Usually not necessary; colonic transit studies; MRI or barium defecography

5-HIAA = 5-hydroxyindoleacetic acid; ALT = alanine transaminase; AST = aspartate transaminase; BP = blood pressure; BUN = blood urea nitrogen; CBC = complete blood count; CNS = central nervous system; COPD = chronic obstructive pulmonary disease; COVID-19 = coronavirus disease 2019; Cr = creatinine; CT = computed tomography; DGP=deamidated gliadin peptide; DM = diabetes mellitus; EGD = esophagogastroduodenoscopy; EMA=endomysial antibody; ESR = erythrocyte sedimentation rate; GERD = gastroesophageal reflux disease; GI = gastrointestinal; HbA_{1C} = hemoglobin A_{1C}; HCG = human chorionic gonadotropin; HIV = human immunodeficiency virus; HR = heart rate; IBD = inflammatory bowel disease; INR = international normalized ratio; KCl = potassium chloride; MRI = magnetic resonance imaging; NSAIDs = nonsteroidal anti-inflammatory drugs; RBC = red blood cell; TFTs = thyroid function tests; tTG = tissue transglutaminase; U/A = urinalysis; VIP = vasoactive intestinal polypeptide.

Modified from Proctor DD. Approach to the patient with gastrointestinal disease. In: Goldman L, Ausiello D, eds. *Cecil Textbook of Medicine,* 23rd ed. Philadelphia: Saunders-Elsevier; 2008.

normalized ratio may be elevated in patients with cholestasis because of malabsorption of vitamin K or in patients with chronic liver disease because of decreased hepatic synthetic function. Serum B_{12} may be decreased in patients with autoimmune gastritis (pernicious anemia), gastric bypass surgery, or malabsorption because of small bowel bacterial overgrowth or disease of the terminal ileum (e.g., Crohn disease).

Specialized laboratory tests that may be useful for the diagnosis of specific diseases include stool *Helicobacter pylori* antigen in patients with duodenal ulcer disease or dyspepsia, antibodies to tissue transglutaminase immunoglobulin A (IgA) or deamidated gluten peptide (IgG) in celiac disease, and CA19-9 in pancreaticobiliary malignant disease.

Stool Examination

Fecal occult blood testing is useful to evaluate iron deficiency anemia and acute or chronic GI blood loss. In patients with acute diarrhea, assessment for infectious agents is indicated if diarrhea is bloody, severe, associated with severe abdominal pain or fever, or if the patient is immunocompromised. In most clinical settings, molecular testing of stool specimens is now preferred for initial screening of a panel of bacteria (including *Clostridioides difficile*), viruses, and parasites, with results available within 1 to 5 hours.[5,6] Stool specimens also may be submitted for leukocyte or lactoferrin testing, culture for routine bacterial pathogens (e.g., *Salmonella, Campylobacter, Shigella*), and, in selected patients, testing for *C. difficile, Escherichia. coli 0157:H7*, Shiga toxin, and parasites (*Giardia, Entamoeba histolytica*). To distinguish among the causes of chronic diarrhea (Chapter 126), stool samples may be sent for assessment of electrolytes, leukocytes (microscopy, calprotectin, or lactoferrin), elastase, and fecal fat.

ENDOSCOPY AND RADIOLOGY

Endoscopy (Chapter 120) and radiographic studies (Chapter 119) play a major role in the evaluation and management of many GI disorders. Esophageal manometry and esophageal pH and impedance monitoring can be useful for the evaluation of heartburn, reflux, and other esophageal symptoms (Chapter 124). Anorectal manometry may be useful in some patients with fecal incontinence and defecatory dysfunction (Chapter 131). Breath tests are commonly used to diagnose *H. pylori* infection (a urease breath test; Chapter 125), lactose intolerance, and small bowel bacterial overgrowth (a hydrogen and methane breath test with lactulose or glucose; Chapter 126).

The diagnosis of a functional GI disorder is made after organic disorders have been excluded by clinical evaluation and limited, directed diagnostic testing. "Overtesting" should be avoided. Thereafter, the emphasis should switch from finding a "cause" of the symptoms to implementing successful coping and adaptive behaviours.

ABDOMINAL PAIN

Abdominal pain, which is a frequent complaint among outpatients in the office setting and emergency department, may be benign and self-limited or the presenting symptom of severe, life-threatening disease. Chronic abdominal pain that has been present for months or years in the absence of other organic illness is almost always functional in origin and does not require urgent evaluation. By contrast, most patients with severe acute abdominal pain require a thorough but emergent evaluation, which may quickly reveal an acute surgical illness (Chapter 128).

PATHOBIOLOGY

Stimulation of hollow abdominal viscera is mediated by splanchnic afferent fibers within the muscle wall, visceral peritoneum, and mesentery that are sensitive to distention and contraction. Visceral afferent nerves are loosely organized, innervate several organs, and enter the spinal cord at several levels. Thus, visceral pain is vague or dull in character and diffuse; patients attempting to localize the pain often move their entire hand over the upper, middle, or lower abdomen. Most visceral pain is steady, but cramping, intermittent pain or "colic" results from peristaltic contractions caused by partial or complete obstruction of the small intestine, ureter, or uterine tubes. In contrast to visceral innervation, a dense network of nerve fibers that follow a spinal T6 to L1 somatic distribution innervates the parietal peritoneum. Pain fibers of the parietal peritoneum are stimulated by stretch or distention of the abdominal cavity or retroperitoneum; direct irritation from infection, pus, or secretions (e.g., caused by a ruptured viscus); or inflammation caused by contact between the parietal peritoneum and an adjacent inflamed organ (e.g., appendicitis). Parietal pain is sharp, well characterized, and localized by the patient to a precise location on the abdomen, often by pointing with one finger.

The GI viscera (liver, biliary system, pancreas, and GI tract) arise during embryologic development from midline structures that have bilateral innervation. Thus, GI visceral pain is typically localized to the abdominal midline.

ACUTE ABDOMINAL PAIN

CLINICAL MANIFESTATIONS

History

The history should determine the time course, character, and location and radiation pattern of the pain (Table 118-2). Severe abdominal pain that begins

TABLE 118-2 TYPICAL MANIFESTATIONS OF KEY CAUSES OF ACUTE AND CHRONIC ABDOMINAL PAIN

CONDITION	LOCATION	QUALITY	ONSET	AGGRAVATING OR RELIEVING FACTORS	ASSOCIATED SYMPTOMS OR SIGNS	DIAGNOSTIC STUDIES
Peptic ulcer disease (Chapter 125)	Epigastric, occasionally RUQ, rarely LUQ	Dyspepsia: mild to moderate aching discomfort, pain, burning, gnawing, postprandial fullness	Days	Variable relief with antacids; may be relieved by, worsened by, or unrelated to meals	Recurrent; associated factors (e.g., *Helicobacter pylori*, aspirin, NSAIDs)	Anemia, upper endoscopy, *H. pylori* testing
Acute pancreatitis (Chapter 130)	Epigastric, radiates to midback (occasionally RUQ or LUQ)	Diffuse, steady, stabbing, penetrating	1-2 hr	Aggravated by food; better when lying still and with narcotics	Severe nausea and vomiting; reduced or absent bowel sounds; associated factors (e.g., alcohol, gallstones)	Elevated amylase and lipase, CT
Acute cholecystitis (Chapter 141)	Epigastric, then moves to RUQ; may radiate to right scapula	Gradual, steady increase, moderate to severe	Hours	May follow a fatty meal; better with narcotics and surgery	Nausea, some vomiting, fever	Elevated WBC count, US or CT
Acute appendicitis (Chapter 128)	Periumbilical, then moves to RLQ	Vague initially; gradual, steady increase to intense, localized, pain	Hours	Unprovoked; better with narcotics and surgery	Anorexia, nausea, obstipation; occasional vomiting, fever late	Elevated WBC count, US or CT
Diverticulitis (Chapter 128)	LLQ or suprapubic	Moderate to severe, steady or cramping, sharp or aching, localized	Hours to days	Unprovoked; better with narcotics and antibiotics or surgery	Anorexia, nausea, distention, constipation or loose stools; partial relief with passage of flatus or BM; fever late	Elevated WBC count, CT
Ruptured viscus and peritonitis (Chapter 128)	Diffuse	Intense	Minutes to hours	Worse with cough or movement; better when lying still or with narcotics or surgery	Fever, anorexia, nausea, vomiting; lack of bowel sounds; tenderness with percussion, light touch, rebound; guarding and rigidity (late); loath to move	Elevated WBC count, CT

TABLE 118-2 TYPICAL MANIFESTATIONS OF KEY CAUSES OF ACUTE AND CHRONIC ABDOMINAL PAIN—cont'd

CONDITION	LOCATION	QUALITY	ONSET	AGGRAVATING OR RELIEVING FACTORS	ASSOCIATED SYMPTOMS OR SIGNS	DIAGNOSTIC STUDIES
Intestinal ischemia (Chapter 129)	Small intestine—periumbilical; proximal (right) colon—periumbilical or RLQ; distal colon—LLQ	Severe, stabbing pain out of proportion to physical findings	Minutes	Chronic ischemia—occurs after eating; acute ischemia—usually unprovoked; better with narcotics, thrombus dissolution, stenting, surgical resection	Nausea, bloody diarrhea; associated factors (e.g., hypotension, cardiac arrhythmias)	Elevated WBC count, CT or MR with angiography, or colonoscopy (colonic ischemia)
Strangulated hernia (Chapter 128)	Localized	Sharp, localized, intense; crampy or steady	Minutes to hours	Previous hernia history; unprovoked; better with narcotics and decompression, including surgery	Anorexia, nausea, vomiting, no stool or flatus passage if obstruction; bowel sounds variable—hyperactive early if obstruction present, but absent bowel sounds late, especially with peritonitis	Elevated WBC count, CT, US
Small or large bowel obstruction (Chapter 128)	Small intestine—periumbilical; proximal (right) colon—periumbilical or right abdomen; distal (left) colon—LLQ	Early—diffuse, colicky, crampy; late—steady and better localized	Hours to days	Aggravated by food; better with narcotics, NGT decompression, or surgery	Distention, anorexia, nausea, vomiting; no stool or flatus passage; small intestine—increased hyperperistaltic (rushes) bowel sounds (early) or quiet abdomen (late); large intestine—bowel sounds variable; associated factors (e.g., hernia, previous surgery)	CT
Abdominal abscess (Chapter 128)	Located over the abscess, usually LLQ or RLQ	Insidious, intense, constant	Days	May be aggravated by movement; better with abscess drainage	Fever, anorexia, nausea, abdominal mass	Elevated WBC count, CT
Acute hepatitis (Chapter 134)	RUQ	Dull or intense; localized	Days	Worse with deep inspiration	Jaundice, anorexia, nausea; liver enlarged and tender to palpation; associated factors (e.g., alcohol, infection)	Abnormal liver test results
GERD (Chapter 124)	Substernal or epigastric	Burning, gnawing	Days to years	Provoked by large or fatty meals or recumbency; relief with antacids	Recurrent; may have regurgitation, dysphagia, or extraesophageal manifestations (e.g., asthma, chronic cough, laryngitis)	Upper endoscopy (usually normal), ambulatory pH/impedance probe
Nonulcer (functional) dyspepsia (Chapter 123)	Epigastric	Mild to moderate discomfort, pain, burning, gnawing, postprandial fullness	Years	May be worsened by meals; cannot be reliably distinguished from ulcer disease by history alone	Other symptoms of functional disorders (IBS, fibromyalgia, pelvic pain)	Normal EGD
IBS (Chapter 123)	Variable; usually lower abdomen	Vague, crampy, sense of urgency	Years	Pain may be precipitated by dietary factors or stress; associated with change in bowel characteristics (e.g., frequency, form, difficulty with passage); relieved with stool passage	Bloating and abdominal distention	Normal sigmoidoscopy, colonoscopy, and CT, but these are usually not necessary for diagnosis
Chronic pancreatitis (Chapter 130)	Epigastric or periumbilical, radiates to midback	Intense, localized	Days to years	Aggravated by food; better with narcotics	Anorexia, nausea, vomiting; associated factors (e.g., alcohol); DM (with advanced disease)	Amylase and lipase may be normal; CT may show calcifications, dilated pancreatic duct, pseudocyst; increased fecal fat and decreased fecal elastase if pancreatic insufficiency
Inflammatory or infectious enterocolitis (Chapters 128 and 262)	Small intestine—periumbilical; large intestine—right or left side of the abdomen over the colon; rectum—tenesmus	Crampy	Hours to days	Better with stool passage and treatment of underlying cause	Nausea, vomiting, bloody diarrhea; associated factors (e.g., infectious—food transmission; IBD—prolonged duration, family history)	Stool studies for culture, colonoscopy with biopsies

CT = computed tomography; DM = diabetes mellitus; EGD = esophagogastroduodenoscopy; GERD = gastroesophageal reflux disease; IBS = irritable bowel syndrome; LLQ = left lower quadrant; LUQ = left upper quadrant; MR = magnetic resonance; NGT = nasogastric tube; NSAIDs = nonsteroidal anti-inflammatory drugs; RLQ = right lower quadrant; RUQ = right upper quadrant; US = ultrasound; WBC = white blood cell count.

suddenly during seconds to minutes indicates a catastrophic event, such as esophageal rupture, perforated peptic ulcer or viscus, ruptured ectopic pregnancy, ruptured aortic aneurysm, acute mesenteric ischemia, or myocardial infarction. Pain that progresses within 1 to 2 hours is consistent with a rapidly progressive inflammatory disorder (e.g., cholecystitis, appendicitis, pancreatitis), acute obstruction of a viscus (small intestinal obstruction, which is often related to adhesions from prior intraperitoneal surgery[7]; ureteral colic), or organ ischemia caused by a strangulated blood supply (volvulus, strangulated hernia, ovarian torsion). Pain that is less severe and develops during several hours is more commonly caused by a medical rather than a surgical condition, including upper GI disorders (dyspepsia), intestinal disorders (gastroenteritis, inflammatory bowel disease), liver disorders (hepatitis, abscess), urinary disorders (cystitis, pyelonephritis), and gynecologic infections; however, the slow evolution of surgical disorders such as cholecystitis (Chapter 141), appendicitis or diverticulitis (Chapter 128), and intra-abdominal abscesses must not be overlooked.

The character of the pain provides important information about whether the symptoms are due to visceral stimulation or parietal stimulation (peritonitis). Patients with peritonitis may report severe localized pain or irritation with activities or maneuvers that stretch or move the parietal peritoneum, such as walking, moving in bed, and coughing; as a result, they tend to lie quietly to avoid painful stimulation. By contrast, patients with visceral pain may move or walk restlessly or attempt a bowel movement in an effort to relieve their symptoms.

The location of pain in the upper, middle, or lower abdomen is a crude but important indicator of the diagnosis (Fig. 118-1). Visceral pain arising from the foregut (esophagus, stomach, proximal duodenum, bile duct, gallbladder, pancreas) most often is manifested in the epigastrium. Pain derived from the midgut (small intestine, appendix, ascending colon, proximal transverse colon) occurs in a periumbilical location. Pain derived from the hindgut (distal transverse colon, left colon, rectum) localizes to the lower midline between the umbilicus and symphysis pubis. Paired intra-abdominal organs such as the kidneys, ureters, ovaries, and fallopian tubes have unilateral innervation that localizes pain to the side of the involved organ. As some surgical conditions progress, the character and location of the pain shift from a visceral to a parietal pain pattern. Thus, early cholecystitis (Chapter 141) may be manifested with vague midline epigastric pain that progresses to sharp right upper quadrant pain as localized peritoneal irritation develops. Likewise, appendicitis (Chapter 128) commonly begins with vague, diffuse periumbilical pain that evolves to sharp, well-localized right lower quadrant pain as peritonitis ensues.

Anorexia, vomiting, diarrhea, distention, and constipation are commonly seen with abdominal pain caused by both medical and surgical disorders. Although nonspecific, the *absence* of any of these symptoms is evidence against an emergent surgical or medical disorder because severe illness usually leads to reflex stimulation or inhibition of gastric and intestinal peristalsis. Vomiting is common in medical and surgical disorders involving the upper GI tract, including acute gastroenteritis, pancreatitis, gastric and small intestinal obstruction, and biliary tract disease. Pain that precedes the onset of vomiting is typical of surgical conditions, whereas the reverse is true of medical conditions (e.g., food poisoning, gastroenteritis). Abdominal pain with prominent diarrhea is most commonly caused by a medical condition (e.g., gastroenteritis, inflammatory bowel disease). Although constipation alone is a nonspecific complaint, the absence of stool passage and flatus is consistent with complete bowel obstruction or paralytic ileus.

Jaundice accompanying acute abdominal pain virtually always indicates a hepatobiliary disorder (Chapter 133), including obstruction of the biliary duct (choledocholithiasis, pancreatic carcinoma, cholangiocarcinoma), complications of acute cholecystitis, acute hepatitis (viral, ischemic), and hepatic malignant neoplasms. The possibility of cholangitis should be considered and excluded in all patients with acute abdominal pain and jaundice, especially if the patient has fever, chills, hypotension, altered mental status, or leukocytosis. Hematemesis with upper abdominal pain suggests a Mallory-Weiss tear, alcoholic gastritis, or peptic ulcer disease. Hematochezia with abdominal pain is most commonly caused by medical conditions such as infectious gastroenteritis or inflammatory bowel disease, but it also may be caused by ischemic colitis or mesenteric ischemia. Gross hematuria may be due to cystitis (Chapter 263) or a ureteral stone (Chapter 111). Abdominal pain with weight loss may be due to inflammatory bowel disease, chronic mesenteric ischemia, or advanced GI malignant neoplasms. In women, a missed menstrual period, adnexal pain, spotting, or cramping may suggest pregnancy, ectopic pregnancy, or spontaneous abortion. Acute pain between cycles may be caused by ovarian follicles or ruptured corpus luteum cysts. Pelvic pain with fever, chills, or cervical discharge suggests pelvic inflammatory disease.

The past medical history and review of systems can provide clues about systemic and extra-abdominal conditions that may be manifested with abdominal pain. Acute coronary syndromes (Chapter 57), heart failure (Chapter 45),

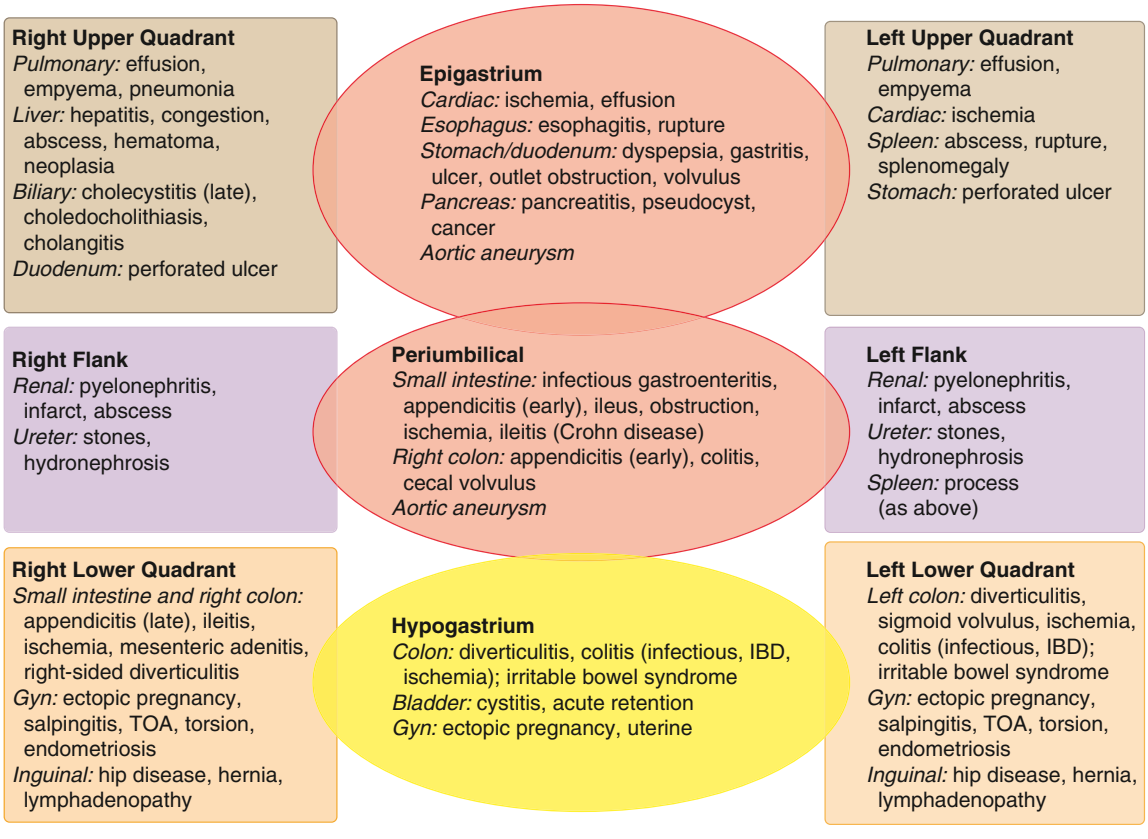

FIGURE 118-1. Differential diagnosis of abdominal pain by its initial location. Gyn = gynecologic; IBD = inflammatory bowel disease; TOA = tubo-ovarian abscess.

pneumonia (Chapter 85), or empyema may cause dyspepsia, epigastric or right or left upper quadrant pain, nausea, and vomiting. Metabolic conditions such as uremia (Chapter 116), diabetes with hyperglycemia or ketoacidosis (Chapter 210), hypercalcemia (Chapter 227), or acute adrenocortical insufficiency (Chapter 208) may cause pain, nausea, vomiting, and diarrhea. Acute intermittent porphyria (Chapter 194) and familial Mediterranean fever (Chapter 254) may cause recurrent episodes of severe pain and peritonitis that may be misdiagnosed, leading to unnecessary surgeries. Other causes of acute abdominal pain include narcotic withdrawal (Chapter 365), insect or reptile bites (Chapter 98), and lead or arsenic poisoning (Chapter 20).

Physical Examination

The physical examination must identify life-threatening illnesses that require urgent surgical evaluation. Nevertheless, the examination must be orderly, careful, and complete. If the examiner immediately palpates the site of maximal pain, the patient is unlikely to relax and to cooperate for the remainder of the examination.

First, the patient should be observed and the abdomen inspected. Most patients remain calm, cooperative, and freely capable of moving during the examination. Patients who are writhing or restless may have pain due to visceral distention (e.g., renal colic, intestinal obstruction), whereas patients who lie motionless may have peritonitis. Gentle shaking of the bed or having the patient cough may elicit sharp, well-localized pain in patients with parietal but not with visceral pain. Auscultation should be performed before percussion or palpation so that intestinal activity is undisturbed. An abdomen that is quiet except for infrequent squeaks or tinkles suggests peritonitis or ileus. Loud peristaltic rushes that occur in synchrony with abdominal pain suggest small bowel obstruction. Light percussion across the upper, middle, and lower abdomen can determine any site of focal tenderness suggestive of peritonitis. Light palpation should be performed with one or two fingers (not the whole hand), beginning away from where the patient localizes the pain and gradually moving to the site of pain. Thereafter, gentle, deeper palpation of the entire abdomen is performed gradually, including the region of tenderness. An attempt should be made to palpate for an abdominal aortic aneurysm (Chapter 63). Examination also should include the inguinal and femoral canals, umbilicus, and surgical scars for evidence of incarcerating hernias. The presence of focal tenderness indicates parietal peritoneal irritation. Voluntary or involuntary tightening of the muscle wall ("guarding") may occur during palpation. With gentle, steady compression of the abdomen with one hand, voluntary guarding usually subsides, allowing the examination to proceed. Persistent involuntary guarding indicates peritonitis with reflex muscle wall contraction. Testing for "rebound tenderness" in patients with suspected peritonitis is not recommended because it causes significant pain and is usually not necessary to establish the diagnosis. When the presentation strongly suggests a nonserious GI disorder but the patient has significant tenderness with palpation, it is useful to use the stethoscope ostensibly to listen for bowel sounds but actually to reproduce the pressure of palpation. A significant discrepancy in the tenderness elicited by the stethoscope and by digital palpation may be seen in patients who are anxious, have functional complaints, or are seeking secondary gain. A digital rectal examination should be performed in most patients with acute abdominal pain to evaluate for tenderness or fluctuance that suggests a perirectal abscess and to assess the stool for signs of overt or occult blood. Women with lower abdominal pain should have a pelvic examination by a skilled examiner to evaluate for gynecologic disease. Some specific and dramatic findings point to particular diagnoses (Table 118-3).

TABLE 118-3 PHYSICAL SIGNS IN PATIENTS WITH ACUTE ABDOMINAL PAIN

SIGN	DESCRIPTION	DIAGNOSIS
Murphy sign	Cessation of inspiration during right upper quadrant examination	Acute cholecystitis
McBurney sign	Tenderness located midway between anterior superior iliac spine and umbilicus	Acute appendicitis
Cullen sign	Periumbilical bluish discoloration	Retroperitoneal hemorrhage Pancreatic hemorrhage Ruptured abdominal aortic aneurysm
Grey Turner sign	Bluish discoloration of flanks	Retroperitoneal hemorrhage Pancreatic hemorrhage Ruptured abdominal aortic aneurysm
Kehr sign	Severe left shoulder pain	Splenic rupture Ectopic pregnancy rupture
Obturator sign	Pain with flexed right hip rotation	Appendicitis
Psoas sign	Pain with straight leg raising against resistance (right side)	Appendicitis

Special Populations

Increased diligence is required in the evaluation of patients in whom abdominal signs and symptoms may be minimal until the disease process is far advanced. Such patients include the elderly (Chapter 24) and patients who have dementia (Chapter 371), psychiatric disturbances (Chapter 362), or spinal cord injuries. An admitting diagnosis of "altered mental status," "failure to thrive," "obstipation," or "fever of unknown origin" may stem from serious intra-abdominal conditions. Disorders that may be overlooked in the elderly include bowel perforation, bowel obstruction, cholecystitis, diverticulitis, volvulus, mesenteric ischemia, and abdominal aortic aneurysm. In patients with chronic liver disease, the presence of ascites may mask the signs and symptoms of serious surgical conditions such as cholecystitis, appendicitis, and diverticulitis. Even in the presence of perforation, signs of peritonitis may be lacking because the ascites fluid separates the visceral peritoneum and parietal peritoneum. Likewise, immunocompromised populations, who are at risk for infectious, drug-related, and iatrogenic complications, may manifest few physical findings or laboratory abnormalities. Owing to the limitations of the clinical evaluation in these vulnerable populations, there should be a low threshold for the use of abdominal imaging.

Abdominal Pain Developing in the Hospital

When pain develops as a new problem in a hospitalized patient, it is usually caused by a limited number of conditions. Postprocedural complications may cause perforation, infection, or bleeding (intraperitoneal, retroperitoneal, or within solid organs). Shunting of splanchnic blood flow in severely ill medical or surgical patients may cause stress gastritis, nonocclusive mesenteric ischemia, or acalculous cholecystitis. Adynamic ileus or acute colonic pseudo-obstruction is common in critically ill or postoperative patients and is manifested as diffuse abdominal pain and distention. *C. difficile* (Chapter 271) colitis is a common cause of pain, diarrhea, and distention, especially in patients receiving antibiotics. Constipation (Chapter 122), which is a common problem in hospitalized patients, may go unnoticed until pain and distention develop. Finally, many medications can cause dyspepsia and abdominal pain.

DIAGNOSIS

Patients with acute abdominal pain should have a complete blood count with differential; leukocytosis is present in most acute surgical conditions (Fig. 118-2). A pregnancy test is required in women of childbearing age. Serum levels of electrolytes, glucose, blood urea nitrogen, and creatinine assess hydration, acid-base status, and renal function. Liver chemistries and pancreatic enzymes should be obtained in most patients, but especially in those with upper abdominal pain, jaundice, or vomiting. An elevation in aspartate or alanine aminotransferase levels may reflect choledocholithiasis with acute biliary obstruction (Chapter 141), acute gallstone pancreatitis (Chapter 130), or a hepatocellular process (Chapter 134). Painful jaundice with a significant rise in the alkaline phosphatase level usually reflects cholestasis caused by extrahepatic biliary obstruction (Chapter 141). Amylase and lipase levels are elevated in most patients with acute pancreatitis, but minor amylase elevations also occur with a perforated viscus or mesenteric ischemia (Chapter 129). Urinalysis may demonstrate pyuria, hematuria, or bacteriuria due to ureteral calculi (Chapter 111) or urinary tract infection (Chapter 263).

Imaging

Ultrasound is preferred in suspected pregnancy and to evaluate for other acute gynecologic disorders, such as tubo-ovarian abscess, ruptured corpus luteum cyst, or ovarian torsion; it is also preferred for the initial evaluation of suspected acute cholecystitis (Chapter 141) and ureteral stones with hydronephrosis and for the bedside evaluation of unstable patients. In most other settings, abdominal computed tomography (CT) with oral and intravenous administration of contrast material (when possible) is preferred and can provide

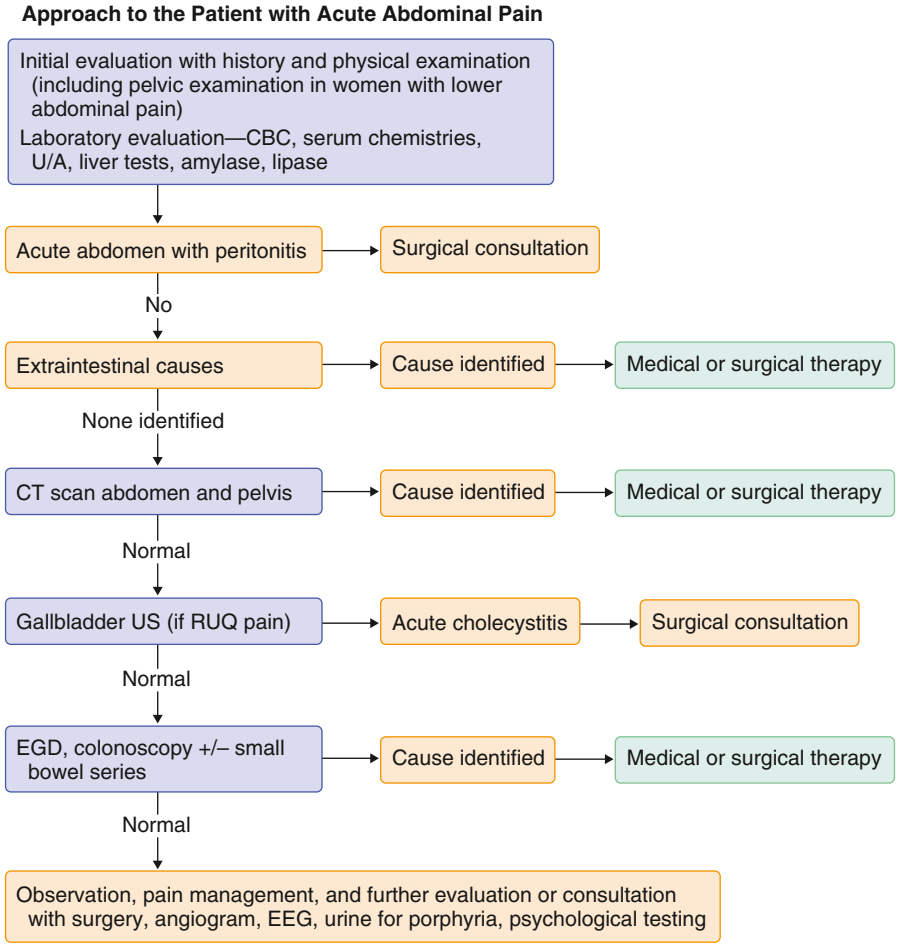

FIGURE 118-2. Approach to the patient with acute abdominal pain. CBC = complete blood count; CT = computed tomography; EEG = electroencephalography; EGD = esophagogastroduodenoscopy; RUQ = right upper quadrant; U/A = urinalysis; US = ultrasonography.

a definitive diagnosis in up to 90% of patients with acute severe abdominal pain[A1] (Chapter 119). Abdominal CT may be falsely negative early in the course of acute pancreatitis, mesenteric ischemia, cholecystitis, appendicitis,[8] and diverticulitis, especially if it is performed without contrast enhancement.

TREATMENT

Once the diagnosis is clear, treatment of the underlying condition is initiated. For uncomplicated acute appendicitis diagnosed by CT scan, antibiotics are an alternative to urgent surgery,[A2] but they are associated with a 25 to 30% rate of readmission or surgery in the next year. As a result, the international consensus is generally for urgent surgery.[9] In patients with diverticulitis, antibiotics are the usual first-line therapy (Chapter 128).[10] In patients with nonspecific acute abdominal pain and no clear diagnosis, early laparoscopy is useful for diagnosis, but outcomes such as complication rates, readmission rates, and length of hospitalization are no better than with a strategy of active observation.

CHRONIC ABDOMINAL PAIN

Chronic or recurrent abdominal pain that has been present for months to years may be caused by structural (organic) disease, but the majority of patients have a functional disorder such as irritable bowel syndrome (Chapter 123). Common organic causes of chronic abdominal pain include medications with GI side effects, peptic ulcer disease (Chapter 125), inflammatory bowel disease (Chapter 127), chronic pancreatitis (Chapter 130), biliary tract disease (Chapter 141), GI cancers (Chapters 178 and 179), and endometriosis (Chapter 218). The clinician should attempt to distinguish patients with symptoms or signs of organic disease, in whom further diagnostic investigation is warranted, from those with probable functional disease (Fig. 118-3). Although functional disorders occur in all age groups, the symptoms usually begin before the age of 40 years. "Alarm" features that suggest a structural disorder and are inconsistent with a functional disorder are fever, severe pain, significant weight loss, jaundice, progressive dysphagia, recurrent vomiting, nocturnal pain or diarrhea, and stools that are bloody or positive for fecal occult blood. Laboratory study findings should be normal with functional disorders; therefore, an unrevealing evaluation for anemia; leukocytosis; and levels of iron, albumin, C-reactive protein, and vitamins A, D, or B_{12} argues against structural or organic disease.

In patients younger than 50 years with a suspected functional disorder and no alarm features (e.g., family history of colon cancer or inflammatory bowel disease or abnormalities on screening blood tests), further testing should be minimized, and the emphasis should be shifted to managing symptoms, coping, and making lifestyle changes (Chapter 123). In patients who may have organic disease, testing often includes a combination of upper GI endoscopy, colonoscopy, and ultrasound or CT imaging.

GAS AND BLOATING

BELCHING

Belching (eructation), which is the involuntary or voluntary release of gas from the esophagus or stomach, commonly occurs during or after a meal. Virtually all belching is caused by swallowed air, which may be increased by eating quickly, drinking carbonated beverages, chewing gum, and smoking. Gas also may be produced within the stomach by antacids, especially sodium bicarbonate, which rapidly neutralize gastric acid and release carbon dioxide. Belching seldom reflects serious GI dysfunction but may be increased in patients with gastroesophageal reflux (Chapter 124), functional dyspepsia (Chapter 123), or gastroparesis (Chapter 122). Chronic, excessive, repetitive supragastric belching is a functional disorder caused by transient ingestion of air into the esophagus (caused by subconscious diaphragmatic contraction and upper esophageal sphincter relaxation) and its subsequent expulsion; it is treated with behavioral modification.

FLATUS

Flatus, or "gas," is a normal byproduct of digestion. Otherwise healthy adults pass flatus 10 to 20 times daily and excrete up to 1500 mL. Thus, it is difficult to distinguish patients with abnormal or excessive gas production from those with only a heightened awareness of or sensitivity to normal production. Increased flatulence with diarrhea may be symptomatic of disorders of malabsorption,

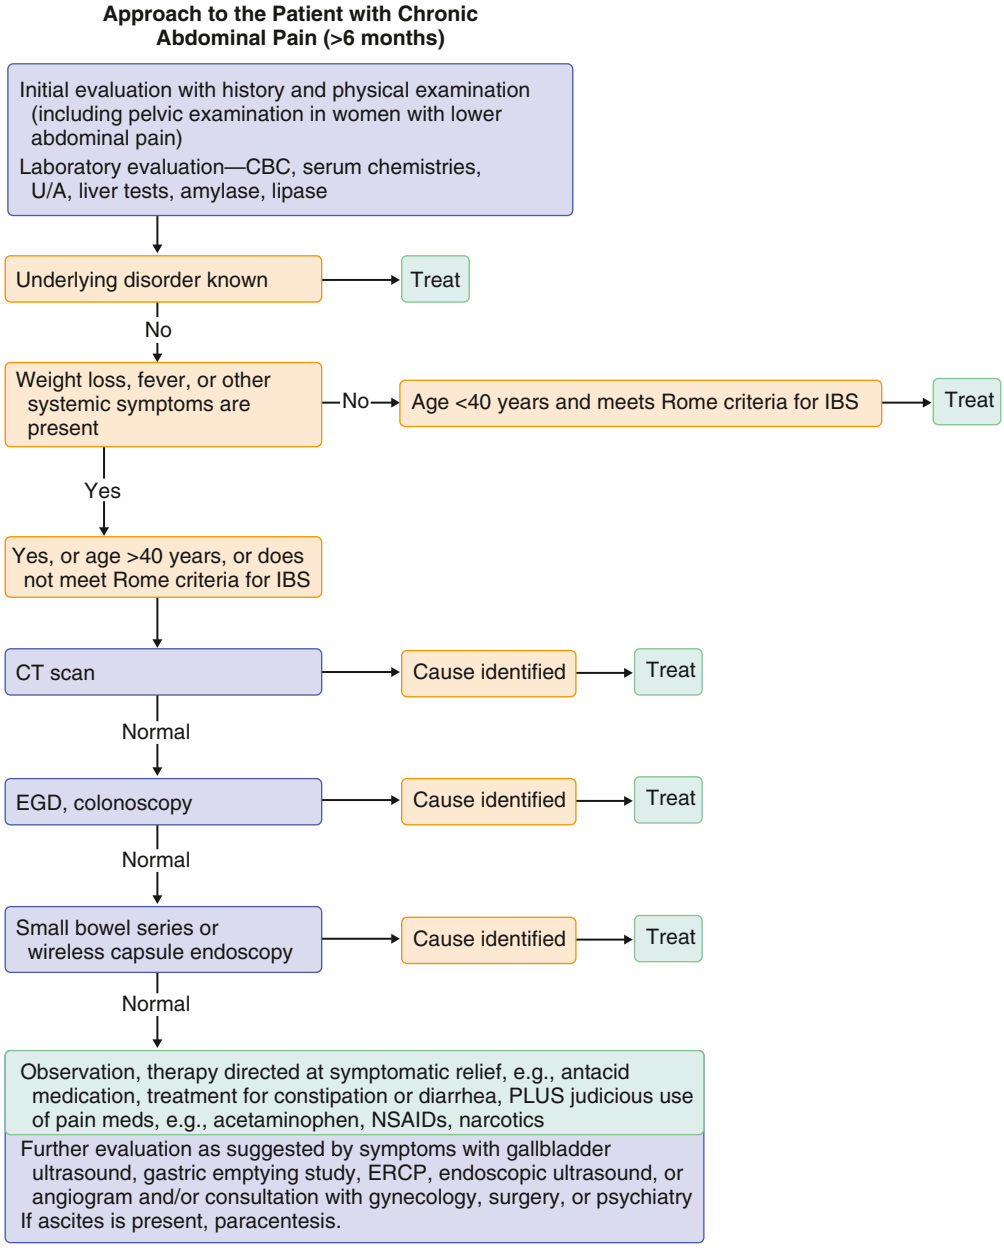

FIGURE 118-3. Approach to the patient with chronic abdominal pain. CBC = complete blood count; CT = computed tomography; EGD = esophagogastroduodenoscopy; ERCP = endoscopic retrograde cholangiopancreatography; IBS = irritable bowel syndrome; NSAIDs = nonsteroidal anti-inflammatory drugs; U/A = urinalysis.

including celiac disease (Chapter 126), pancreatic insufficiency (Chapter 130), and small intestinal bacterial overgrowth (Chapter 126).

In normal adults, flatus is derived from two sources: swallowed air and colonic bacterial fermentation of FODMAPs (fermentable oligosaccharides, disaccharides, and monosaccharides and polyols), which are short-chain carbohydrates that may be incompletely absorbed in the small intestine and result in the colonic production of carbon dioxide or methane. FODMAPs include lactose (dairy products), fructose, fructans, polyols, and galacto-oligosaccharides. Fructose is present in fruit, especially apples and pears, and is a major component of corn syrups that are widely used as sweeteners. Polyols include sorbitol, which is a natural sugar in stone fruit (peaches, apricots, plums, prunes) and a common added sweetener in sugar-free candies, as well as trehalose, which is present in mushrooms. Fructans and oligosaccharides are plentiful in cruciferous vegetables (cabbage, broccoli, cauliflower, Brussels sprouts, turnips, rutabagas), garlic, onions, legumes (beans, soy, lentils, peas), pasta, and whole grains.[11]

BLOATING AND DISTENTION

Bloating and distention are common complaints among patients with functional GI disorders (Chapter 123).[12] As chronic, isolated symptoms, they are almost never caused by serious structural disease. Functional bloating may be caused by heightened sensitivity to minor increases in intestinal gas or impaired transit of gas, even though the total volume of intestinal gas is within normal limits.

The acute onset of distention in conjunction with alarm symptoms such as cramping pain, weight loss, nausea, vomiting, obstipation, or diarrhea warrants further evaluation for disorders that cause intestinal obstruction (Chapter 128) or malabsorption (Chapter 126).

TREATMENT

Patients with long-standing flatulence in the absence of other symptoms or signs of GI disease can be treated conservatively. Avoidance of carbonated beverages, chewing gum, sorbitol- and fructose-containing sweeteners, and gas-producing vegetables improves symptoms in most patients.[A3] Lactase deficiency may be confirmed by a lactose breath test. Underlying GI illness is suggested by the recent onset of flatulence with other symptoms of organic disease, including weight loss, abdominal pain, diarrhea, distention, and abnormal laboratory studies (Chapter 126). A positive fecal fat analysis confirms malabsorption and merits further investigation (see Table 126-6). Suspected small bowel bacterial overgrowth may be confirmed by carbohydrate breath tests[A4] or treated empirically with antibiotics.

Rifaximin (550 mg three times daily for 2 weeks) is effective for functional bloating, pain and loose or watery stool, but dietary and behavioral changes and reassurance may also be useful.[A5] Although some clinical studies suggest benefit with probiotics, the overall data are inconclusive.[13] In one randomized trial of patients with irritable bowel syndrome with predominant bloating, fecal transplantation improved bloating, pain, and flatulence.[A6]

INVOLUNTARY WEIGHT LOSS

The unintentional loss of more than 5% of baseline weight within a 12-month period is frequently due to a serious underlying medical or psychiatric illness.[14] Weight loss is seldom the sole presenting sign of medical disorders, but it is often revealed during the clinical evaluation of other complaints. Chronic weight loss in the elderly is commonly caused by depression; dementia; difficulty with chewing or swallowing; malignant disease; medications; alcoholism; or physical and social limitations to procuring, preparing, and eating meals (Table 118-4) (Chapter 23). Gradual, mild weight loss occurs in some elderly patients because of the loss of lean body mass. In young patients, weight loss is more commonly caused by eating disorders (Chapter 200), endocrine disorders (Chapters 207 and 208), or chronic GI conditions such

TABLE 118-4 CAUSES OF INVOLUNTARY WEIGHT LOSS

CONDITION	QUALITY	DURATION	AGGRAVATING OR RELIEVING FACTORS	ASSOCIATED SYMPTOMS OR SIGNS	DIAGNOSTIC STUDIES
WEIGHT LOSS SECONDARY TO GASTROINTESTINAL CAUSES					
GI, pancreatic, or hepatobiliary malignant disease (Chapters 178-181)	Progressive, fast	Months	Better with cancer therapy (e.g., surgery, XRT, chemotherapy)	Dysphagia (esophageal); anorexia, nausea, vomiting (gastric, small or large bowel obstruction); visible or occult blood in stool; altered bowel habits; jaundice or hepatomegaly (biliary obstruction, hepatic tumor, metastatic disease); iron deficiency anemia	CBC, FOBT, ferritin, CEA, CA19-9, AFP, EGD, colonoscopy, abdominal CT, PET
Malabsorption (Chapter 126) (poor absorption of nutrients due to pancreatic insufficiency, small intestinal mucosal disorders, or bacterial overgrowth)	Progressive, slow	Months to years	Diarrhea or steatorrhea, excessive flatulence; worse with eating and resolves with NPO status	Usually associated with increased appetite; may have anemia (iron, B_{12}, folate), osteoporosis, or osteomalacia (vitamin D, calcium, phosphorus); easy bruising (vitamin K), night blindness (vitamin A)	Stool for fecal fat (qualitative or quantitative); fecal elastase; vitamins A and D and INR; calcium, ferritin, B_{12}, albumin; celiac disease antibodies (e.g., IgA anti-tTG, or antiendomysial antibodies, IgG deamidated gliadin peptide); EGD with small bowel biopsy; breath test for bacterial overgrowth
Inflammatory bowel disease (especially Crohn disease) (Chapter 127)	Progressive, slow	Months	Eating causes pain, cramps, increased diarrhea and urgency; improved by low-residue diet or NPO status	Bloody stools, abdominal cramps and pain, perianal disease, extraintestinal manifestations (e.g., oral ulcers, uveitis, erythema nodosum, arthralgias)	CBC, albumin, ESR, CRP, fecal calprotectin, colonoscopy with biopsies, CT or MR enterography, wireless capsule study
GI motility disorders (Chapter 122)	Intermittent, slow	Years	Worse with eating	Nausea, vomiting, distention, diarrhea, or constipation may be present	EGD and colonoscopy, gastric emptying study, CT or MR enterography, surgical full-thickness intestinal biopsies
Cirrhosis (Chapter 139)	Muscle wasting with edema, so weight may increase	Months to years	Worse with salt or fluid intake	Ascites, peripheral edema	Liver biopsy
Chronic intestinal ischemia (Chapter 129)	Progressive	Months to years	Worse with eating	Afraid to eat; postprandial abdominal pain, nausea; associated atherosclerotic disease	CT or MR angiography
WEIGHT LOSS SECONDARY TO NONGASTROINTESTINAL CAUSES					
Poor or inadequate calorie intake due to social factors (Chapter 197)	Intermittent or progressive, acute (hospitalized) or chronic	Days to months to years	Common in elderly, teenagers; exacerbated by poor dentition or poorly fitting dentures	Will eat if food is made available	Review dietary log and how food is obtained and prepared
Medications	Intermittent or progressive	Months	Worse with medication; resolves with discontinuation of offending drug	Anorexia, nausea, vomiting	Review alcohol, recreational drugs, and prescription medications (stimulants, antidepressants, metformin, glucagon-like peptide-1 analogs, dopamine, anticholinergics, cardiovascular agents)
Non-GI malignant disease	Progressive	Months	Better with cancer therapy (e.g., surgery, XRT, chemotherapy)	Anorexia, nausea, vomiting; pain; metastatic disease	Calcium, cortisol; CT for underlying disease, PET
Endocrine disorders: DM, hyperthyroidism, adrenal insufficiency (Chapters 207, 208,and 210)	DM—appetite increased or decreased, early satiety; hyperthyroidism—increased appetite	Months to years	Worse with disease chronicity	DM: gastroparesis, neuropathy, retinopathy, nephropathy Adrenal insufficiency: nausea, vomiting, diarrhea, abdominal pain	Serum glucose, Hgb A_{1c}, TFT, cortisol

TABLE 118-4 CAUSES OF INVOLUNTARY WEIGHT LOSS—cont'd

CONDITION	QUALITY	DURATION	AGGRAVATING OR RELIEVING FACTORS	ASSOCIATED SYMPTOMS OR SIGNS	DIAGNOSTIC STUDIES
Chronic infections, including HIV and TB (Chapters 299 and 359)	Progressive, fast	Months	Better with directed therapy, megestrol acetate (Megace)	Nausea, anorexia, other infections	HIV test, PPD, cultures, biopsies if necessary
Systemic inflammatory disorders	Progressive, moderate	Months to years	Better with directed therapy, megestrol acetate (Megace)	Arthritis, rash, vasculitis	ANA, RF, ESR, CRP
Chronic renal failure (Chapter 116)	Progressive, slow; edema may increase weight	Months to years	Better with dialysis, megestrol acetate (Megace)	Nausea, anorexia, weight gain	BUN, Cr, 24-hr creatinine clearance
Advanced COPD or heart failure (Chapters 45 and 76)	Progressive, slow	Months to years	Better with oxygen and specific treatment	Fatigue, dyspnea, edema, wasting	Pulmonary function testing or two-dimensional echocardiography
Psychiatric illness: depression, manic-depressive illness (Chapter 362)	Progressive, slow	Months to years	Depression common in elderly; flat affect; manic phase associated with hyperactivity and decreased intake	Psychological testing	
Psychogenic eating disorders—anorexia nervosa, bulimia (Chapter 200)	Intermittent or progressive	Months to years	Worse with stressors	Refusal to eat, loss of tooth enamel, calluses and healing ulcerations of hand	Psychiatric testing
Substance abuse (alcohol, opiates, CNS stimulants)	Intermittent or progressive	Months	Resolves with discontinuation	Anorexia, nausea, vomiting	Careful interview; patients may deny or minimize

AFP = α-fetoprotein; ANA = antinuclear antibody; BUN = blood urea nitrogen; CBC = complete blood count; CEA = carcinoembryonic antigen; CNS = central nervous system; COPD = chronic obstructive pulmonary disease; Cr = creatinine; CRP = C-reactive protein; CT = computed tomography; DM = diabetes mellitus; EGD = esophagogastroduodenoscopy; ESR = erythrocyte sedimentation rate; FOBT = fecal occult blood test; GI = gastrointestinal; Hgb = hemoglobin; HIV = human immunodeficiency virus; INR = international normalized ratio; MR = magnetic resonance; NPO = nothing orally; PET = positron emission tomography; PPD = purified protein derivative; RF = rheumatoid factor; TB = tuberculosis; TFT = thyroid function test; tTG = tissue transglutaminase; XRT = x-ray therapy.
Modified from Proctor DD. Approach to the patient with gastrointestinal disease. In: Goldman L, Ausiello D, eds. *Cecil Textbook of Medicine,* 23rd ed. Philadelphia: Saunders-Elsevier; 2008.

as inflammatory bowel disease (Chapter 127) or celiac disease (Chapter 126). In chronic medical conditions, involuntary weight loss is usually caused by a combination of decreased appetite (anorexia) and varying degrees of cachexia; examples include advanced malignant disease, chronic infections (human immunodeficiency virus [HIV], tuberculosis), heart failure, chronic kidney or liver disease, end-stage lung disease, and adrenal insufficiency. Weight loss that occurs in the presence of normal or increased appetite suggests increased metabolism and energy expenditure caused by endocrine disorders, such as poorly controlled diabetes (Chapter 210) or hyperthyroidism (Chapter 207), or GI disorders that result in food malabsorption (Chapter 126). Chronic GI disorders that cause progressive narrowing or obstruction of the esophagus (cancer, achalasia), stomach (cancer, peptic ulcer disease with gastric outlet obstruction), small intestine (Crohn disease), or arterial circulation (chronic mesenteric ischemia) may cause weight loss as a result of dysphagia, vomiting, or postprandial pain that limits the ability to ingest sufficient calories.

DIAGNOSIS

The cause of weight loss (see Table 118-4) is usually evident from the history, physical examination, and routine laboratory studies, including complete blood count, electrolytes, liver chemistries, thyroid-stimulating hormone, urinalysis, and, when appropriate, HIV serology (Fig. 118-4). A chest radiograph should be obtained in patients who smoke, have any respiratory symptoms, or are older than 40 years. In one large study, patients with involuntary weight loss had a two- to three-fold increased risk of a new cancer diagnosis within the next 2 years, but the absolute rate of such a diagnosis was only 2.2%.[15]

Signs of dehydration or severe malnutrition may require an assessment for nutritional deficiencies (Chapter 197) and nutritional support (Chapter 198). Other symptoms and signs necessitate consideration of additional diagnostic testing. Weight loss with increased appetite merits an assessment of thyroid function (Chapter 207), glucose intolerance (Chapter 210), and malabsorption (Chapter 126). Suspected malabsorption may be confirmed by a positive fecal fat analysis. GI symptoms suggesting obstruction or occult GI malignant disease can be evaluated with upper GI endoscopy, upper GI radiographic series, colonoscopy, or abdominal CT. Psychiatric evaluation may be warranted in patients with signs of depression, early dementia, or eating disorders. In up to 25% of patients, no cause of weight loss is found.[16]

NAUSEA AND VOMITING

Nausea is an unpleasant feeling of the impending need to vomit. *Vomiting* is the forceful oral expulsion of gastric contents as a result of retrograde contraction of the duodenum and antrum with compression of the thoracoabdominal musculature. Nausea and vomiting may be caused by a number of GI and non-GI disorders, but they are best categorized according to chronicity and the presence of abdominal pain. The acute onset of vomiting *with* severe abdominal pain suggests a serious illness potentially requiring surgical intervention, including GI obstruction (Chapter 128), mesenteric ischemia (Chapter 129), pancreatitis (Chapter 130), biliary colic (Chapter 141), and conditions causing peritonitis (Chapter 128), such as appendicitis or a perforated viscus. Acute vomiting *without* abdominal pain is most commonly caused by pregnancy (Chapter 221), myocardial infarction (Chapter 58), medications (including chemotherapy), migraine headache (Chapter 367), food poisoning (Chapter 262), infectious gastroenteritis (Chapter 262), hepatitis (Chapters 134 and 135), upper GI bleeding, postoperative ileus, motion sickness (Chapter 396), vestibular neuritis (Chapter 396), or acute central nervous system disease. Gastrointestinal symptoms (nausea, vomiting, or watery diarrhea) are present in up to 10% of patients who are infected with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2; Chapter 336) and may precede respiratory symptoms. Chronic or recurrent nausea and vomiting *with* abdominal pain are commonly caused by GI disorders that result in the partial or intermittent obstruction of the stomach or small intestine and conditions that result in chronic intestinal pseudo-obstruction (Chapter 122). Chronic nausea and vomiting *without* abdominal pain may be due to disorders that impair gastric emptying or small intestine motility and non-GI causes, including medications, cannabinoids,[17] pregnancy, intracerebral disorders, cardiac disease, endocrine disease, labyrinth disorders, psychiatric disease (including bulimia), gastroparesis, cyclical vomiting syndrome, and functional disorders. Vomiting of undigested food eaten hours earlier suggests gastric obstruction or gastroparesis. Abdominal distention or feculent emesis suggests obstruction of the small intestine.

DIAGNOSIS

Most cases of acute vomiting without abdominal pain are self-limited and require no evaluation (Fig. 118-5). Medication-related symptoms and pregnancy should be excluded. With severe vomiting, serum electrolyte values

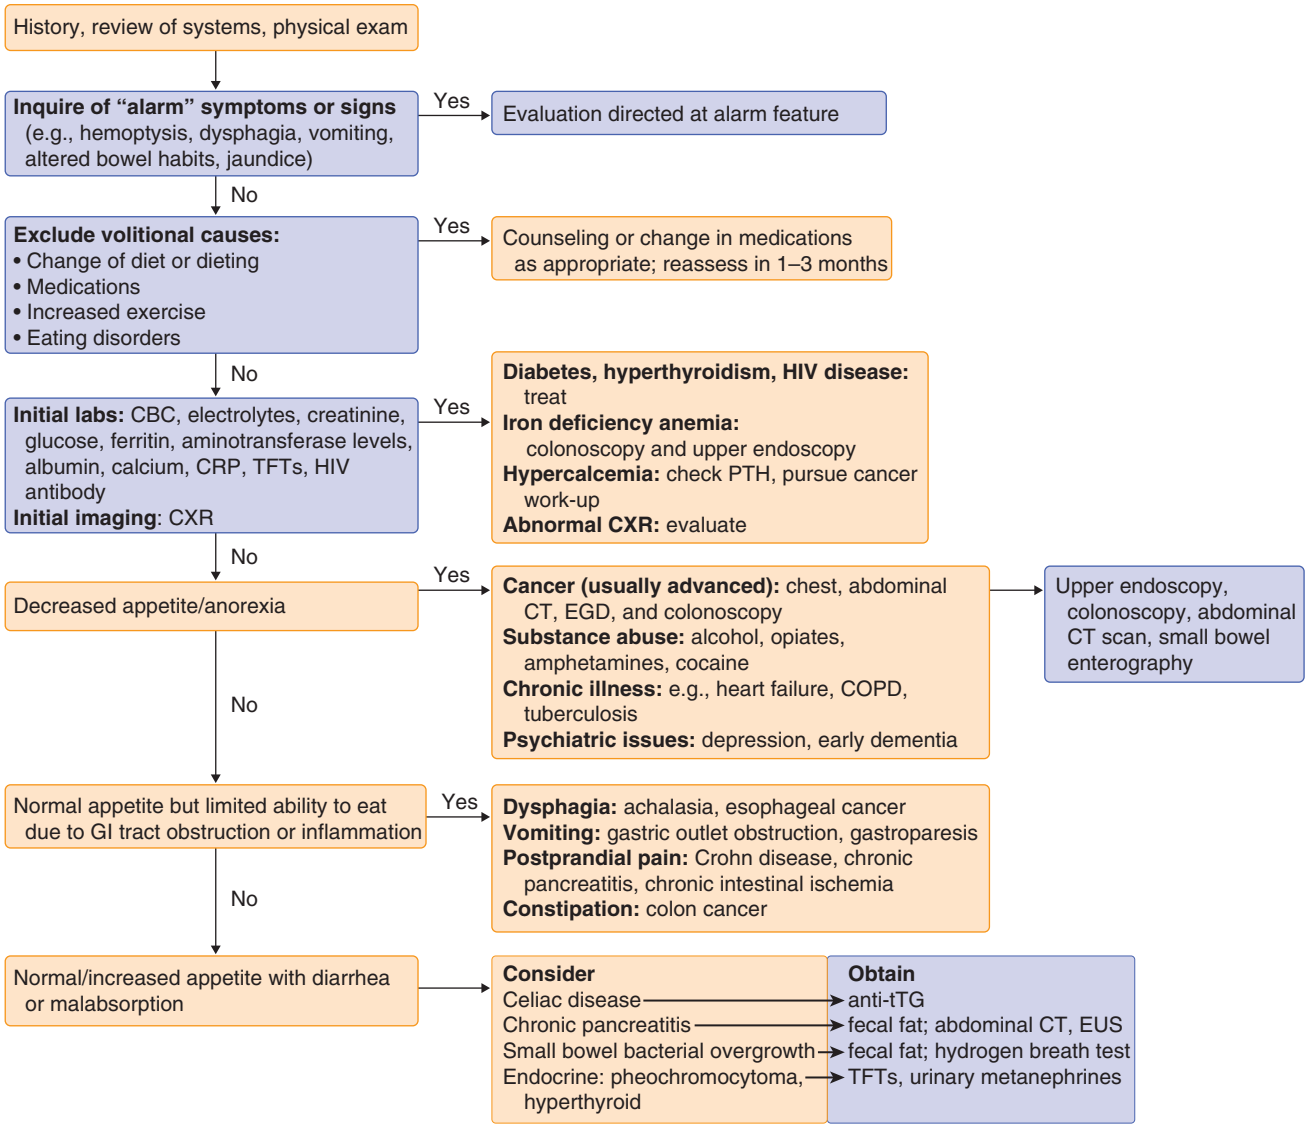

FIGURE 118-4. **Approach to the patient with unintentional weight loss of more than 5%.** CBC = complete blood count; COPD = chronic obstructive pulmonary disease; CRP = C-reactive protein; CT = computed tomography; CXR = chest radiograph; EGD = esophagogastroduodenoscopy; EUS = endoscopic ultrasound; GI = gastrointestinal; HIV = human immunodeficiency virus; PTH = parathyroid hormone; TFTs = thyroid function tests; tTG = tissue transglutaminase.

should be obtained. Hyperglycemia may cause acute gastroparesis. Increased liver chemistries or pancreatic enzymes suggest hepatobiliary or pancreatic disease. In patients with acute abdominal pain and vomiting, abdominal plain radiography or CT is performed to look for evidence of GI obstruction, a perforated viscus, or pancreaticobiliary disease. In patients with chronic vomiting of uncertain cause, the goal is to distinguish structural GI disorders, GI motility disorders, and non-GI disorders. Esophagogastroduodenoscopy, enterography, abdominal cross-sectional imaging, GI motility studies, and head CT or magnetic resonance imaging may be indicated.

TREATMENT

The approach to the medical treatment of nausea and vomiting depends on the cause (Table 118-5). Patients who are receiving moderately emetogenic chemotherapy are frequently managed with a 5-HT_3 receptor antagonist[18] and dexamethasone; a neurokinin-1 receptor antagonist[19] or olanzapine[A7] can be added for highly emetogenic regimens.[20] For patients with mildly emetogenic regimens or vomiting from other causes, treatment with single or combinations of anticholinergic agents, dopamine receptor antagonists, 5-HT_3 receptor antagonists,[A8] or cannabinoids[A9] usually provide symptomatic relief.[21] For refractory vomiting due to gastroparesis, gastric electrical stimulation[A10] or peroral endoscopic pyloromyotomy[22] may be considered.

CONSTIPTION

Constipation (Chapter 122), which is the most common digestive symptom, occurs in 15% of the population. Constipation may refer to fewer than three bowel movements per week; hard or lumpy stools; or difficulty during defecation, characterized by straining, a sensation of obstruction or incomplete evacuation, or the need to engage in manual manipulations to promote evacuation. Constipation may be caused by systemic conditions that slow colonic transit, including neuromuscular disease, endocrine disorders, and electrolyte abnormalities, or by lesions that obstruct the passage of stool through the distal colon or anorectum, such as neoplasms, strictures, prolapse, and aganglionosis (Hirschsprung disease).[23] Opioid-induced constipation is increasingly common owing to the opioid epidemic.

TREATMENT

Most patients do not have an apparent cause and are deemed to have chronic idiopathic constipation owing to colonic inertia, dyssynergic defecation, or functional disorders (e.g., irritable bowel syndrome). Most patients can be successfully treated with adequate fluids, fiber supplements, osmotic agents (polyethylene glycol), and/or nonprescription stimulant laxatives (e.g., once-daily bisacodyl, 5 to 10 mg, or senna, 17.6 to 34.4 mg).[A11] Management of chronic refractory constipation may require linaclotide (72 to 290 μg daily), plecanatide (3 mg daily), lubiprostone (24 μg twice daily), or prucalopride (1 to 2 mg daily; see Table 122-3), whereas patients with dyssynergia may respond to biofeedback.[24] For opioid-induced constipation, a combination of an osmotic and stimulant laxative is recommended as initial treatment. Patients who have an inadequate response may benefit from the addition of a peripherally acting μ-opioid receptor antagonist (e.g., naloxone, naloxegol, or naldemedine) or the serotonin-4 receptor agonist prucalopride (1 to 2 mg daily; Table 122-3).[A12]

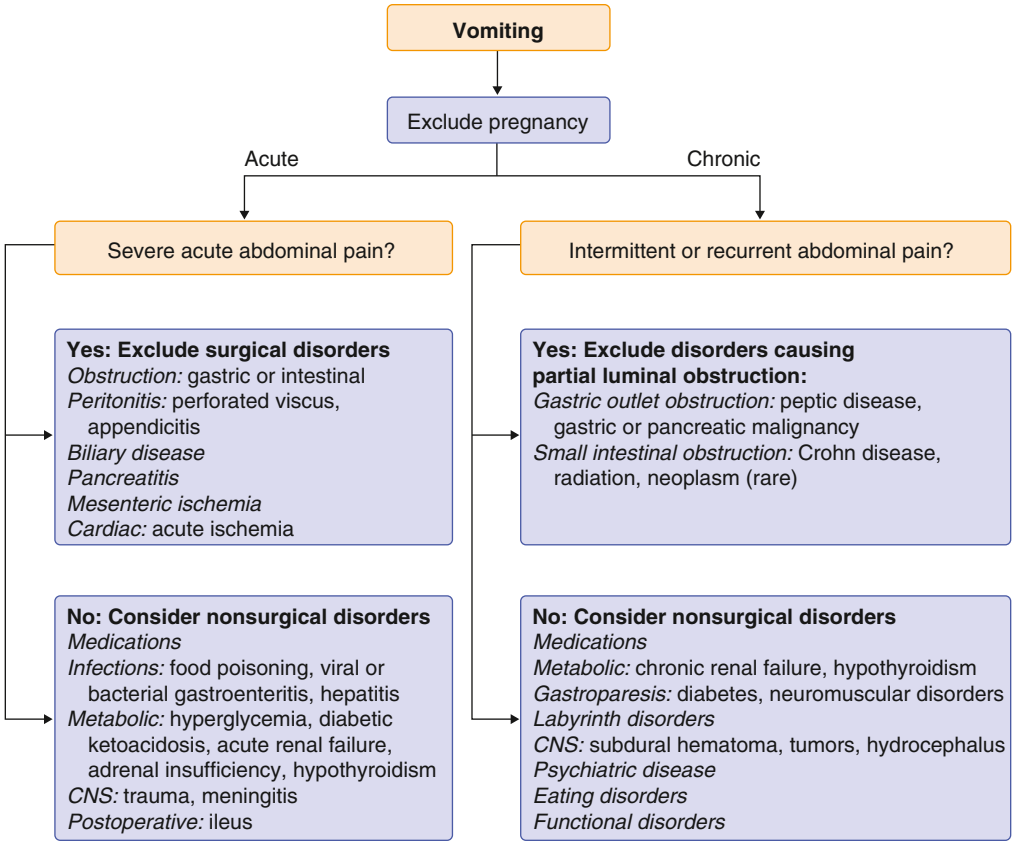

FIGURE 118-5. Approach to the patient with vomiting. CNS = central nervous system.

TABLE 118-5 MEDICAL TREATMENT OF NAUSEA AND VOMITING

DRUG	USUAL INDICATIONS	USUAL DOSE (RANGE)	ROUTE	COMMENTS
ANTICHOLINERGIC-ANTIHISTAMINE AGENTS	Most commonly: GIDz, motion sickness, vertigo			Side effects: sedation, dizziness, delirium, blurred vision, glaucoma, bronchospasm, tachycardia, urinary retention Avoid concomitant alcohol or CNS depressants; use with caution in elderly patients
Scopolamine patch	MS	1.5 mg/72 hr	Patch	
Dimenhydrinate	MS	50 mg (50-100 mg) q4-6h	PO, IM, IV	Maximum 400 mg/24 hr
Cyclizine	MS, GIDz	50 mg q8h	PO, IM	Maximum 200 mg/24 hr
Meclizine	MS, V	25-50 mg q24h	PO	
Diphenhydramine	GIDz	25-50 mg q6h 50-100 mg q6h	PO, IV IM	
Promethazine	GIDz, PONV, MS	25 mg (12.5-25 mg) q6-12h 25 mg (12.5-50 mg) q4-6h	PO, PR IV, IM	Phenothiazine derivative, but lacks significant antidopaminergic effects Avoid perivascular extravasation or subcutaneous injection(severe tissue necrosis)
Trimethobenzamide	GIDz, PONV	200 mg q6-8h	IM	
DOPAMINE RECEPTOR ANTAGONISTS	Most commonly: acute, nonsurgical gastrointestinal disorders (viral gastroenteritis), PONV, CTX			Side effects: neuromuscular (extrapyramidal) symptoms—agitation, restlessness, involuntary movements, dystonia, torticollis, laryngospasm, Parkinson-like features
Prochlorperazine	GIDz, PONV, CTX with low-emetic risk	5-10 mg q6-8h 25 mg q12h	PO, IV, IM PR	Maximum dose 20-40 mg/24 hr; avoid subcutaneous injection (irritation)
Metoclopramide	GIDz Mildly emetogenic CTX	10 mg (10-20 mg) q6-8h 1-2 mg/kg before and 2 hr after CTX	PO, IV, IM IV	Modest efficacy at these doses High doses infrequently used owing to availability of safer, more effective CTX regimens; use with diphenhydramine to reduce adverse side effects
Droperidol	PONV	2.5 mg (1.25-5 mg) preinduction and q4-6h as needed	IV, IM	May cause QTc prolongation and torsades de pointes; use is restricted to patients who fail to respond to other agents

TABLE 118-5 MEDICAL TREATMENT OF NAUSEA AND VOMITING—cont'd

DRUG	USUAL INDICATIONS	USUAL DOSE (RANGE)	ROUTE	COMMENTS
Olanzapine	Highly emetogenic CTX: used in combination with 2-3 other antiemetic agents	10 mg q24h on days 1-4	PO	Antipsychotic that blocks dopamine D2 and serotonin 5HT-2 receptors; side effects include sedation and hyperglycemia
CORTICOSTEROIDS				
Dexamethasone	PONV CTX	4-8 mg once preinduction 8-20 mg on day 1; 8 mg on days 2-4	PO, IV PO, IV	Most beneficial when used with other agents (e.g., 5-HT_3 RA, neurokinin-1 RA)
BENZODIAZEPINES				Used to reduce anxiety and anticipatory vomiting
Lorazepam	CTX	1-2 mg q4-6h	PO, IV	
CANNABINOIDS				May stimulate appetite; adverse side effects (sedation, dizziness, dysphoria, dry mouth) limit use
Dronabinol	GIDz, CTX	5-10 mg q6-8h	PO	
Nabilone	GIDz, CTX	1-2 mg q12h	PO	
5-HT_3 RECEPTOR ANTAGONISTS	PONV, CTX			All except palonosetron may cause QTc prolongation (dose-dependent) with risk of cardiac arrhythmias PONV prevention: give IV immediately before anesthesia induction Prevention of CTX-induced vomiting: give single dose 30 min (IV) to 1 hr (PO) before CTX
Ondansetron	PONV CTX, RadTx	4 mg once 4-8 mg 8 mg once	IV PO IV	
Granisetron	CTX, RadTx	1 mg twice daily 1 mg once	PO IV	
Dolasetron	CTX, PONV	100 mg once daily	PO only	
Palonosetron	CTX PONV	0.25 mg once 0.5 mg 0.075 mg	IV PO, 1-3 days IV	Second generation antagonist with higher affinity for 5-HT3 receptors and longer half-life; does not cause QTc prolongation
NEUROKININ-1 RECEPTOR ANTAGONISTS	Highly emetogenic CTX			Used exclusively in combination with a 5-HT_3 RA or dexamethasone
Aprepitant		125 mg on day 1; 80 mg on days 2-3	PO	
Rolapitant		180 mg 1-2 hr before CTX	PO	
Fosaprepitant		150 mg on day 1	IV	Aprepitant 80 mg PO on days 2-3
Netupitant 300 mg/palonosetron 0.5 mg combination		1 capsule 1 hr before CTX	PO	
ANTIEMETIC REGIMENS FOR CHEMOTHERAPY				
Mildly emetogenic CTX	Option 1 Option 2 Option 3	Dexamethasone 8 mg Dopamine receptor antagonist 5-HT_3 RA	IV or PO	One dose only One dose only One dose only
Moderately emetogenic CTX		Day 1: 5-HT_3 RA plus dexamethasone 8 mg with or without neurokinin-1 RA	IV or PO	Days 2-3: continue oral 5-HT_3 RA and/or dexamethasone 8 mg to reduce delayed emesis
Highly emetogenic CTX		Day 1: 5-HT_3 RA plus dexamethasone 12 mg plus neurokinin-1 RA plus olanzapine	IV or PO	Days 2-4: olanzapine and dexamethasone 8 mg PO daily; if aprepitant given on day 1, continue 80 mg PO days 2-4. Regimens may vary.

5-HT_3 = serotonin or 5-hydroxytryptamine$_3$; CNS = central nervous system; CTX = chemotherapy; GIDz = acute, nonsurgical gastrointestinal disorders associated with nausea and vomiting (e.g., viral gastroenteritis); IM = intramuscularly; IV = intravenously; MS = motion sickness; PO = orally; PONV = postoperative nausea and vomiting; PR = per rectum; RA = receptor antagonist; RadTx = radiation therapy–induced nausea and vomiting; V = vertigo.

Modified from Proctor DD. Approach to the patient with gastrointestinal disease. In: Goldman L, Ausiello D, eds. *Cecil Textbook of Medicine*, 23rd ed. Philadelphia: Saunders-Elsevier; 2008.

GASTROINTESTINAL BLEEDING

GI bleeding (Chapter 121) may be acute and clinically apparent (overt) or chronic, slow, and clinically inapparent (occult). The location of acute GI bleeding is described as either upper or lower, according to whether the source is proximal or distal to the ligament of Treitz (distal duodenum). Upper GI bleeding, which is three times more common than lower GI bleeding, is manifested by bloody emesis (hematemesis), coffee ground emesis, and, in most cases, black stools (melena). Common causes of significant bleeding are peptic ulcer disease, esophageal varices, Mallory-Weiss tears, erosive gastritis or esophagitis, and vascular ectasias.[25] Major lower GI bleeding is manifested by large-volume maroon or bright red bloody stools (hematochezia). Although 80 to 90% of patients with hematochezia have a lower source of bleeding, massive upper GI bleeding also may cause hematochezia. Approximately 95% of major lower GI bleeding arises from the colon and 5% from the small intestine. Lower GI bleeding is increased in patients older than

50 years, in whom diverticulosis accounts for 60% of cases; the remainder are due to ischemia, neoplasms, ulcers, vascular ectasias, or hemorrhoids. In patients younger than 50 years, bleeding is more commonly attributable to inflammatory bowel disease, hemorrhoids, or infectious colitis, but the incidence of colonic neoplasia is increasing in patients ages 40 to 50 years.[26]

Occult GI bleeding refers to GI blood loss that is small in volume and not apparent to the patient but is detectable by tests for fecal occult blood. Chronic occult bleeding may result in iron deficiency anemia.[27] Both upper endoscopy and colonoscopy should be performed to look for a source of occult bleeding, most commonly gastroesophageal or colonic neoplasia, erosive esophagitis or gastritis, ulcer disease, or vascular ectasia. In patients with recurrent iron deficiency and occult blood loss in whom no source is found on upper and lower endoscopy, video capsule endoscopy, CT enterography, or enteroscopy is performed to look for a small bowel source (vascular ectasia, ulcer, or neoplasm)

FECAL INCONTINENCE

Fecal incontinence (Chapter 131) is dependent on a number of factors, including a solid or semisolid stool, a compliant and distensible rectal reservoir, the ability to sense rectal fullness, an intact internal anal sphincter (an involuntary muscle innervated by the enteric nervous system), an intact external anal sphincter and puborectalis (voluntary muscles innervated by the pudendal nerve), and the mental and physical ability to reach a toilet facility when needed.[28] Minor incontinence, which occurs in 10% of people older than 70 years, is characterized by the inability to control flatus or by the seepage of fecal matter that results in soiling of the perianal area and undergarments. It tends to be intermittent, occurring after bowel movements; when coughing, lifting, or passing flatus; or when stools are loose. Major incontinence is characterized by the partial or complete inability to control bowel movements reliably, resulting in gross, involuntary loss of feces and the need to wear a diaper. It occurs in less than 1% of the population and is virtually always caused by a central nervous system disorder that results in diminished awareness of bowel needs, neuropathy, or damage to the anal sphincters.

OTHER GASTROINTESTINAL COMPLAINTS

Heartburn, esophageal regurgitation, dysphagia,[29] odynophagia, and noncardiac chest pain suggest esophageal disease (Chapter 124). *Dyspepsia*, which refers to bothersome, intermittent, mild to moderate upper abdominal or epigastric symptoms (burning, pain, early satiation, postprandial fullness) can be caused by peptic ulcer disease (Chapter 125) or esophageal disease (Chapter 124), or it can be functional in origin (Chapter 123).[30] An orderly diagnostic approach (Fig. 118-6) can help distinguish among the various causes, avoid unnecessary testing, and minimize symptoms.

Diarrhea, which is defined pathophysiologically as an increase in stool weight to more than 200 g/day, can be caused by malabsorption of osmotically active substances or by increased intestinal secretion of electrolytes and water. In clinical practice, however, stool weight is seldom quantified, and the term *diarrhea* refers to an increase in stool liquidity or frequency (more than three bowel movements per day). Acute and chronic diarrhea (Chapter 126) should be distinguished because the evaluation and treatment are different. In young adults with chronic diarrhea, the leading causes are irritable bowel syndrome (Chapter 123), inflammatory bowel disease (Chapter 127), microscopic colitis (Chapter 126), bile acid diarrhea,[31] malabsorption, drugs, food additives, and diabetes (Chapter 210).

119 DIAGNOSTIC IMAGING PROCEDURES IN GASTROENTEROLOGY

LAURA R. CARUCCI

A variety of imaging procedures may be performed to evaluate the gastrointestinal (GI) tract and hepatobiliary system for a spectrum of symptoms, including abdominal pain (Chapter 118), nausea (Chapter 118), vomiting, heartburn (Chapter 123), diarrhea (Chapter 126), constipation (Chapter 122), bloating, GI bleeding (Chapter 121), weight loss (Chapter 118), or abnormal laboratory test results. Imaging modalities utilized for these procedures include radiography, fluoroscopy, ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine. Each modality provides varying utility with advantages and disadvantages.[1,2] In addition, these modalities offer advanced techniques for GI and hepatobiliary imaging, including CT and MR enterography, CT colonography (virtual colonoscopy), MR cholangiopancreatography (MRCP), MR elastography, CT and MR angiography, and positron emission tomography (PET)/CT.

RADIOGRAPHIC PLAIN FILMS

Radiography provides quick, low-cost, readily available, and portable evaluation of the abdomen and pelvis. Abdominal radiographs may be ordered to evaluate acute abdominal pain and to assess for obstruction, ileus, perforation, post-surgical changes, tubes, and catheters. Different tissue types absorb a varying amount of the radiation beam. Bone absorbs more of the beam and will appear white, whereas gas will transmit more of the beam to the detector and appear black. Radiographs therefore can be utilized to evaluate the bowel gas pattern, calcifications, radiopaque foreign bodies, and the osseous structures, and they may also provide some information about the soft tissues. Although radiography is a readily available first-line modality, abdominal radiographs are less sensitive and specific than CT for many processes involving the abdomen and pelvis, and CT can provide much more detailed information on the overall extent and severity of disease processes.

Abdominal radiographs show the distribution of bowel gas and caliber of bowel. A combination of supine and upright or decubitus radiographs is preferred over supine imaging alone and can provide more detail about potential bowel obstruction or extraluminal air. The pattern of bowel gas and air-fluid levels can help distinguish between entities such as small bowel obstruction (Fig. 119-1), colonic obstruction, volvulus, or ileus. In addition to bowel gas, radiographs may reveal gas in atypical or unexpected locations, including pneumoperitoneum (Fig. 119-2), pneumatosis (Fig. 119-3), pneumobilia, portal venous gas, retroperitoneal gas, subcutaneous emphysema, gas in an abscess, or gas in the gallbladder.

Pneumoperitoneum may be recognized on supine radiographs by the appearance of gas on both sides of the bowel wall (Rigler sign); linear, angulated, or triangular areas of lucency; gas in the most non-dependent portion of the abdomen in the midline, under the central tendon of the diaphragm; or outlining spaces and structures such as the falciform ligament (see Fig. 119-2). An upright or decubitus radiograph increases the sensitivity for detecting free air. With optimal patient positioning and technique, as little as 1 to 2 mL of free air can been seen on abdominal radiography. However, pneumoperitoneum may be identified in only 50% of patients with documented visceral perforation because of technical limitations, including poor image quality, suboptimal field of view, and exclusion of the uppermost peritoneal cavity on the image. CT is the most accurate and sensitive diagnostic modality for detecting pneumoperitoneum.

Abdominal radiographs are also useful to evaluate radiopaque foci such as calcifications (gallstones, renal stones, fecoliths), foreign bodies (ingested or inserted foreign bodies, ballistic fragments), surgical devices (bariatric lap band) (Fig. 119-4), drains, tubes, and retained surgical material (sponge, lap pads, needles). Radiography can localize radiopaque intra-abdominal foreign bodies with a sensitivity of 90% and specificity of 100%.

FLUOROSCOPY

Fluoroscopy studies use contrast agents that may be swallowed, injected, or instilled into the GI tract in conjunction with radiographic images. Fluoroscopy studies are relatively quick, inexpensive, minimally or noninvasive, and widely available. Typical GI fluoroscopy procedures that may be performed include modified barium swallow, esophagram, upper GI series, upper GI series with small bowel follow-through, contrast enema, colostomy enema, and defecography.

Contrast agents utilized include water-soluble iodinated contrast material, barium, and air. Water-soluble contrast is preferred for possible leaks,

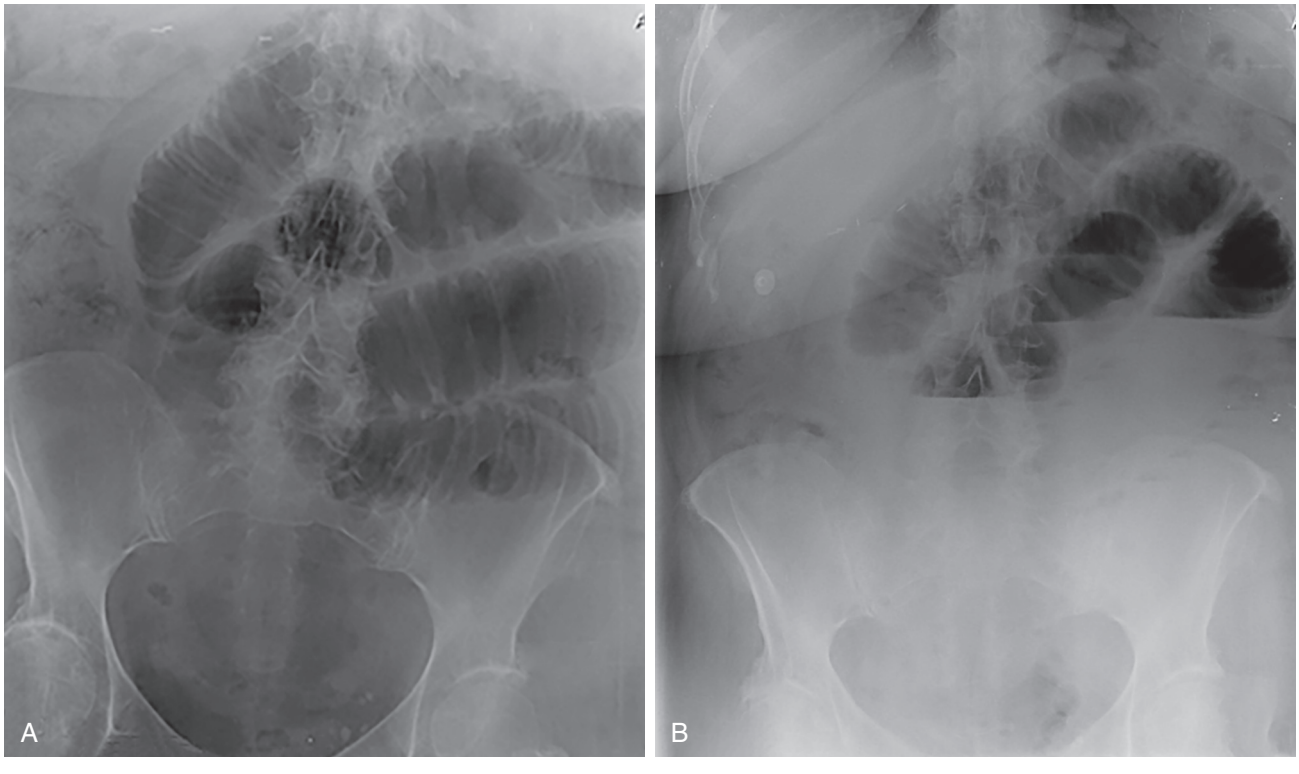

FIGURE 119-1. Small bowel obstruction. Supine (A) and upright (B) radiographs of the abdomen show dilated gas-filled loops of small bowel with a small amount of gas in the colon. The colon is not dilated. Small bowel air-fluid levels are noted on the upright radiograph. The findings are consistent with small bowel obstruction.

ABSTRACT

A variety of imaging procedures may be performed to evaluate the gastrointestinal (GI) tract and hepatobiliary system for a spectrum of symptoms, including abdominal pain, nausea, vomiting, heartburn, diarrhea, constipation, bloating, GI bleeding, weight loss, or abnormal laboratory test results. Imaging modalities utilized for these procedures include radiography, fluoroscopy, ultrasound (US), computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine. Each modality provides varying utility with advantages and disadvantages. In addition, the modalities offer advanced imaging techniques for GI and hepatobiliary imaging, including CT and MR enterography, CT colonography (virtual colonoscopy), MR cholangiopancreatography (MRCP), MR elastography, CT and MR angiography, and PET/CT. Many of these modalities may also be utilized for interventional procedures.

nuclear medicine

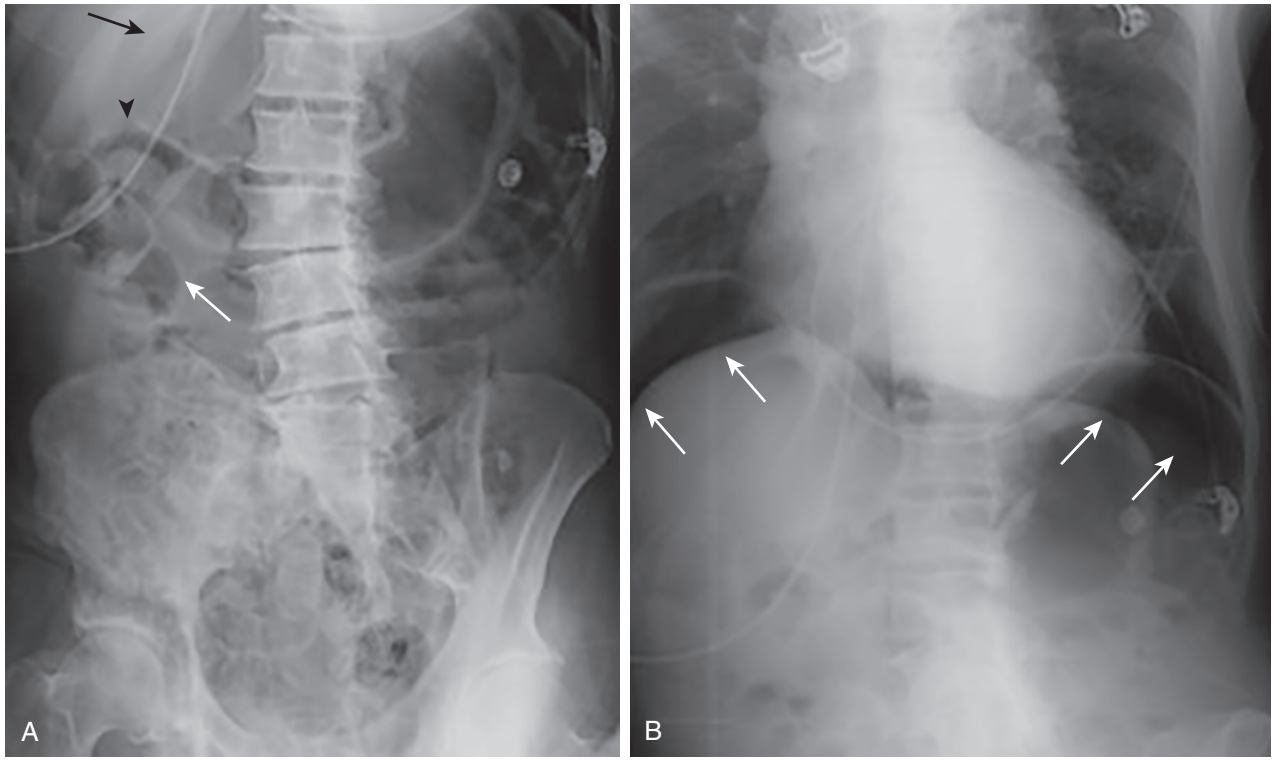

FIGURE 119-2. Pneumoperitoneum. A, A supine radiograph of the abdomen shows pneumoperitoneum. There is increased lucency throughout the upper abdomen (*black arrow*) with angulated gas in the right upper quadrant (*arrowhead*), and both sides of the bowel wall are visible (Rigler sign) (*white arrow*). **B,** An upright radiograph confirms a large amount of free air layering under the diaphragm (*arrows*).

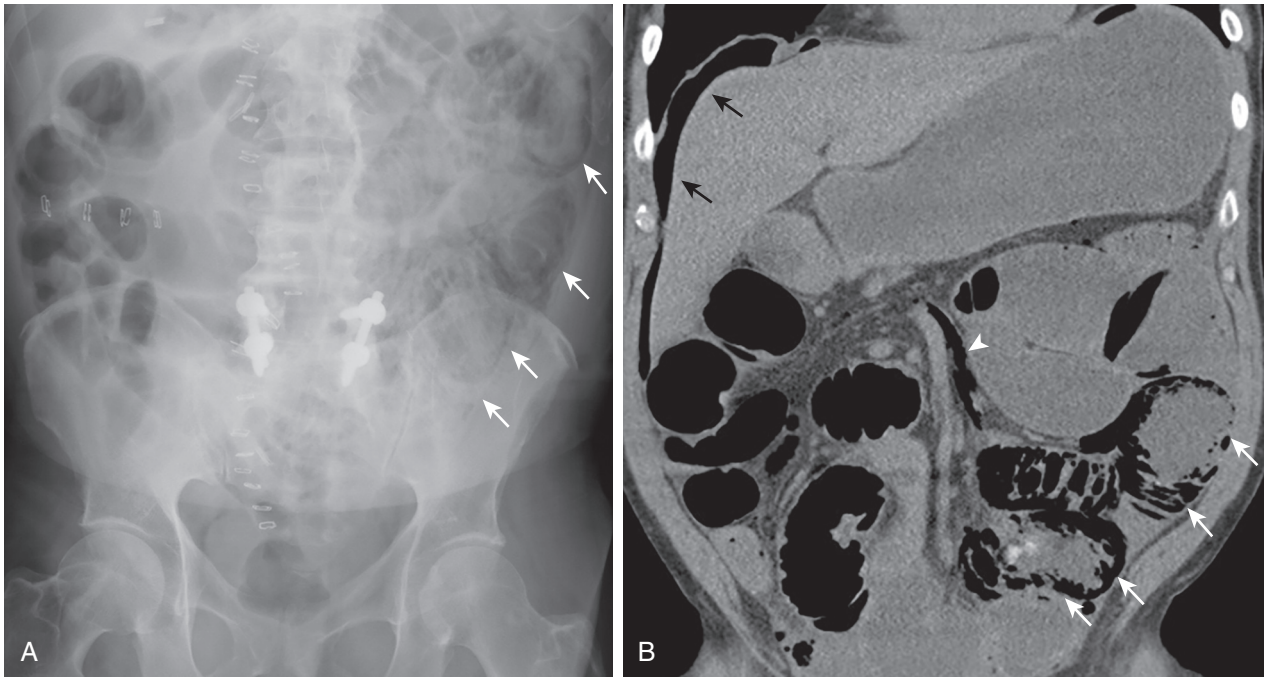

FIGURE 119-3. Pneumatosis. A, A supine radiograph of the abdomen shows dilated small bowel loops with lucency in the bowel wall due to pneumatosis (*arrows*). Also note skin staples and hardware in the lumbar spine. Pneumatosis is much more readily visible on the coronal computed tomographic (CT) image without intravenous contrast (*white arrows*). **B,** Also seen on the CT is associated mesenteric venous gas (*arrowhead*) and free air (*black arrows*).

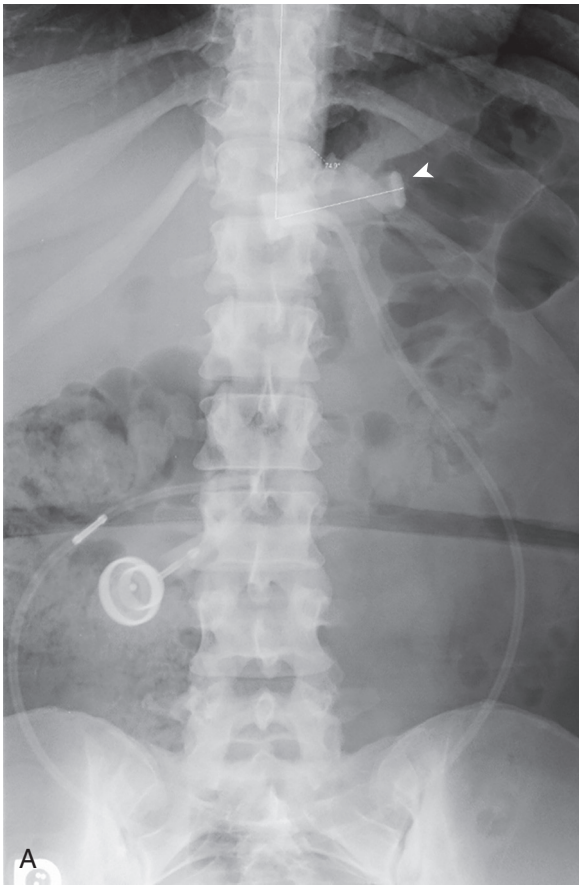
perforations, suspected impacted foreign bodies, and following trauma, surgery, or instrumentation. Barium is preferred otherwise.

Double contrast techniques, which utilize barium in conjunction with air to distend the lumen, are best for mucosal detail (Fig. 119-5). Single contrast techniques are used for debilitated or postoperative patients and to evaluate for leaks (Fig. 119-6).

GI fluoroscopy studies evaluate the bowel lumen but provide limited information about surrounding structures other than secondary findings, such as mass effect and displacement. Fluoroscopy studies provide anatomic, structural, mucosal, and functional information about the bowel. In particular, fluoroscopy studies may detect congenital anomalies, infectious or inflammatory conditions (including inflammatory bowel disease; Chapter 127), filling defects (polyps, masses) (see Fig. 119-5), outpouchings (e.g., ulcers [Chapter 125], diverticula [Chapter 128]), extravasation (leak) (see Fig. 119-6), fistulae, and obstruction (e.g., mass, stricture, adhesive disease, intussusception). Also, fluoroscopic studies are ideally suited to evaluate post-surgical anatomy and complications



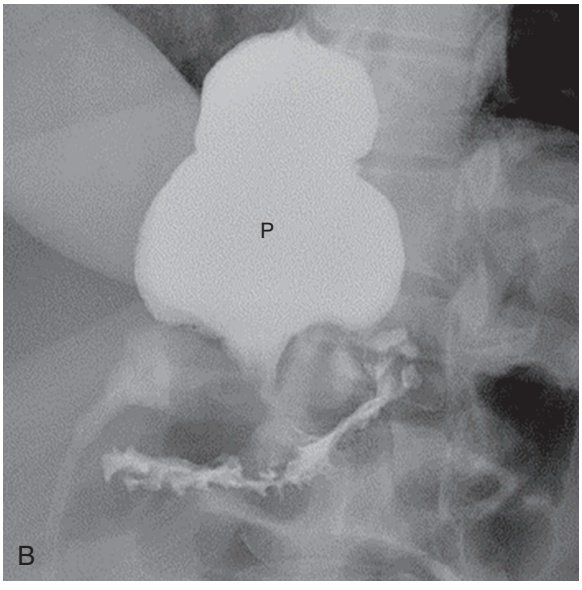


FIGURE 119-4. Gastric band bariatric surgery: band slippage with fundic herniation. **A,** A supine radiograph of the abdomen shows a gastric band device. The radiograph allows for evaluation of the surgical components, including the band itself (*arrowhead*), the connecting tubing, and the injectable reservoir. The inflatable band around the proximal stomach is too inferiorly located and horizontal in position (*arrowhead*). **B,** An upper gastrointestinal fluoroscopic spot image shows a dilated gastric pouch (*P*) above the band, with partial obstruction owing to band slippage with fundic herniation.

(see Fig. 119-4). Although CT is a high-yield study for diagnosis of small bowel obstruction and its cause, upper GI series with small bowel follow-through can further evaluate the cause and degree of obstruction and provide useful information about bowel transit time. Fluoroscopy can also be used for interventions, including feeding tube and drainage catheter placement and repositioning. For patients with inflammatory bowel disease, however, CT and MR enterography are now much more commonly performed than is a fluoroscopic small bowel follow-through. Similarly, CT colonography is more often performed than a double contrast barium enema to screen for colorectal cancer.

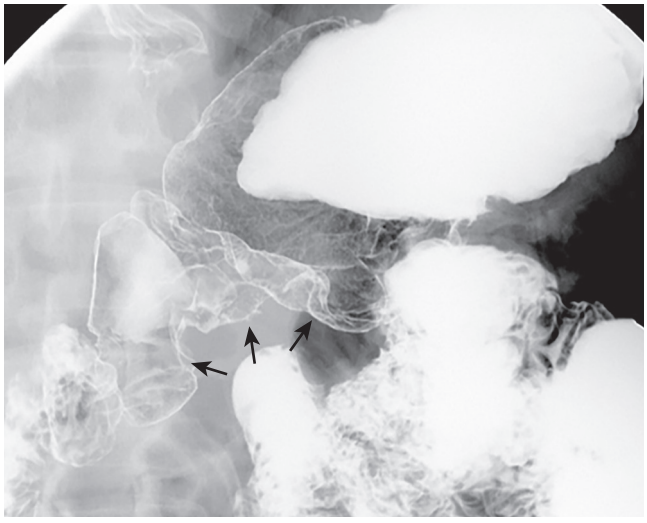

FIGURE 119-5. Gastric cancer. A double contrast upper gastrointestinal fluoroscopic spot image shows a lobulated mass along the greater curvature of the gastric body (*arrows*), consistent with a primary gastric neoplasm.

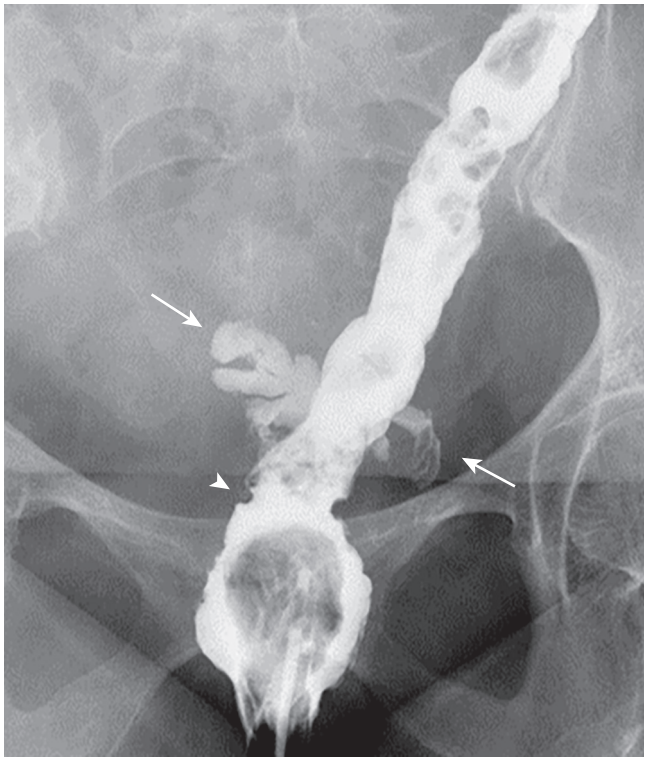

FIGURE 119-6. Colorectal anastomotic leak. A single contrast enema utilizing water-soluble contrast shows a colorectal anastomosis (*arrowhead*) as well as a large collection of amorphous extraluminal contrast (*arrows*) owing to anastomotic leak.

Fluoroscopy, which allows for real-time imaging and observing changes over time, can be used to evaluate the swallowing mechanism, esophageal motility and reflux, and bowel transit time. For example, an esophagram can assess for a spectrum of structural and mucosal abnormalities (including ulcer, stricture, mass, and hiatal hernia), evaluate esophageal motility, and detect gastroesophageal reflux and its complications (Fig. 119-7).[3] Modified barium swallow studies and esophagrams constitute a larger percentage of fluoroscopy studies now performed,[4] because the pharynx and esophagus are not as readily evaluated with cross sectional techniques.[5] Modified barium swallow can evaluate the swallowing mechanism, assess for aspiration using various consistencies and compensatory maneuvers, and determine potential strategies to improve swallowing function[6]; it is particularly useful in patients who have neurologic and musculoskeletal conditions, trauma, recurrent upper respiratory infections, and aspiration pneumonia.

FIGURE 119-7. Barrett esophagus. A fluoroscopic spot image from an esophagram shows a patulous gastroesophageal junction; marked spontaneous gastroesophageal reflux was also seen at fluoroscopy. A focal stricture with mild associated irregularity in the mid to upper thoracic esophagus (*arrow*) is due to Barrett esophagus.

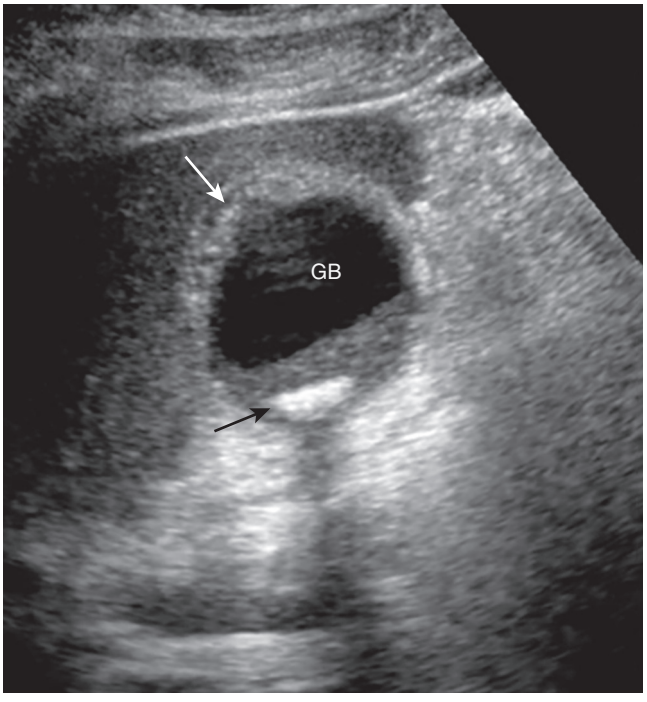

FIGURE 119-8. Cholelithiasis and acute cholecystitis. Ultrasound of the gallbladder (*GB*) shows echogenic, shadowing stones (*black arrow*) surrounded by layering sludge. Also noted is gallbladder wall thickening (*white arrow*) with trace adjacent fluid. A sonographic Murphy sign was also noted upon scanning.

ULTRASOUND

Abdominal ultrasound provides real-time imaging that utilizes high-frequency sound waves emitted by a transducer or probe, most often placed on the skin surface. Sound waves bounce back to the transducer to varying degrees based on the type of tissue, thereby creating images of the solid organs and vasculature of the abdomen. Ultrasound is noninvasive, portable, and does not utilize ionizing radiation or iodinated contrast material. These characteristics make ultrasound an excellent first test to evaluate patients who have suspected disease or abnormalities of the liver, gallbladder, biliary tree, spleen, pancreas, kidneys, and the abdominal cavity, as well as the inferior vena cava, aorta, and portal vein. Ultrasound may also be performed utilizing transvaginal, transrectal, or endoscopic probes, and it may be utilized for image-guided biopsy and intervention.

However, images are acquired only where the probe is placed, and ultrasound is therefore operator dependent. Also, it may be difficult to evaluate the entire contents of the abdomen owing to a large body habitus, the patient's positioning, artifact from skin dressings, and artifact from bowel gas. Ultrasound waves are blocked by bowel gas, thereby often limiting evaluation of the common bile duct and pancreas. As a result, more detailed evaluation often requires CT or other modalities.

A liver Doppler examination provides more detailed information about the hepatic vasculature and can evaluate vascular patency, direction of flow, and vascular waveforms. Doppler ultrasound techniques can also be used to diagnose vascular thrombosis (Chapter 129), varices (Chapter 139), cavernous transformation of the portal vein, aneurysms, and vascular anomalies (Chapter 129).

Ultrasound is well suited to evaluate the gallbladder (Chapter 141) and right upper quadrant pain.[7] Sound waves travel through fluid, thereby making ultrasound an ideal modality to evaluate the gallbladder. The normal gallbladder is fluid-filled, transmits sound, and appears hypoechoic (dark) on ultrasound. Gallstones appear echogenic (bright) and result in "acoustic shadowing" as the sound waves fail to propagate through stones (Fig. 119-8). Ultrasound is the method of choice for the diagnosis of gallstones with high sensitivity and accuracy (>95%), and ultrasound can differentiate cholelithiasis from sludge, polyps, or masses. In the setting of acute cholecystitis, ultrasound may reveal gallstones, gallbladder wall thickening, adjacent fluid, gallbladder distension (see Fig. 119-8), and a sonographic Murphy sign (focal tenderness corresponding to a sonographically localized gallbladder). Biliary ductal dilation may be recognized, but the cause may not be revealed if the common duct and pancreas are obscured by bowel gas. MR or CT may be performed to evaluate for the etiology of biliary obstruction (i.e., pancreatic mass, choledocholithiasis).

Ultrasound is useful to assess for diffuse hepatic processes, and it can evaluate the liver's size, morphology, and echotexture. In cirrhosis (Chapter 139), the liver appears echogenic, heterogeneous, and nodular in contour (Fig. 119-9).[8] Ultrasound can also identify findings of portal hypertension, including splenomegaly, ascites, and collateral vessels. Ultrasound can detect focal solid organ lesions and can readily determine a cystic or solid nature of a lesion. Doppler techniques can be utilized to determine the lesion's vascularity (see Fig. 119-9). CT and MR are superior to ultrasound overall to characterize liver lesions (i.e., benign lesions, primary tumor, metastasis), but contrast-enhanced ultrasound can assist in characterizing a liver lesion sonographically. Ultrasound following intravenous (IV) injection of a contrast agent, consisting of gas within microbubbles, can show enhancement of the lesions.

COMPUTED TOMOGRAPHY

CT, which uses x-ray technology, can image the entire contents of the abdomen and pelvis within only a few minutes, while providing excellent anatomic detail. Images can be reconstructed in multiple planes, and 3D images can also be generated. Abdominopelvic CT, which allows for evaluation of the bowel as well as solid organs, mesentery, peritoneum, and vasculature, is often performed with iodinated intravenous contrast to provide more detailed evaluation of abdominal contents. Oral contrast may be administered as well to help evaluate the bowel. Contrast may also be administered rectally or injected into the bladder, a fistula, or a drainage catheter prior to imaging.

CT of the abdomen and pelvis is ideally suited to evaluate patients who present with an acute abdomen (Chapters 118 and 128), because CT can detect even minimal pneumoperitoneum and can evaluate the entirety of the bowel and abdominal vasculature. Free air, pneumatosis, abscesses, and signs of infection, including peritonitis, are more readily visualized on CT than with radiography (see Fig. 119-3). CT also can evaluate for bowel processes, including appendicitis (Chapter 128 and Figs 128-3 and 128-4),[9] diverticulitis (Chapter 128 and Fig 128-6; Fig. 119-10),[10] volvulus, intussusception (Fig. 119-11), infectious and inflammatory conditions (including inflammatory bowel disease; Chapter 127), ischemia (Chapter 129),[11] trauma, perforation,

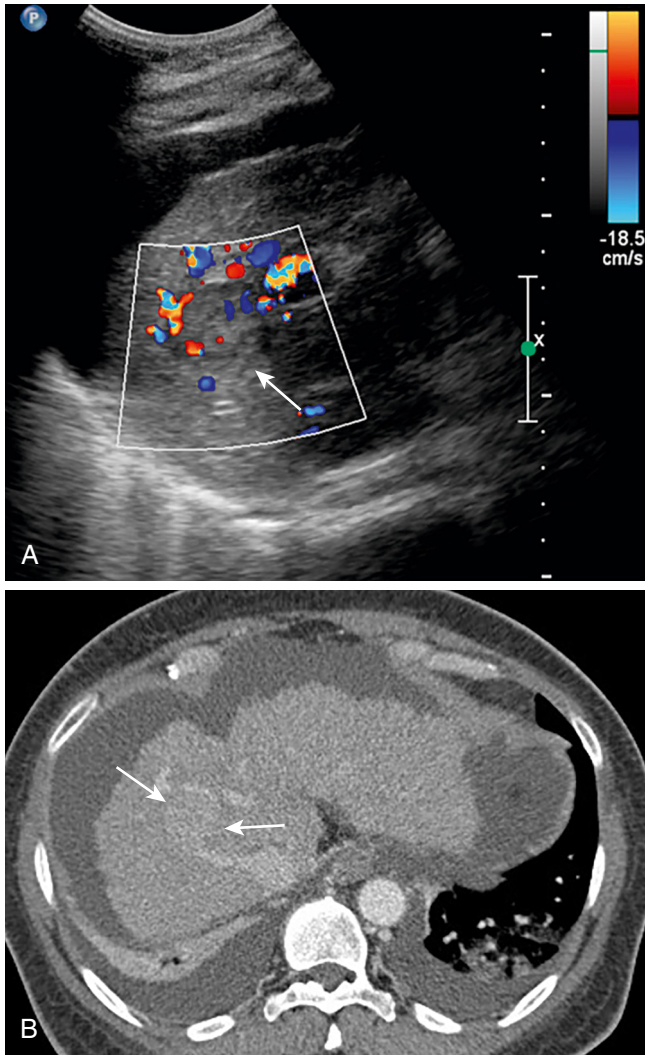

FIGURE 119-9. Cirrhosis with hepatocellular carcinoma. A, Abdominal ultrasound using color Doppler technique shows a small, nodular, echogenic, and heterogeneous liver due to cirrhosis. A focal mass is noted with internal vascularity seen with color Doppler (*arrow*). There is perihepatic fluid. **B,** Contrast-enhanced axial computed tomographic image in the same patient shows a nodular, cirrhotic liver; ascites; and a corresponding enhancing liver lesion (*arrows*) consistent with hepatocellular carcinoma.

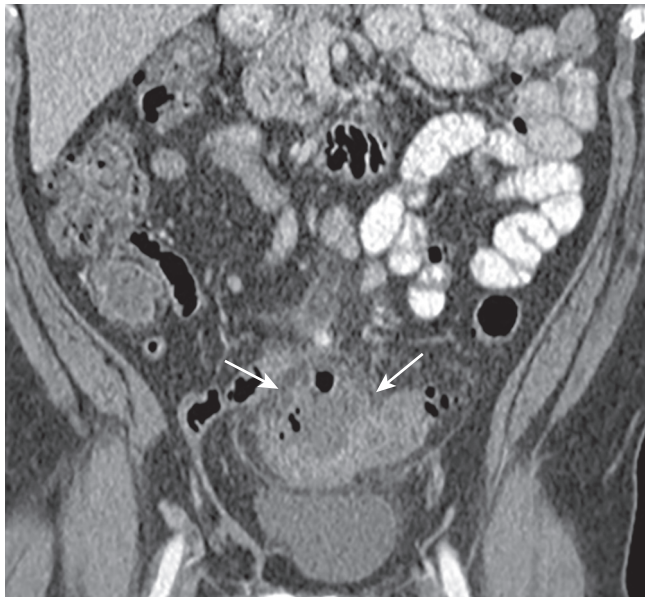

FIGURE 119-10. Acute sigmoid diverticulitis with abscess. A coronal contrast-enhanced computed tomographic image reveals diverticulosis in the sigmoid colon. There is focal sigmoid colon wall thickening with adjacent inflammatory change and an abscess (*arrows*) along the sigmoid colon due to diverticulitis.

FIGURE 119-11. Small bowel obstruction due to intussusception following Roux-en-Y gastric bypass. A coronal contrast-enhanced CT image shows markedly dilated small bowel consistent with obstruction and due to intussusception (*arrows*) at the jejunojejunal anastomosis in a patient status post Roux-en-Y gastric bypass. Note clips near the gastrojejunal anastomosis (*arrowhead*).

fistulas, bowel obstruction, and intrinsic or extrinsic masses. CT also allows for diagnosis of relatively benign entities that may mimic more severe pathology by presenting with an acute abdomen, such as epiploic appendagitis and omental infarction.

CT can detect diffuse processes involving the liver, including cirrhosis, along with its possible associated findings and complications, such as splenomegaly, ascites, collateral vessels, or hepatocellular neoplasm (see Fig. 119-9). Diffuse pancreatic processes, such as pancreatitis (Chapter 130) and its associated complications (such as ascites, fluid collections, vascular thromboses, and pseudoaneurysms), also are well characterized with CT. CT is better than ultrasound for detailing whether a lesion is likely benign or malignant (i.e., hepatic hemangioma, cyst, primary tumor, or metastasis).

Ultrasound, which is more sensitive than CT for the detection of cholelithiasis, should be the first-line procedure for the evaluation of the gallbladder itself. However, CT allows for visualization of the entire biliary tree and the underlying cause of biliary obstruction (i.e., pancreatic mass), but MR is more sensitive for the detection of choledocholithiasis.

In addition to bowel and solid organs, the mesentery and peritoneum are also included in their entirety on CT, thereby allowing for diagnosis of mesenteric masses, tumor implants, adenopathy, hematoma, abscesses, ascites, peritonitis, and carcinomatosis. CT can assess for disease spread throughout the abdomen and pelvis. CT with IV contrast also allows for evaluation of the mesenteric and hepatic vasculature (Fig. 119-12), aorta, inferior vena cava, and any potential collateral vessels. CT is often utilized to diagnose and stage primary tumors in the abdomen and pelvis and to assess for metastases to lymph nodes, solid organs, the peritoneum, and bone (Fig. 119-13). CT is also utilized to evaluate the therapeutic response of tumors.

CT angiography is useful to diagnose atherosclerotic disease, arterial thrombosis, embolic disease, vasculitis, aneurysms, dissections, vascular encasement by tumor, mesenteric ischemia, or GI bleeding. Slight protocol and image timing modifications allow for more optimal evaluation of these processes, and noninvasive CT angiography has largely replaced conventional angiography for many indications.

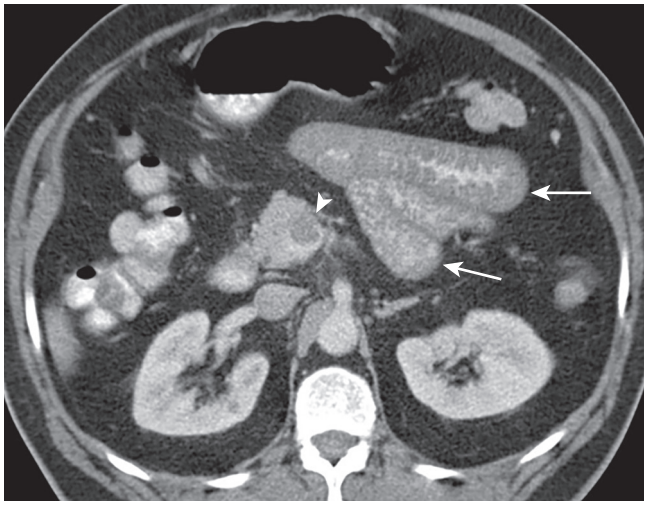

FIGURE 119-12. Superior mesenteric vein (SMV) thrombosis. An axial computed tomographic image with intravenous contrast shows a filling defect in the SMV consistent with thrombus (*arrowhead*). Associated jejunal wall thickening (*arrows*) is due to ischemic changes.

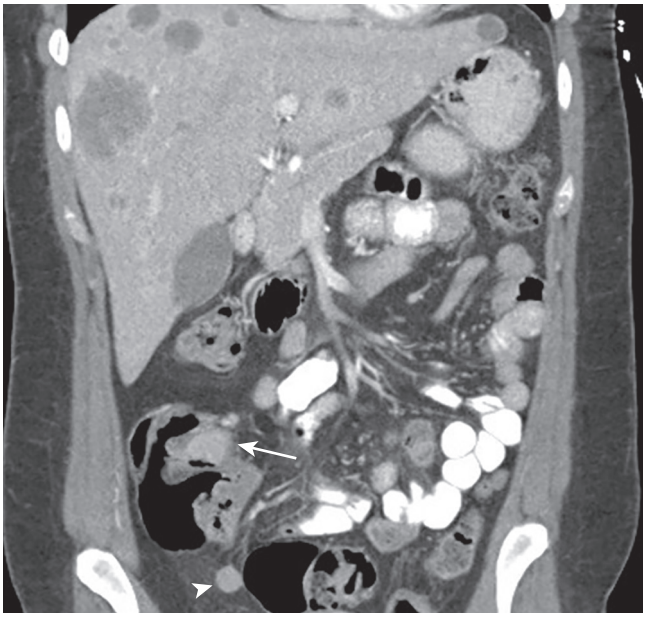

FIGURE 119-13. Metastatic neuroendocrine tumor. A coronal contrast-enhanced computed tomographic image shows an enhancing mass along the ileocecal valve (*arrow*) consistent with a primary neuroendocrine tumor. Multiple hepatic metastases are noted as well as a peritoneal tumor implant in the right lower quadrant (*arrowhead*).

CT enterography is a CT study optimized to evaluate the small bowel. Neutral oral contrast is administered to distend the bowel, and IV contrast is given to evaluate the bowel wall and its enhancement pattern. CT enterography can identify areas of bowel involvement and active inflammation in inflammatory bowel disease, as well as assess for complications such as strictures, fistulas, abscess, and obstruction. CT enterography can also evaluate for possible small bowel masses and determine a cause for low-grade, intermittent, or chronic small bowel obstruction.

CT colonography, or virtual colonoscopy, is a low-radiation-dose, noninvasive, safe, and effective screening examination for colorectal cancer. CT colonography can detect pre-cancerous polyps before cancer develops.[12] The entire colon is evaluated without the need for the patient to be sedated. 2D and 3D display techniques are utilized to "fly-through" the inside of the colon (Fig. 119-14). CT colonography is now widely accepted as an alternative to conventional colonoscopy for screening for colorectal cancer.[13]

MAGNETIC RESONANCE IMAGING

MRI, which utilizes a strong magnetic field to generate high-resolution images that can be acquired in any plane, provides excellent soft tissue detail, thereby allowing for better characterization of focal lesions as compared with CT. As with CT, MRI can image the entire abdominal contents. MRI allows for many imaging options, and studies are typically tailored for a specific provided indication. However, MRI requires much longer time for image acquisition and therefore may lead to problems with claustrophobia as well as respiratory or motion artifact. The strong magnetic field necessary for MRI also leads to artifacts, safety issues, and certain contraindications, largely related to implanted devices (infusion pumps, vascular clips, implants, certain pacemakers).

MRI can evaluate diffuse processes involving a solid organ, such as the liver, and associated findings. MRI allows for detection and characterization of focal lesions even better than CT. For example, MRI can differentiate focal liver lesions based on their tissue properties, including cysts, biliary hamartomas, hemangiomas, focal nodular hyperplasia, hepatocellular carcinomas (Chapter 181), and metastases (Fig. 119-15). Intravenous gadolinium-based contrast media aid in the characterization of lesions and vascular involvement (Fig. 119-16). The characterization of liver lesions in particular may be further improved with hepatocyte-specific gadolinium contrast agents that are taken up by the liver and excreted in bile, thereby allowing for the differentiation of lesions such as focal nodular hyperplasia versus metastasis. MRI may also be used to diagnose and stage tumors, such as rectal cancer; MRI can localize the

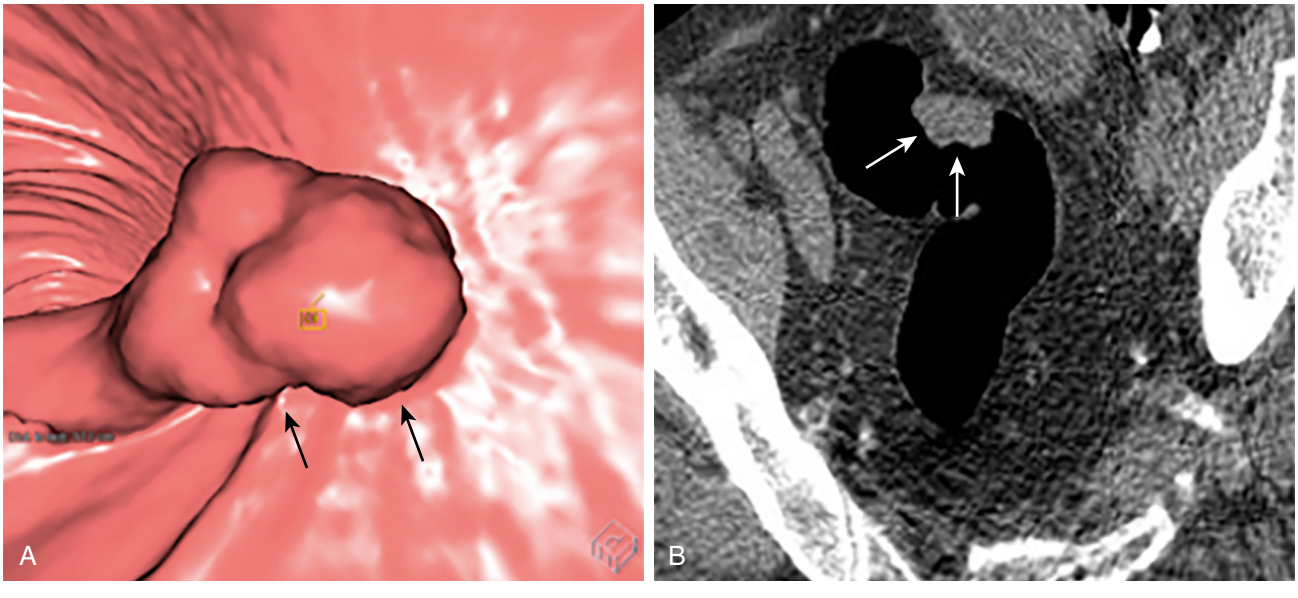

FIGURE 119-14. Polypoid lesion in the sigmoid colon on screening computed tomographic colonography. A, 3D intraluminal fly-though and (B) 2D axial computed tomographic image show a 2.5-cm lobulated polypoid lesion in the sigmoid colon (*arrows*).

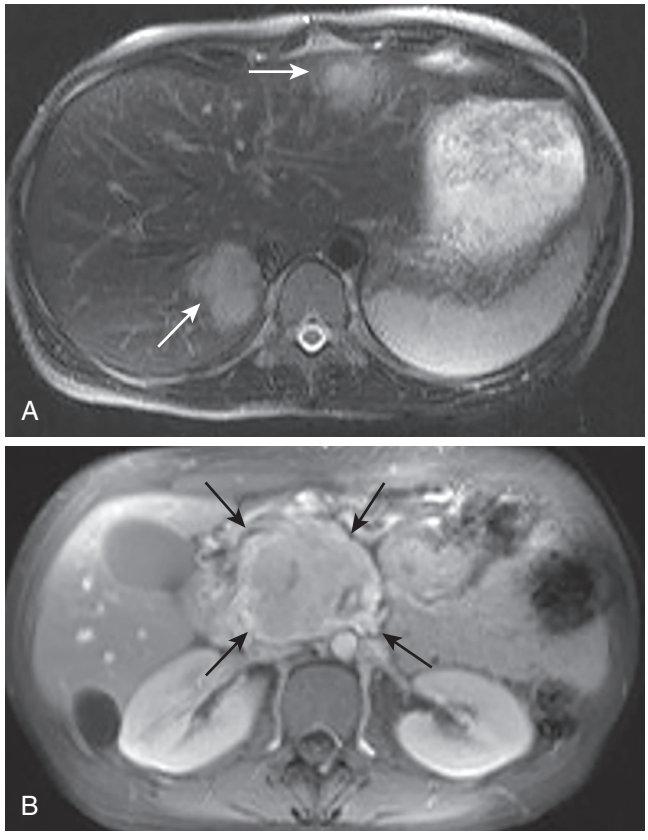

FIGURE 119-15. Pancreatic neuroendocrine tumor with liver metastases. A, Axial T2-weighted magnetic resonance (MR) image shows two moderately bright lesions in the liver (*arrows*). Heterogenous enhancement was seen following contrast (not shown). Imaging features are consistent with hepatic metastatic disease. **B,** Axial post contrast T1 fat-suppressed MR image in the abdomen more inferiorly shows a large heterogenous mass in the proximal pancreas (*arrows*) consistent with pancreatic neuroendocrine tumor.

tumor, evaluate the extent of tumor in the rectal wall, and assess for involvement of surrounding lymph nodes and other structures.

MRI allows for quantitative evaluation in the liver. MRI can be used to detect and quantify hepatic fat (hepatic steatosis) (Fig. 119-17) and hepatic iron deposition (hemosiderosis, hemochromatosis; Chapter 196).[14] In addition, MR elastography is a noninvasive technique to evaluate for liver stiffness and therefore estimate and stage fibrosis in patients with liver disease.[15]

MRI can identify biliary obstruction and determine its cause, including choledocholithiasis and pancreatic masses (Fig. 119-18). MR cholangiopancreatography (MRCP), which is a noninvasive method to evaluate the biliary

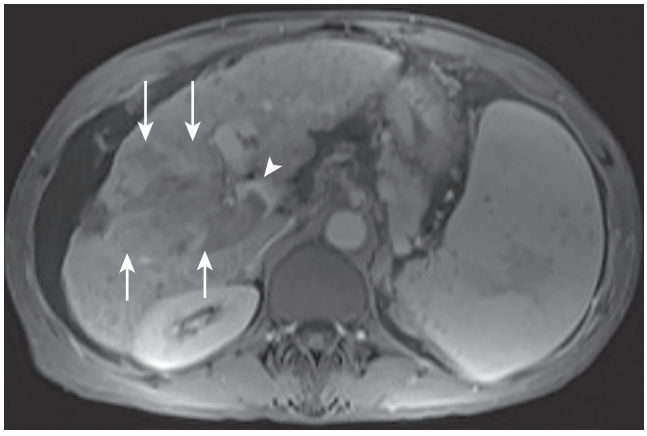

FIGURE 119-16. Hepatocellular carcinoma with tumor thrombus in the main portal vein. Axial post contrast T1 fat-suppressed MR image of the abdomen shows cirrhosis with ascites and splenomegaly. There is a large ill-defined mass in the right lobe (*arrows*) consistent with hepatocellular carcinoma. There is extent into the main portal vein with tumor thrombus (*arrowhead*).

and pancreatic ducts, has replaced endoscopic retrograde cholangiopancreatography for many diagnostic indications. MRCP sequences are optimized to show fluid, such as in the biliary tree and pancreatic duct. This technique is useful to diagnose biliary stones (Fig. 119-19), strictures, cholangitis, masses, variant anatomy, and the relationship of masses to the ducts.

MR angiography may be especially useful in patients who cannot undergo CT angiography because of renal insufficiency or allergy to iodinated contrast agents. MR enterography can evaluate disease activity and response to therapy in patients with inflammatory bowel disease, as well as associated complications, such as stricture (Fig. 119-20), fistula, obstruction, and abscesses. As with CT enterography, neutral oral contrast and IV contrast are administered to determine the bowel wall enhancement pattern. MRI allows for a more detailed evaluation of bowel wall thickening and can determine the presence of edema or fibrosis in the bowel wall. Since it has no ionizing radiation, MR enterography is especially useful in younger patients who have inflammatory bowel disease and who will need multiple examinations over time.

NUCLEAR MEDICINE

Functional nuclear medicine studies for GI processes include gastric emptying and hepatobiliary scintigraphy. A gastric emptying study can diagnose gastroparesis and delayed gastric emptying (Chapter 122). A small meal tagged with radioactive material is ingested and images are obtained over the stomach over time to determine how the stomach empties. Hepatobiliary scintigraphy (cholescintigraphy, hepatobiliary iminodiacetic acid [HIDA] scan) can diagnose problems with hepatic function, the bile ducts, and the

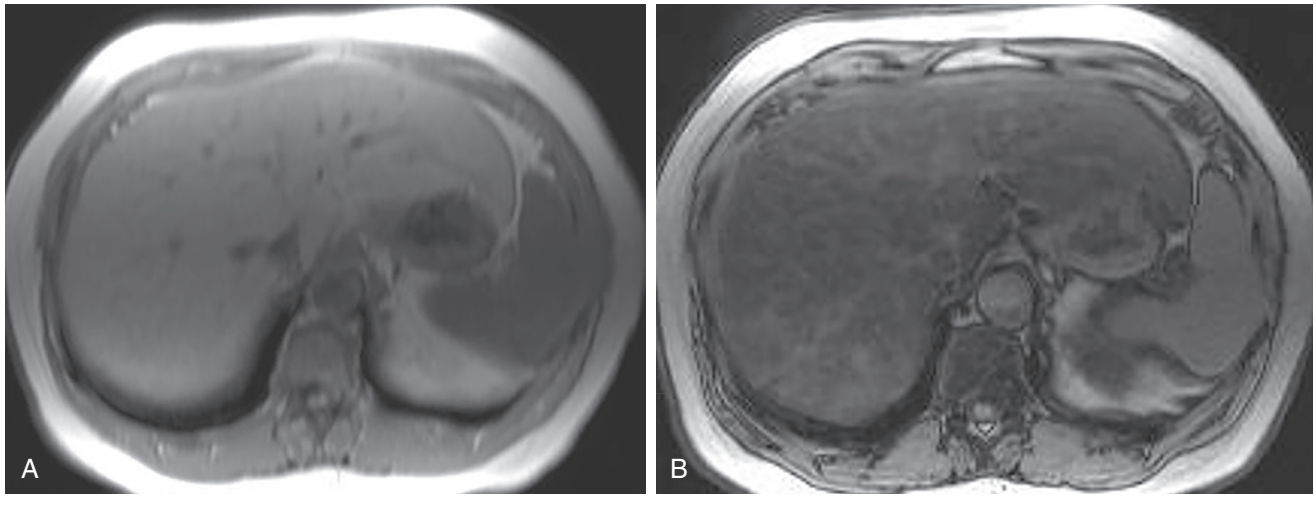

FIGURE 119-17. Hepatic steatosis with chemical shift imaging. Axial T1 in-phase **(A)** and out-of-phase **(B)** magnetic resonance images show pronounced loss of signal intensity throughout the liver on out-of-phase images as compared with in-phase images (the liver is darker) due to diffuse hepatic steatosis.

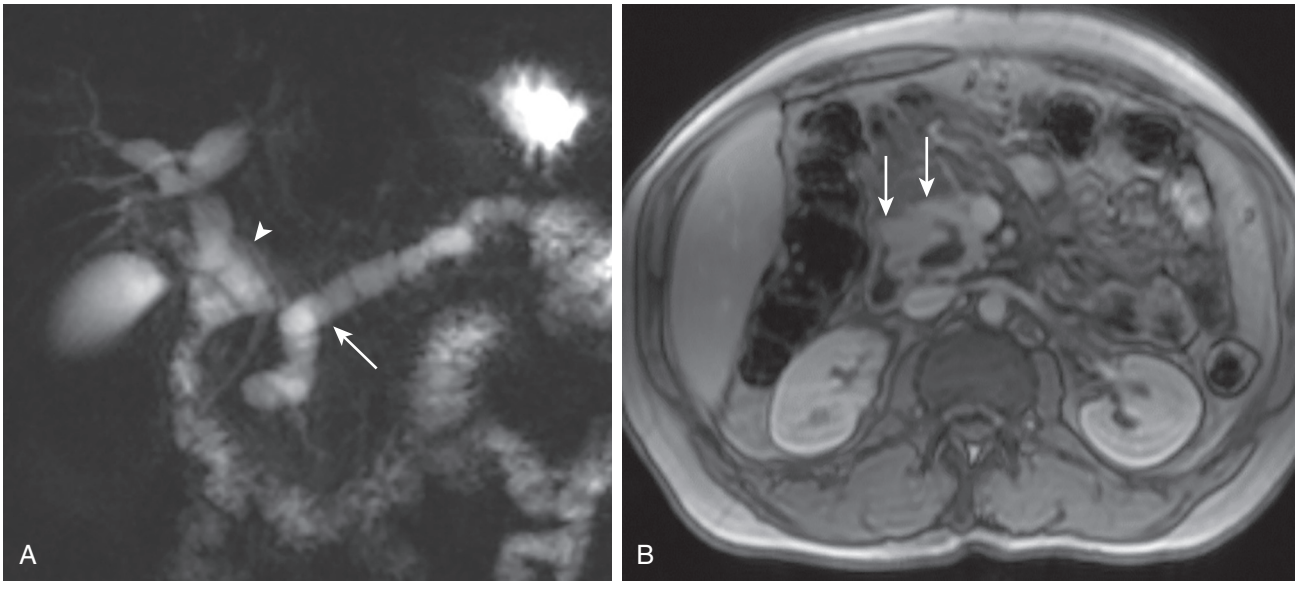

FIGURE 119-18. Biliary and pancreatic ductal dilatation due to pancreatic head cancer. A, Coronal thick slab T2-weighted magnetic resonance cholangiopancreatography image shows a double duct sign with biliary (*arrowhead*) and pancreatic (*arrow*) ductal dilatation with abrupt transition in the proximal pancreas. There is an indwelling biliary stent. **B,** Axial post contrast T1 fat-suppressed magnetic resonance image shows a mass in the pancreatic head (*arrows*) consistent with primary pancreatic cancer.

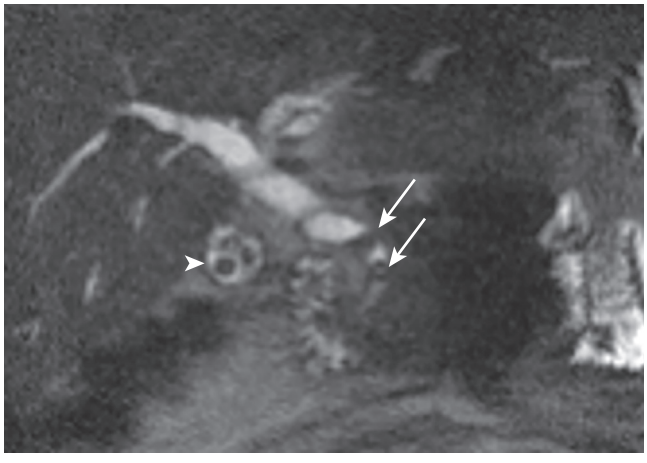

FIGURE 119-19. Choledocholithiasis. Coronal T2-weighted magnetic resonance cholangiopancreatography image shows biliary ductal dilatation with two filling defects in the common duct (*arrows*) consistent with choledocholithiasis. Also note stones in the gallbladder (*arrowhead*).

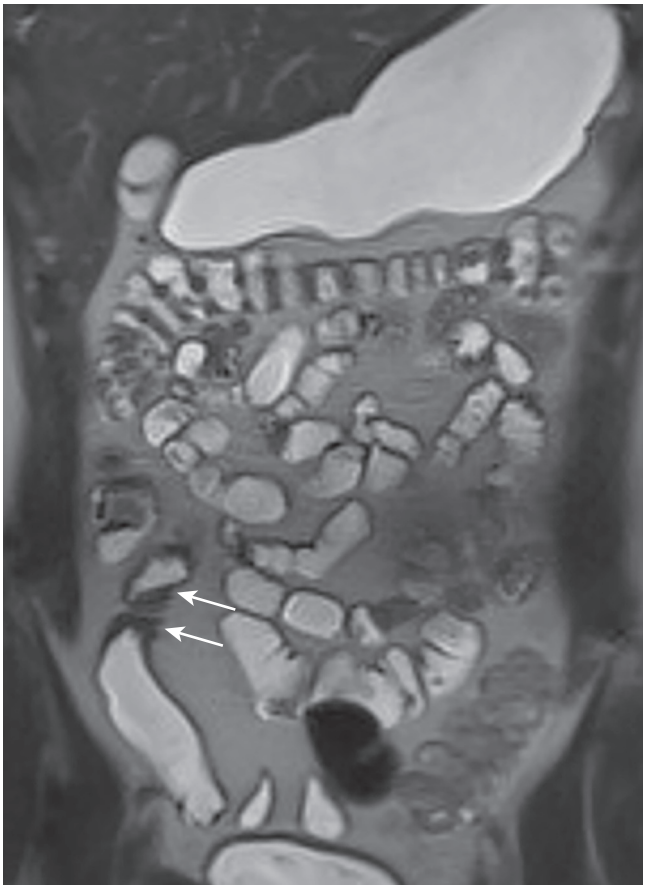

FIGURE 119-20. Crohn disease on magnetic resonance (MR) enterography. A coronal T2-weighted MR image shows Crohn involvement of the distal ileum with wall thickening and associated fibrofatty proliferation of the mesentery. There is a mild stricture (*arrows*) with mild proximal dilatation.

gallbladder (Chapter 141). A radiolabeled agent is injected intravenously, taken up by the liver, excreted in bile, and subsequently enters the small bowel. Images over time show how well the gallbladder empties and can be used to diagnose acute cholecystitis, acalculous cholecystitis, biliary obstruction, bile leaks or fistulas, and congenital biliary anomalies. This study may be especially useful following an indeterminant ultrasound for possible acute cholecystitis.

GI bleeding scintigraphy is a noninvasive means to diagnose and localize a site of active GI bleeding (Chapter 121), with a reported sensitivity of 93% and specificity of 95%. This study, which is most often performed with 99mTc-tagged red blood cells, can detect active bleeding into the bowel lumen at a rate as low as 0.1 mL/min. This study also allows for imaging over several hours, so it may be especially beneficial in the setting of intermittent bleeding.

Nuclear medicine studies are also useful to diagnose and stage tumors. A ^{111}In-labeled octreotide study (Octreoscan) can be used to visualize tumors bearing somatostatin receptors, because octreotide is a somatostatin analog. This approach is especially useful for diagnosis, staging, and follow-up of neuroendocrine tumors (gastrinoma, insulinoma, and glucagonoma; Chapter 213), carcinoid tumors, paragangliomas, and pancreatic islet cell tumors (Chapter 211).

Positron emission tomography with ^{18}F-labeled fluorodeoxyglucose (^{18}F-FDG PET) is a powerful imaging tool for evaluating many cancers and provides functional information about cancer cells. ^{18}F-FDG, a glucose analog, accumulates in malignant tissues because malignant cells have an elevated rate of glycolytic activity as compared with normal surrounding cells. Malignant cells therefore exhibit increased uptake of ^{18}F-FDG on imaging. ^{18}F-FDG PET used in conjunction with CT (i.e., PET/CT) can provide biologic, functional, and anatomic information, and areas of increased uptake can be correlated with accompanying CT images (Fig. 119-21). This approach can be used to diagnose and stage tumors, to search for metastatic disease, and to assess for residual or

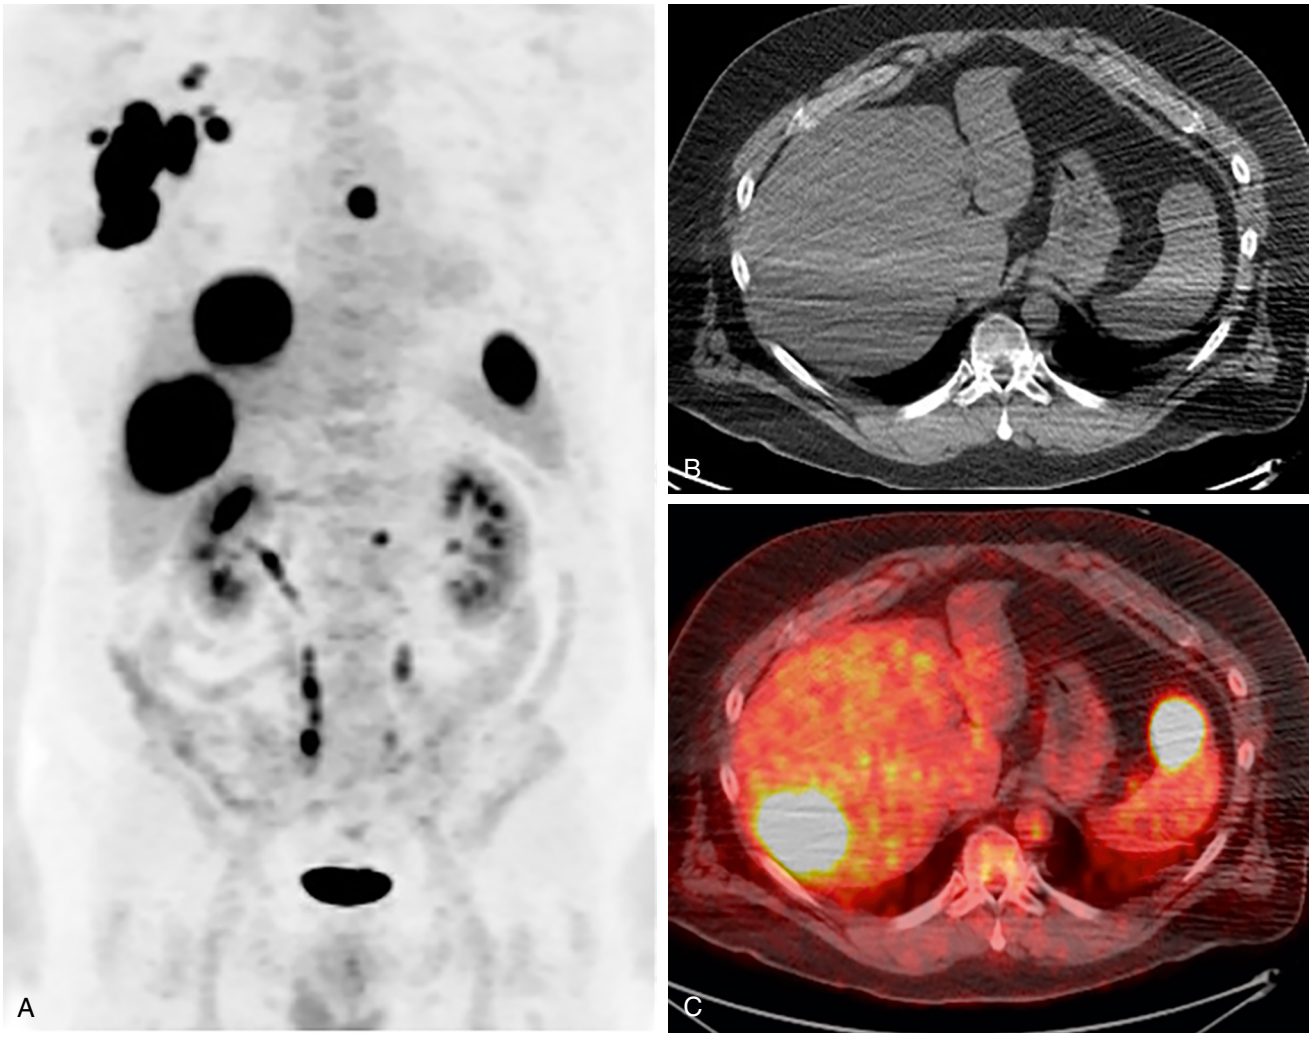

FIGURE 119-21. **Metastatic disease on positron emission tomography/computed tomography (PET/CT). A,** Coronal PET image shows increased uptake in right axillary lymphadenopathy and mediastinal lymphadenopathy as well as liver and spleen involvement. **B,** Lesions in the liver and spleen are barely perceptible on the axial noncontrast CT image. **C,** These lesions are much more conspicuous on the fused axial PET/CT image.

recurrent tumor after treatment. Because PET provides metabolic information, it is superior to CT alone to distinguish active tumor from treated scar. PET/MR, which utilizes high-resolution MR images in conjunction with PET, is a promising new technology with similar attributes but is currently much less readily available than PET/CT.

INTERVENTIONAL PROCEDURES

A variety of interventional procedures (Chapter 120) may be performed in the GI tract and hepatobiliary system using fluoroscopy, ultrasound, or CT guidance. In some cases, a combination of modalities may allow for the safest procedure. MR guidance is much less common because of the longer time needed to acquire images and special considerations owing to the magnetic field.

Interventional image-guided procedures include fine needle aspiration or core biopsy of a mass, drainage of an abscess, placement of a percutaneous cholecystostomy tube, biliary drainage and intervention, paracentesis, and placement of a feeding tube. CT- or ultrasound-guided tumor ablation (including cryoablation, thermal ablation, and alcohol ablation) may be performed for liver tumors (Chapter 181), and is especially useful for unresectable tumors and in patients who are poor surgical candidates.

Vascular interventional procedures include treatment of aneurysms or pseudoaneurysms (such as from pancreatitis), diagnosis and treatment of GI bleeding, placement of a transjugular intrahepatic portosystemic shunt (Chapter 139), and chemoembolization. Chemoembolization may be used to treat primary or metastatic liver lesions (Chapter 181). Chemotherapeutic agents are injected directly into the artery that supplies a tumor, and the artery is then embolized, thereby trapping the medications in the area of the tumor and allowing for treatment with higher chemotherapeutic doses but less systemic toxicity.

120 GASTROINTESTINAL ENDOSCOPY

KENNETH K. WANG

The three major applications of gastrointestinal (GI) endoscopy in medicine include: diagnostic applications to define the source of gastrointestinal bleeding, to stage gastrointestinal cancers, and to obtain samples for histology or culture; therapeutic applications, such as providing hemostasis, resecting lesions, remodeling of the GI tract to manage obesity and to create passages, either between lumens or to fluid collections; and combined modality procedures with interventional radiology or surgery. In current practice, GI endoscopy has evolved from being primarily a straightforward diagnostic endoscopic technique for the colon and upper GI lumen to being a more versatile diagnostic and now therapeutic technique.

In the United States, endoscopy in healthy individuals is typically performed under deep sedation with propofol, but conscious sedation with midazolam and fentanyl is an alternative in straight-forward procedures (Chapter 400). In appropriate patients who desire to drive soon after the procedure or who cannot be accompanied by a family member or friend, the procedure can be performed without sedation.

Ideally, patients should discontinue anticoagulants and antiplatelet agents long enough before the procedure to reverse their effects (Chapter 70) and restart them in consultation with the specialists who recommended them (Table 120-1).[1] Bridging anticoagulation (Fig. 399-3) generally increases the risk of periprocedural bleeding without reducing the risk of thromboembolism[A1] and should be considered only in patients who are at very high risk of thromboembolism.[2]

Each procedure has specific indications but also carries risks (Table 120-2).

DIAGNOSTIC ENDOSCOPY

UPPER GI ENDOSCOPY

Upper endoscopy consists of examination of a portion of the posterior pharynx including the epiglottis, upper esophageal sphincter area, larynx, and vallecula.

TABLE 120-1 ANTITHROMBOTIC THERAPY FOR ELECTIVE ENDOSCOPY

Thrombotic Risk Low to High	*ENDOSCOPIC RISK OF BLEEDING*	
	LOW*	**HIGH†**
	Continue anticoagulant	Discontinue warfarin, then restart warfarin on same day of procedure Delay reinitiating DOAC until adequate hemostasis is achieved
	Continue antiplatelet agent	Continue aspirin and discontinue $P2Y_{12}$ inhibitors for at least 5 days and switch to aspirin (or continue aspirin if on dual therapy)
		If high risk for thrombosis,‡ strongly consider bridge therapy with LMWH (e.g., enoxaparin, 1.5 mg/kg q24h or 1.0 mg/kg q12h) until oral anticoagulant is again effective Delay reinitiating DOACs until adequate hemostasis is achieved

*Diagnostic upper gastrointestinal endoscopy, colonoscopy, or flexible sigmoidoscopy, including mucosal biopsy; endoscopic retrograde cholangiopancreatography; capsule endoscopy; enteral stent deployment (controversial); endoscopic ultrasound without fine-needle aspiration; argon plasma coagulation; Barrett ablation.

†Polypectomy, biliary or pancreatic sphincterotomy, treatment of varices, percutaneous endoscopic gastrostomy or jejunostomy, therapeutic balloon-assisted enteroscopy, endoscopic ultrasound with fine-needle aspiration, endoscopic hemostasis, tumor ablation, cystogastrostomy, ampullary resection, endoscopic mucosal resection, endoscopic submucosal dissection, pneumatic or bougie dilation.

‡Any mitral valve prosthesis, any caged-ball or tilting disc aortic valve prosthesis, recent (within 6 months) cerebrovascular accident or transient ischemic attack, recent (within 3 months) venous thromboembolism, severe thrombophilia (deficiency of protein C, protein S, or antithrombin; antiphospholipid antibodies).

DOAC = direct-acting oral anticoagulant; LMWH = low-molecular-weight heparin.

Adapted from ASGE Standards of Practice Committee, Acosta RD, Abraham, NS, et al. The management of antithrombotic agents for patients undergoing GI endoscopy. *Gastrointest Endosc.* 2016;83:3-16.

The entire esophagus and stomach are visualized. The duodenal bulb as well as the first and second portions of the duodenum are part of the standard examination.

INSTRUMENT

Flexible endoscopes are equipped with a high-resolution video chip at the end of a flexible tube and two fiberoptic light bundles. The endoscope has a water channel for irrigation of the camera lenses and a suction channel that can remove liquids and doubles as an instrument channel through which a variety of accessories (e.g., biopsy forceps to obtain tissue, brushes to obtain cytologic specimens, snares to remove polyps, or bipolar probes to cauterize bleeding vessels) can be passed.

PREPARATION

All upper endoscopic procedures require fasting for at least 6 hours prior to the procedure to permit adequate visualization. Patients who are receiving a per oral endoscopic myotomy for achalasia should be on clear liquids for 2 days prior to the procedure. Broad spectrum antibiotics (e.g., cefazolin 2 g intravenously preprocedure) are routinely given due to the stasis and bacterial overgrowth in the esophagus. Chronic medications can be taken orally the morning of the procedure, with minimum oral fluids to help pass the pills.

In patients who have a history of aspiration or cognitive impairment, preprocedural tracheal intubation may be advisable to protect the airway. Preprocedural intubation also is often required to prevent aspiration of blood in patients who have an active upper GI bleed, especially patients who are known to have cirrhosis and portal hypertension, because they will not be fully alert after the procedure. Patients with gastroparesis or with gastric or esophageal obstruction should also be considered for airway protection because of the likelihood of retained food.

INDICATIONS

A common indication for upper GI endoscopy is to determine the presence of a GI disease such as ulcers or esophagitis and/or and to explain a symptom (Table 120-3).

THE PROCEDURE

Unless the patient is intubated, the procedure is performed with the patient in the left lateral position to decrease the chance of aspiration. The esophagus is inspected, especially for esophagitis and varices, and then the stomach is inspected for gastric varices, ulcers, evidence of intestinal metaplasia or gastritis, and neoplasms (Fig. 120-1). Retroflexion is necessary in the fundus of the stomach to visualize the gastric cardia as well as the incisura, which is one of the most likely sites for intestinal metaplasia. The endoscope then is passed down to the second portion of the duodenum. The standard endoscope visualizes the papilla of Vater in only about 50% of cases because it is on the side wall of the duodenum and not within the field of view.

Adjuncts to Standard Endoscopy

Contrast agents that can increase the visibility of flat neoplasms include Lugol solution, which is diluted and sprayed on the surface of the squamous esophagus to help diagnose squamous neoplasia. The normal squamous mucosa takes up the iodine and appears brown, whereas neoplastic areas with either cancer or dysplasia will not take up the iodine and appear as unstained tissue that should be biopsied or resected depending on the degree of suspicion. A widely used alternative is narrow-band imaging, which uses blue light to illuminate the mucosa and highlight its features, particularly the small mucosal capillary patterns that become distorted in dysplastic tissue. In the stomach, a mixture of acetic acid and indigo carmine can detect gastric carcinoma and also enhance its borders to guide en bloc removal. Despite their utility, however, dyes are not popular in Western countries because of the difficulties in application and the contamination they create in the endoscope. Nonetheless, in high-risk patients, such as those with Lynch syndrome (Chapter 179), contrast agents can enhance detection of small early gastric cancers. Other tools to aid in the diagnosis of premalignant disease include devices such as confocal laser endomicroscopy that can magnify the views of the mucosa and assess the leakiness of the microvascular system, but this approach is infrequently used clinically in part because it requires administration of intravenous fluorescein. Volume laser endomicroscopy, which is a version of optical coherence tomography, has the potential to scan large areas of tissue at high resolution without contrast agents and is commercially available for scanning the esophagus.

ABSTRACT

Gastrointestinal endoscopy, which is an important tool for the diagnosis and treatment of gastrointestinal diseases, can also be the easiest way to diagnose systemic disorders, such as amyloidosis or graft versus host reactions. In addition to standard procedures, such as endoscopy, colonoscopy, and instrumentation of the biliary and pancreatic ducts, endoscopic procedures can be used to resect neoplasms, create a myotomy, reshape the stomach, and repair postsurgical leaks or complications. These minimally invasive techniques often can replace traditional surgical or radiological procedures or be used synergistically with them.

TABLE 120-2 COMPLICATIONS OF ENDOSCOPY

ENDOSCOPIC COMPLICATION	INCIDENCE (%)	SPECIFIC PROPHYLAXIS
GENERAL COMPLICATIONS		
Complications related primarily to sedation (cardiovascular and postprocedure respiratory depression, aspiration)	0.6-0.7	Airway protection with massive upper gastrointestinal bleeding Preprocedure medical evaluation, intraprocedure and postprocedure monitoring Anesthesiology consultation for high-risk patients
Perforation	0.1-0.3 (upper endoscopy) 0.14-0.25 (colonoscopy)	None (except careful technique, possible benefit to "underwater" technique)
Bleeding	0.3 (upper endoscopy) 0.7-2.5 (polypectomy)	Carefully balance risk and benefits Discontinue or reduce anticoagulant use before high-risk procedures
Bacteremia and infection complications (endocarditis, bacterial ascites)	<0.1	Antibiotics for patients at risk for endocarditis (patients with artificial valves, pulmonary-systemic shunts, previous history of endocarditis), with synthetic vascular grafts, and with bacterial ascites (cirrhotics)
Death	0.6 (upper endoscopy) 0.2 (colonoscopy)	
COMPLICATIONS ASSOCIATED WITH SPECIALIZED PROCEDURES		
Pancreatitis (ERCP)	3-20	Rectal indomethacin
Cholangitis (ERCP)	0.1-2	Preprocedure antibiotics
Wound infections (PEG)	3-4	Preprocedure antibiotics

ERCP = endoscopic retrograde cholangiopancreatography; PEG = percutaneous endoscopic gastrostomy.

TABLE 120-3 INDICATIONS FOR UPPER GI ENDOSCOPY

- Dyspepsia unresponsive to medical therapy
- Development of alarm symptoms including dysphagia, odynophagia, weight loss
- Persistent symptoms of reflux despite medical therapy
- Surveillance for upper GI malignancy
- Bleeding thought to be due to upper GI source or occult GI bleeding

GI = gastrointestinal.

ENDOSCOPIC ULTRASONOGRAPHY

Endoscopic ultrasonography combines an endoscope with an ultrasound array at its tip to visualize anatomy in three dimensions. Pulse doppler signals can assess blood flow, and elastography can assess tissue characteristics.

INSTRUMENT

A circular array instrument is best for mapping out the visceral surface of the esophagus and duodenum, whereas a linear array ultrasound endoscope is used for needle aspiration and biopsy because it can use Doppler ultrasound to ensure that the needle bypasses vascular structures and can observe the needle throughout its entire passage into a lymph node or organ.

PREPARATION

The preparation for an upper GI endoscopic ultrasound is similar to endoscopy. Coagulation parameters should be normalized before endoscopic ultrasonography, fine-needle aspiration, or biopsy may be performed. Deep sedation is generally used because of the length of the procedure.

INDICATIONS

The most common indications for endoscopic ultrasound are to stage esophageal, gastric, pancreatic, and biliary cancers by determining their depth, degree of circumferential involvement, and overall size.[3,4] Fine-needle biopsy is indicated for lesions that require more knowledge of tissue architecture (e.g., lymphoma) or type of infiltration (e.g., autoimmune pancreatitis). Ultrasound can guide fine-needle aspiration of lymph nodes or metastases to solid organs, especially in the liver. It can also be an adjunctive test to stage pulmonary cancer when lymph nodes are not accessible from the bronchi. Other indications include defining a lesion's vascularity, measuring portal pressure, or assessing and treating arterial vessels that feed bleeding lesions such as ulcers.

PROCEDURE

The echoendoscope is passed into the esophagus like a routine endoscope. However, the transducer portion of the endoscope is rigid and is of greater diameter than an endoscope, so passage can be more difficult in the presence of mechanical obstructions, such as an esophageal diverticulum or bone spurs in the cervical spine. Scanning begins in the posterior pharynx, where structures such as the thyroid gland and carotid arteries are very apparent. The aortic arch, aortic-pulmonic window, descending aorta, left atrium, and pulmonary vessels can be examined. Generally, examinations follow the aorta into the abdomen, where visualization of the gastro-hepatic ligament, superior mesenteric artery, and celiac axis provides landmarks in the abdomen. The celiac axis gives rise to the splenic artery and allows visualization of the body and tail of the pancreas. The left lobe of the liver is easily scanned, as is the gallbladder. From the duodenum, the portal vessel, biliary tree, and pancreatic head can be visualized, and ultrasound can be used to guide biopsy of a pancreatic mass (Fig. 120-2). Any lesions such as lymph nodes can be sampled with the linear echoendoscope. Some lesions that appear obvious on computed tomographic (CT) scanning may be invisible to ultrasound, but small lesions around the pancreas are generally better visualized on endoscopic ultrasound. Biopsies and aspirates can be routinely performed.

Under ultrasound guidance, therapeutic stents can be placed across the gastric wall into the gallbladder to decompress an inflamed gallbladder[5] or into the jejunum to bypass an obstruction caused by pancreatic cancer. Vascular access with endoscopic ultrasound can measure portal pressures, embolize arterial bleeding sites that cannot be approached by interventional radiology, and define feeder vessels for bleeding ulcers.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY (ERCP)

Endoscopic retrograde cholangiopancreatography (ERCP) can examine the biliary tree and pancreatic ducts. ERCP commonly includes fluoroscopy to visualize the dye infused within the pancreatic or biliary system, so all patients should be appropriate candidates for exposure to contrast agents and radiation.

INSTRUMENT

The typical side viewing endoscope has a rigid tip very similar in length to the echoendoscope, with the same issues regarding passage into the esophagus. The therapeutic duodenoscope is about 125 cm long with a 4.2-mm working channel that allows for passage of accessories such as the cholangioscope. The channel also has a lever that permits the user to angle a catheter into the ampulla of Vater.

PREPARATION

Patients should be fasting as for routine upper GI endoscopy. The instrument visualizes at 90 degrees to the axis of the endoscope and has no forward viewing capacity, so the esophagus must be known to be free of diverticula, strictures, or tumors. In preparation for the injection of dye and for the interventional procedure, coagulation status must be determined and normalized if possible. If the risk of precipitating pancreatitis is high (i.e., younger patient age, female

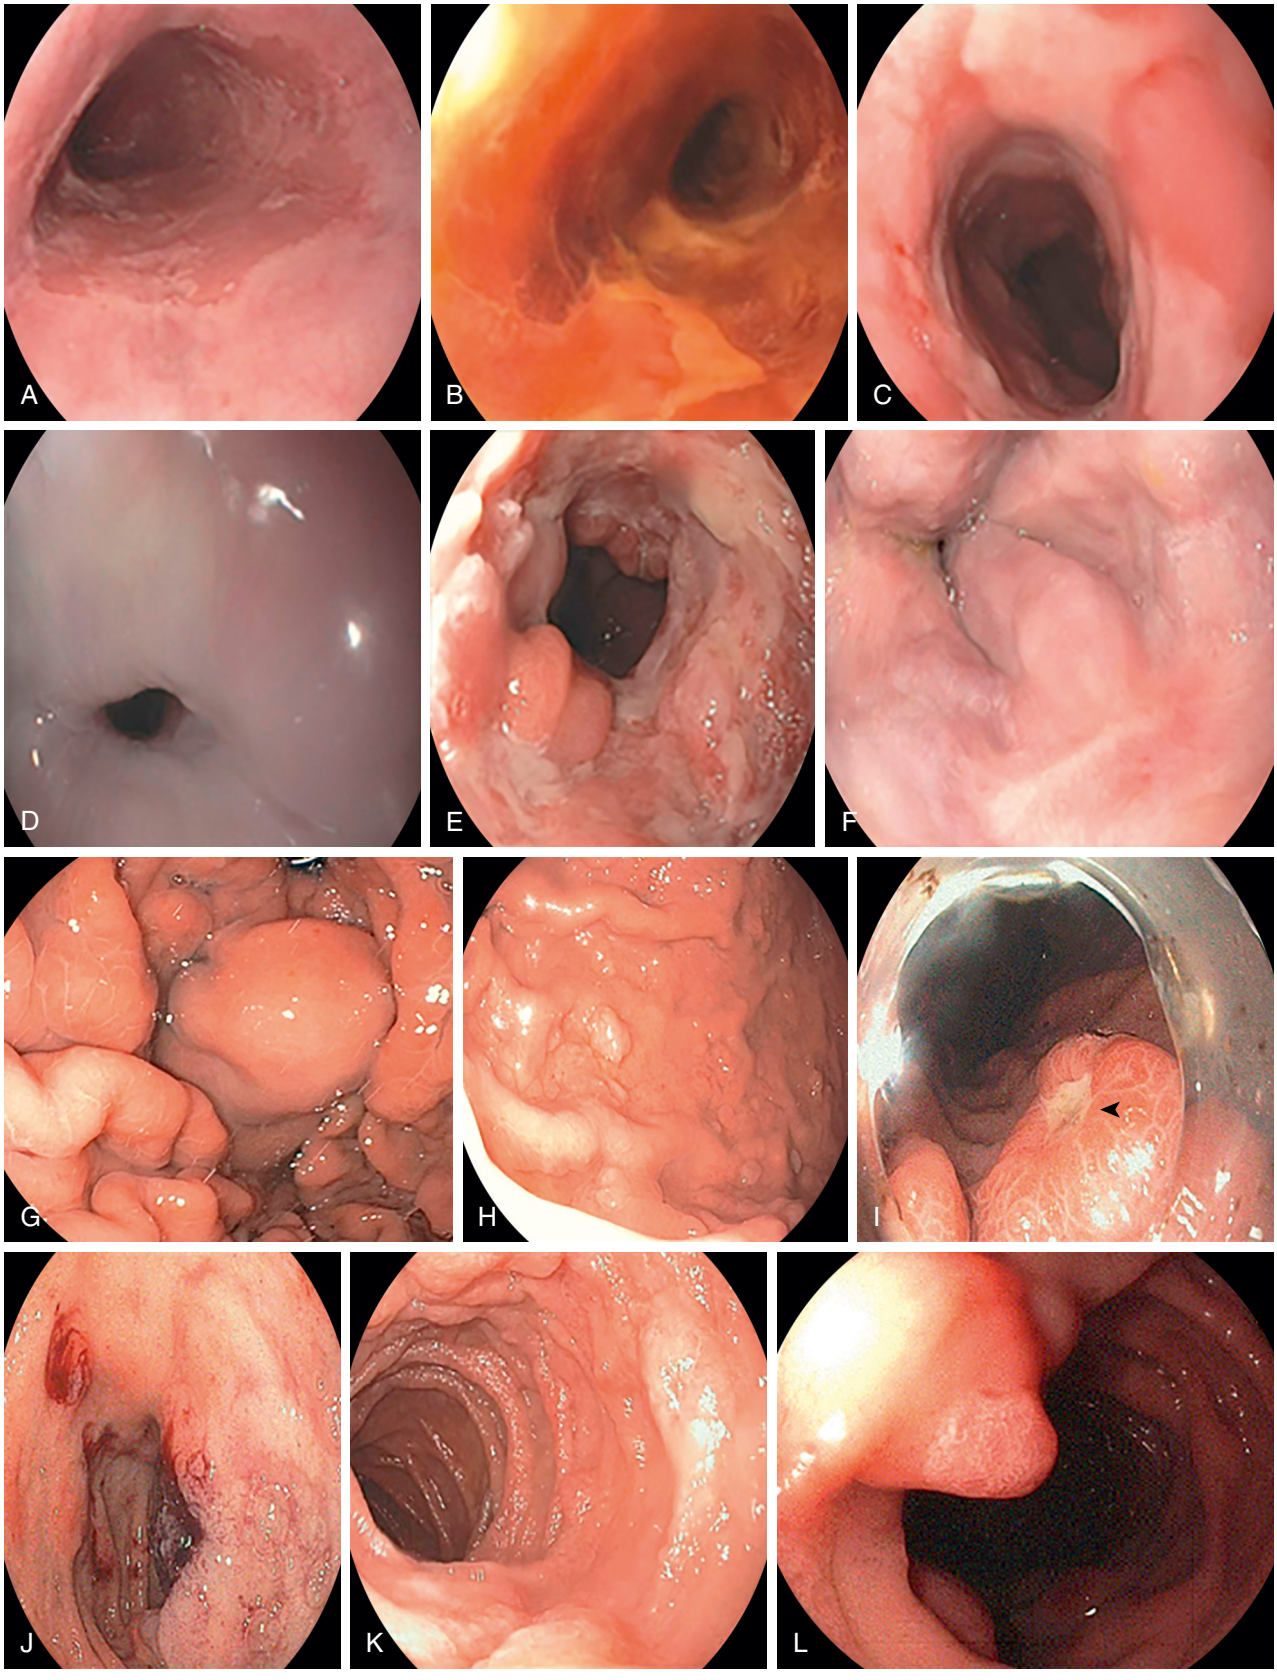

FIGURE 120-1. **Endoscopic images of abnormalities that can be observed in the upper gastrointestinal tract. A,** Barrett esophagus with areas of salmon colored mucosa indicative of esophageal intestinal metaplasia. **B,** After Lugol solution has been applied to the esophageal mucosa, areas of whitish appearing mucosa that do not take up iodine suggest dysplasia. **C,** Streaks of inflammation consistent with relatively severe erosive esophagitis. **D,** Esophageal stricture with narrowing of the esophageal lumen but no evidence of inflammation. **E,** Excavating distal esophageal cancer. **F,** Submucosal esophageal varices near the gastroesophageal junction without evidence of recent bleeding. **G,** Rugal folds in the stomach, with the expanded fold in the center of the figure representing a gastric varix. **H,** Hyperplastic polyp, which is common in patients who are taking proton pump inhibitors and generally are benign, in the center of the field. **I,** Ulcer (*black arrow*) elevated in the body of the stomach. **J,** Duodenal ulcer in the bulb of the duodenum. **K,** Adenoma (the center of the image) in the duodenum, where adenomatous polyps can be found, although benign Brunner glands are often found in the duodenal bulb. **L,** Normal ampulla of Vater.

(Courtesy of Pankaj Jay Pasricha, MD.)

gender, sphincter of Oddi dysfunction, previous pancreatitis, abnormal serum bilirubin), pre-procedural prophylaxis with a sulindac (100 mg) enema can decrease the risk of ERCP-induced pancreatitis.[A2]

INDICATIONS

ERCP is usually performed to evaluate obstructive jaundice, pancreatitis, or a pancreatic mass when other imaging tests are equivocal or demonstrate lesions that require therapy, such as a common bile duct stone. For example, suspected choledocholithiasis warrants ERCP for diagnosis and potential treatment (Fig. 120-3). ERCP also is often performed for chronic pancreatitis and ampullary polyps. In acute pancreatitis (Chapter 130), ERCP is often delayed until inflammation has subsided unless suspected pancreatic ductal disruption necessitates stenting. Indeterminate biliary or pancreatic ductal strictures found on magnetic resonance cholangiopancreatography (Chapter 119) may require brushings and biopsies on ERCP to define their histology.

PROCEDURE

The endoscope is typically introduced in a blind fashion using manual guidance. When the instrument passes into the second portion of the duodenum, the ampulla of Vader can be identified. The pancreatic duct is usually found directly perpendicular to the mucosa, whereas the common bile duct is much more angulated. In patients who have a pancreas divisum, the minor papilla, which is usually found at the first portion of duodenum, may need to be cannulated to access the main pancreatic duct. Once the appropriate duct is identified on fluoroscopy with contrast or with the use of a guidewire through the endoscope, accessories can be introduced for therapeutic (e.g., to extract a stone or to place a stent to bypass a stenosis or tumor) or diagnostic (e.g., to obtain tissue from an indeterminate stricture or mass) purposes. Small caliber endoscopes can be passed through a therapeutic duodenoscope (larger operating channel required) to visualize the pancreatic or biliary ducts and take small biopsies or cytologic specimens from any suspicious lesions.[6]

ENTEROSCOPY

In standard upper GI endoscopy, visualization usually extends only to the second portion of the duodenum. The easiest way to visualize the entire duodenum and a significant distance (about a half meter) into the jejunum is to use push enteroscopy, which is generally performed with a pediatric colonoscope. Most occult bleeding GI lesions (Chapter 121) are visible using this technique. Other accessories permit the endoscopist to extract foreign bodies, take specimens for diagnosis, perform a polypectomy, place a stent, dilate strictures, and even treat bleeding lesions such as telangiectasias. If the lesion is beyond the reach of these instruments, more technically difficult procedures can be employed.

PREPARATION

Preparation is as for upper GI endoscopy.

INSTRUMENT

The standard push enteroscope is usually a dedicated pediatric colonoscope that is passed orally through the stomach and into the small bowel. Single balloon enteroscopy with an overtube allows the enteroscope to be guided into the small bowel. Single balloon procedures can examine altered anatomy, such as in patients who have had bariatric surgery with a Roux-Y anastomosis.

To traverse the full jejunum, a double balloon system, with balloons on both an overtube and on the distal end of the endoscope, can be inflated and deflated to plicate the small bowel onto the shaft of the endoscope. By collapsing the small bowel onto its sheath, the endoscope can be slowly manipulated through the entire small bowel. A motorized spiral enteroscopy[7] device with an overtube that corkscrews the intestine over the tube is an emerging alternative to using a balloon to pull the intestine over the overtube. An endoscopic tattoo can be placed at the furthest distal extent of the antegrade enteroscopy, so that a colonoscopic examination from below can advance through the ileocecal valve and then to the tattoo, thereby confirming that the entire small bowel has been investigated.

INDICATIONS

The indications for enteroscopy are usually related to occult gastrointestinal bleeding (Chapter 121) or further definition of a lesion visualized on small bowel imaging. It can be used to define extent of disease, such as in celiac sprue (Chapter 126) or inflammatory bowel disease (Chapter 127), if needed. Therapeutic uses include aid in placing jejunal feeding tubes, dilating strictures, aid in performing ERCP in cases of altered anatomy such as after bowel bypass, and removal of small intestinal polyps.

PROCEDURE

Patients are positioned in the left lateral position to reduce the risk of aspiration. The advancement of this device requires fluoroscopy to confirm the location of the enteroscope when lesions are found. In addition, treatment options are limited given the long length (200 cm) of the instrument. The instrument is valuable in the diagnosis of conditions that have eluded other techniques, such blood loss in the small intestine (Chapter 121), small intestinal masses (Chapter 179), and inflammatory and malabsorptive conditions of the intestines (Chapter 126).

COLONOSCOPY

Colonoscopy is used for diagnostic and therapeutic purposes from the rectum to the ileocecal valve. Use of a colonoscope requires familiarity with the anatomy of the colon and the tendency of the colon to twist and form loops in the sigmoid and transverse colon, thereby causing difficulty in advancing the instrument unless these loops can be reduced. The colon's haustral folds also can make visualization more difficult.

INSTRUMENT

A standard adult colonoscope is about 168 cm in length and has a larger channel for suction and passage of accessories compared with an upper GI endoscope. However, the diameter of the colonoscope is also larger and the insertion tube is more flexible to allow retroflexion at various critical points in the colon, such as in the cecum or in the rectum. The diameter of the colonoscope can identify significant colonic strictures because it will be unable to pass through them.

PREPARATION

A good colonic preparation, which is essential for a complete examination,[8] often is the most unpleasant part of the procedure, and patients will be more adherent if they are strongly encouraged to take the preparations as directed.[A3] Common high-volume preparations use a nonabsorbable osmotic agent (polyethylene glycol) mixed with water and drunk by the patient in a split-dose fashion (half the evening prior to the procedure and the other half the morning of the procedure). This split-dose method is better tolerated and more effective in clearing stool than are single-dose regimens.[A4] Refrigerating the solution is often beneficial in decreasing its taste, and sucking on lemon wedges or ice cubes also can blunt its flavor. Some patients find that drinking the solution through a straw also can decrease its unpleasant taste. Finally, chewing gum before drinking a glass of the solution also makes the preparation more palatable. Although patients often rely on the color of the effluent and the absence of solid stool as indicators of adequate preparation, patients should continue to take the complete bowel preparation until the entire preparation is consumed to ensure an adequate colonic preparation. In patients who are at risk of a poor preparation (e.g., patients who have had poor preparations in the past, nonambulatory or hospitalized patients, and patients who are unable to consume the full preparation, such as patients with diabetic gastroparesis), it also may be necessary to begin a liquid diet 24 to 36 hours before the scheduled colonoscopy and increase the amount of solution to avoid solid foods in the GI tract and to ensure adequate colonic cleansing. The consequences of inadequate preparation include the need to repeat the preparation for another procedure, the inability to detect significant lesions in the colon, and an increased risk of adverse events such as perforation or bleeding.

INDICATIONS

Colonoscopy is most commonly performed to screen for colon cancer (Chapter 179). It is also indicated to evaluate possible lower GI bleeding (Chapter 121) from conditions such as a tumor or polyp (Chapter 179), inflammatory bowel diseases (Chapter 127), diverticular disease (Chapter 128), or a mucosal telangiectasia (Figs. 120-4 and 120-5).

PROCEDURE

The procedure typically begins with the patient on the left lateral position, which generally allows easier passage into the sigmoid colon. The patient may be switched to the supine position once the splenic flexure is reached, particularly when using water immersion, which is better tolerated and very useful when removing polyps, rather than carbon dioxide insufflation, which is often uncomfortable and can produce nausea and bloating postprocedure. The water immersion technique instills warm water into the colon to distend it.

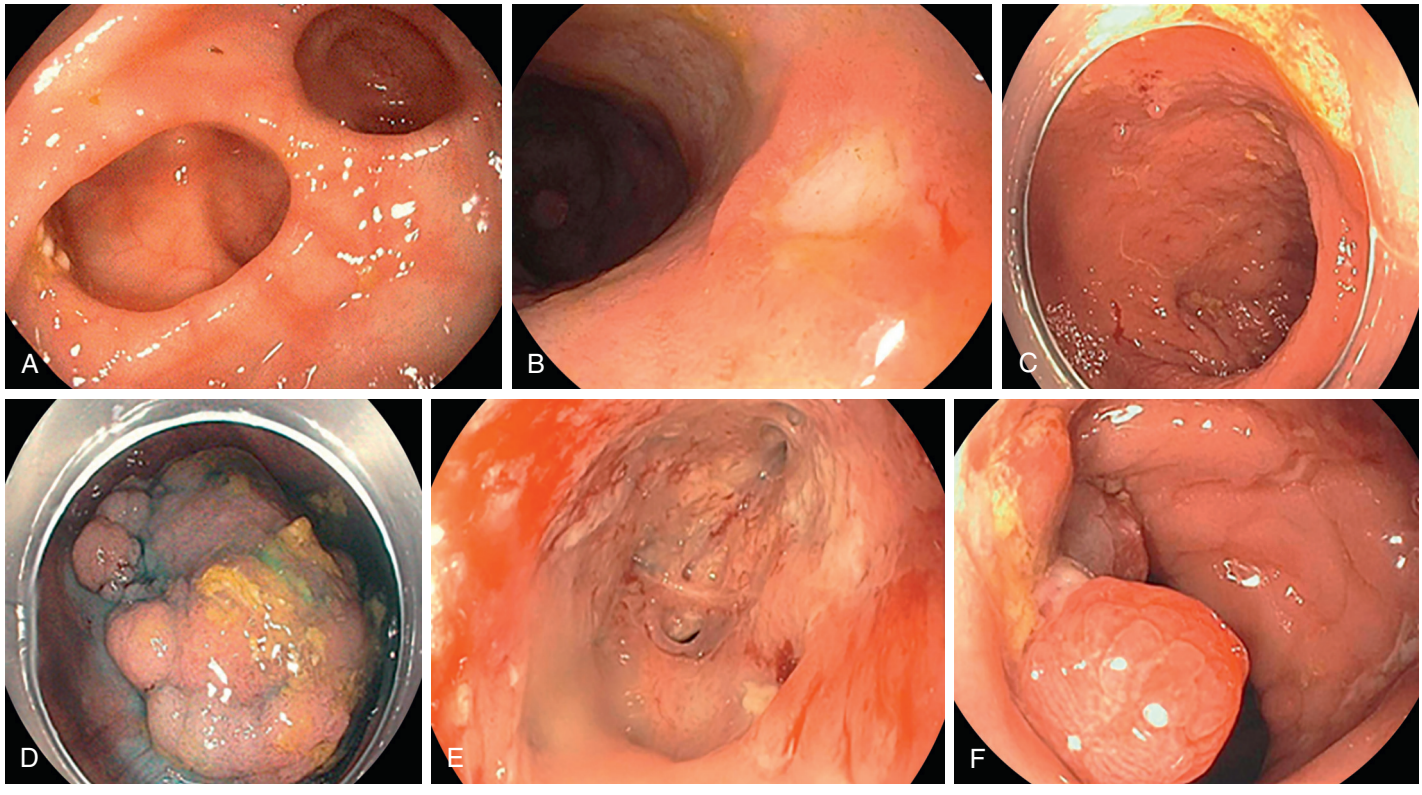

FIGURE 120-4. Images of colonic pathology. A, Large mouthed colonic diverticula, which are normal findings particularly in older patients. **B**, Colonic ulcer often found in the context of inflammatory bowel disease, most commonly Crohn disease. **C**, Chronic ulcerative colitis, with small pseudopolyps indicative of chronic disease. **D**, Large colonic polyp, likely an adenoma; despite its size this polyp can usually be removed endoscopically. **E**, Ulcerated colon with a fistula at the base. Colonic ulcers can fistulize to bladder, vagina, small bowel, and stomach depending on location of the fistula. **F**, Ulcerated polyp with polypoid edges, suspicious for malignant transformation.

FIGURE 120-5. Mucosal telangiectasia (arteriovenous malformation) in the colon. The patient presented with hematochezia. The lesion was subsequently cauterized endoscopically. (Courtesy of Pankaj Jay Pasricha, MD.)

FIGURE 120-6. Typical normal-appearing small bowel on capsule endoscopy. Although resolution is far less than standard endoscopy, villi can easily be appreciated on the capsule images.

The hypotonic nature of the fluid allows water to infiltrate the mucosa, thereby making removal of colon polyps easier. Examination of the cecum and right side of the colon is generally better on withdrawal with the patient supine.

Since polyps are often found and removed, patients must have their anticoagulants and antiplatelet medications stopped in sufficient time to ensure adequate hemostasis.[9] Removal techniques using small wire snares are routine, but specialized snares can grasp even flat polyps, and combination devices can inject fluid underneath the polyps to aid in safe removal by providing a cushion underneath the lesion. Water immersion polypectomy likewise can facilitate mucosa swelling with hypotonic fluid without the need for an injection. If a colonoscopy is being performed to evaluate gastrointestinal bleeding, however, polypectomy will often be deferred because postprocedural bleeding could easily be confused with bleeding from the original hemorrhagic site.[10]

CAPSULE ENDOSCOPY

Capsule endoscopy was initially developed to detect lesions in the small bowel. Steerable capsules can also visualize the stomach and the colon. With current high-resolution imaging, the capsule can detect bleeding sites and flag sites of mucosal abnormalities for further endoscopic review.

INSTRUMENT

The device is literally a swallowed capsule, which is about 11 mm in diameter and 26 mm in length, with a camera that is mounted on one or both ends and can take 2 to 18 images per second depending on the type of device. The cameras are battery powered and can image for a total of about 8 to 12 hours. The patient is connected to an antenna that is strapped to the skin over the abdomen and can receive and store the images for download to a workstation.

PREPARATION

Prior to imaging the small bowel for bleeding, patients are usually requested to avoid eating foods that might leave debris in the small bowel, such as fruit or vegetable seeds. Patients also should avoid iron supplements temporarily. Beginning the day before the procedure, a bowel preparation solution is usually given in the evening to help remove any food debris that may obscure important lesions. After ingesting the capsule, the patient may start ingesting clear liquids about 2 hours later and light food about 4 hours later. Patients cannot be near strong electromagnetic fields (e.g., magnetic resonance scan) until the capsule is excreted. The patient also should be sure the recorder is operational by inspecting its blinking light.

INDICATIONS

The three most common indications for capsule endoscopy are to find the site of obscure bleeding, to define the extent of inflammatory bowel disease, and to investigate a finding on other imaging, such as a suspicious lesion that is lymphoma.[11] A more controversial indication is to investigate the cause of chronic abdominal pain.

PROCEDURE

The patient returns the recorder, which can be downloaded and reviewed by an appropriately trained physician. The artificial intelligence in the software will identify areas of suspicious lesions, which are tagged for review. Areas of potential bleeding are also indicated. The physician can then review all images for potential sources of bleeding or areas of abnormality that may indicate bleeding such as ulceration (Fig. 120-6). Since images are not reviewed until after the capsule has passed, current devices cannot be used therapeutically; however, new generations of steerable capsules under magnetic control may be equipped with potential therapies, such as hemostatic sprays that could be released when a suspicious area is identified.

ADVANCED ENDOSCOPY

ADVANCED IMAGING

With the use of in vivo dyes such as fluorescein, even capillary blood flow can be visualized. The glandular structure and the microenvironment of early neoplastic lesions can be visualized using confocal laser endomicroscopy via a standard endoscope, via endoscopic ultrasound-guided fine-needle aspiration into cystic structures, or a duodenoscope to view the wall of the bile duct. Optical coherence tomography can visualize 7 linear cm of esophagus with one scan, thereby allowing reconstruction of the mucosa into two- and three-dimensional images that assess the extent of dysplasia. Electronic enhancement methods are replacing chromoendoscopy with dyes for detecting gastric neoplasia. The visualization of blood vessels in luminal tumors can predict the depth of tumor invasion with excellent accuracy.

TISSUE RESECTION

Most large polyps and early cancers can be removed with advanced endoscopic techniques. One example is endoscopic mucosal resection, by which a small cap is applied to the tip of the endoscope to allow suction to draw tissue into the cap, and then a wire snare with cautery is used to resect the tissue. The tissue is withdrawn into the cap and removed via the endoscope. Variations of this technique include the application of bands that pinch the tissue after it is drawn into the cap to allow the easier application of the snare. Endoscopic submucosal dissection can resect large lesions en bloc, thereby completely removing all neoplastic tissue by cutting around the area of neoplasia and then carefully dissecting the mucosa from the underlying muscle layer. For Barrett esophagus (Chapter 124), en bloc mucosal resection followed by ablation therapy can reduce the risk of progression from low-grade dysplasia to higher grade dysplasia.[A5,A6]

Per-oral myotomy[12] is useful for treating achalasia, with outcomes at least equivalent to open surgery in appropriate patients.[A7] It is also useful for some cases of pyloric gastric outlet obstruction and gastroparesis.[13] This technique is performed by making a mucosal incision to permit the endoscope to be passed into the submucosa to tunnel along the muscularis propria. The muscle layer can then be incised similar to a Heller myotomy, except usually only the inner circular muscle layer is cut. The tunnel can be sealed with hemostatic clips afterwards, thereby permitting easier closure.

In the colon, routine cautery of tissue surrounding a resected polyp can be performed using the avulsion technique, which entails grasping tissue with a small forceps that can apply electrocautery to the edges of the resection. This technique decreases the risk of recurrent polyps.

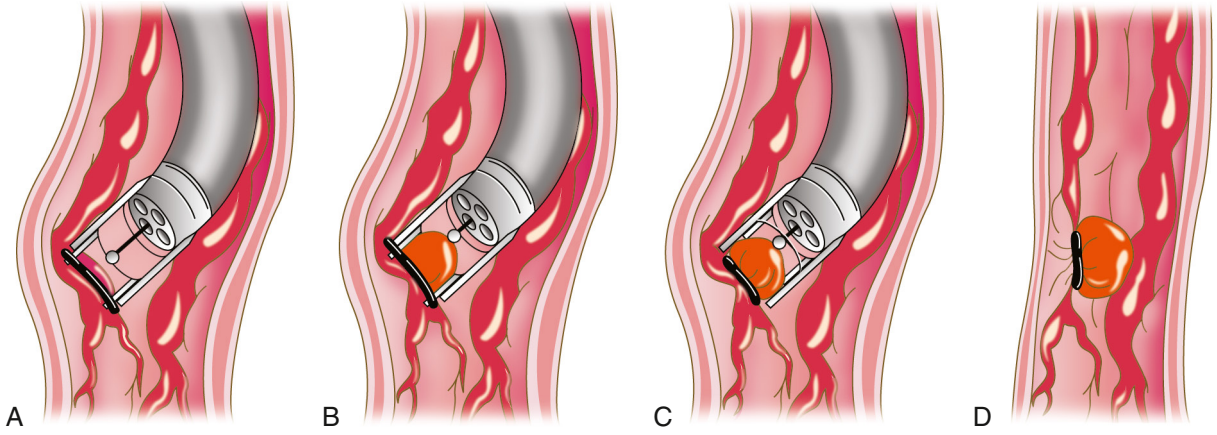

FIGURE 120-7. Endoscopic variceal ligation technique. A, The endoscope, with attached ligating device, is brought into contact with a varix just above the gastroesophageal junction. **B,** Suction is applied, drawing the varix-containing mucosa into the dead space created at the end of the endoscope by the ligating device. **C,** The tripwire is pulled, releasing the band around the aspirated tissue. **D,** Completed ligation. (From Pasricha PJ. Gastrointestinal endoscopy. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine,* 26th ed. Philadelphia: Elsevier; 2020:834-840.)

ESOPHAGEAL VARICES

Patients with portal hypertension commonly undergo an endoscopy to exclude possible esophageal or gastric varices (Chapter 139). Prophylactic treatment is recommended in patients who have bled previously, when large esophageal varices are present, and when the endoscopy shows variceal stigmata such as pseudoaneurysms or fibrin clots that are consistent with prior bleeding. Active variceal bleeding can be difficult to treat endoscopically because the bleeding areas may not be visible. Temporizing measures to include using a tube that can tamponade the bleeding by occluding the vessels at the gastroesophageal junction with a balloon. If this approach is unsuccessful, the esophageal balloon can then be inflated to tamponade the esophageal varices. Once bleeding is controlled, variceal banding (Fig. 120-7) can be performed to occlude the varices. Bleeding gastric varices are usually best managed by carefully injecting cyanoacrylate glue, which produces clotting within the vessel.

REMODELING ORGANS

Endoscopic devices to create a fundoplication for controlling gastroesophageal reflux disease (Chapter 124)[14] are useful only in selected cases because repair of the diaphragmatic hernia also is required in patients who have hernias that are large enough to require a procedure to control reflux.[A8] In bariatric procedures, the stomach can be plicated endoscopically, similar to a surgical gastric sleeve procedure but without removal of gastric tissue.[15] Other endoscopic procedures for weight loss include the short-term (less than 6 months) placement of gastric balloons that cause early satiety and moderate weight loss.[A9] Malabsorption can be produced either by bypassing the duodenum with a stent or by ablating the duodenal mucosa.[16]

CREATING ANASTOMOSES

The endoscopic creation of a percutaneous opening into the lumen of the GI tract can provide access for feeding into the stomach (percutaneous endoscopic gastrostomy) or jejunum (in patients at high risk for aspiration) in patients who require long-term nutrition (Chapter 198). The creation of an anastomosis between the bile duct and the stomach, using endoscopic ultrasound-guided placement of a stent under fluoroscopy, can decompress biliary obstruction in patients who have pancreatic or distal biliary cancers (Chapters 180 and 181). Placing a stent to bypass a duodenal obstruction caused by a pancreatic tumor is another palliative option.[17] However, these internal anastomoses usually provide only short-term palliation because of evolving anatomy as the tumor progresses.

REPAIR OF SURGICAL COMPLICATIONS

Endoscopic techniques can repair anastomotic leaks, drain abscesses around luminal surfaces, complete surgical resection of tumors that have positive neoplastic margins, and restore luminal integrity in areas of postoperative stenosis. For stenosis caused by surgical ischemia, temporary stenting with fully covered metal can provide short-term relief, but restenosis often occurs when the stent is removed because long-term stent deployment leads to erosion of the stent and the potential for perforation and bleeding. Drainage of abscesses can be achieved by endoscopic ultrasound-guided placement of lumen-apposing metal stents into the abscess and then cleaning out the abscess with the endoscope;[18] as the abscess drains away, the stents can eventually be removed. Sponges with low vacuum can be placed in the lumen of abscesses around the esophagus to help clear them.

COMBINED PROCEDURES

In rendezvous procedures, an interventional radiologist advances wires into the biliary system to help the endoscopist identify the location of a hidden papilla or pass a stricture that cannot be passed using wires inserted proximally via the papilla. In severe esophageal strictures, a gastrostomy can be performed, and then an endoscope can be placed into the stomach, where it is then advanced proximally toward the mouth to rendezvous with an endoscope passed by a gastroenterologist from the throat.[19] Using cutting tools, a lumen can be constructed between the two endoscopes. Full thickness resections of the gastrointestinal tract are often both more efficient and safer for the patient when performed as combined procedures by an endoscopist and surgeon, with the closure of the defect performed laparoscopically.

121 GASTROINTESTINAL HEMORRHAGE

THOMAS O. KOVACS AND DENNIS M. JENSEN

Gastrointestinal (GI) hemorrhage can be manifested clinically as overt bleeding from the upper GI tract (esophagus, stomach, and duodenum), lower GI tract (colon), or obscure locations (usually in the small intestine).[1] Alternatively, it can occur as occult bleeding detected by iron deficiency anemia (Chapter 145) or by a positive result of fecal occult blood testing (Chapter 179).

GI hemorrhage is a common worldwide clinical problem and continues to be associated with significant morbidity and mortality. The annual hospitalization rate for upper GI bleeding is now estimated to be about 300,000 hospitalizations per year in the United States. Lower GI bleeding occurs less frequently, at about 20% of the rate of upper GI bleeding, but increases substantially with age and may occur more frequently than upper GI bleeding in the elderly. Overall, for patients hospitalized for GI bleeding, 40% occurs in the upper GI tract, 25% in the lower GI tract, and 35% in an undefined location. Mortality rates from upper GI hemorrhage are high, varying from 3.5 to 7% in the United States.

UPPER GASTROINTESTINAL BLEEDING

CLINICAL MANIFESTATIONS

Upper GI bleeding occurs proximal to the ligament of Treitz. Patients with upper GI bleeding usually present with hematemesis (vomiting blood or coffee-ground material) or melena (black, tarry stool). In large series, about 50% of patients have hematemesis and melena, about 30% have hematemesis alone, and about 20% have only melena. On occasion, however, hematochezia (passage per rectum of red blood or clots) may be the only manifestation of a bleeding ulcer, and about 15% of all patients who present with hematochezia have an upper GI source. Peptic ulcer disease (Fig. 121-1) is the most common cause of acute upper GI hemorrhage, accounting for about 40% of cases. Other common causes are esophageal and gastric varices and erosive esophagitis. Variceal bleeding, which occurs in the setting of portal hypertension, is discussed in Chapter 139. Other conditions, such as Mallory-Weiss tears (Fig. 121-2; Chapter 124), angiodysplasia, watermelon stomach, tumors, and Dieulafoy lesion, occur less frequently than peptic ulcer (Table 121-1). The mortality from nonulcer bleeding is comparable to that from ulcer hemorrhage in high-risk patients, so all causes of upper GI hemorrhage contribute to the morbidity and cost of care associated with it.

DIAGNOSIS

Initial assessment includes a medical history, vital signs, physical examination (including digital rectal examination), and laboratory evaluation. Patients should be asked questions that can help determine the diagnostic possibilities for the bleeding source. For example, peptic ulcer bleeding (Chapter 125) should be suspected in patients taking daily aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs). For patients with known or suspected liver disease, bleeding related to portal hypertension (such as varices or portal hypertensive gastropathy; Chapter 139) should be strongly considered. Heavy alcohol intake or vomiting should suggest a Mallory-Weiss tear (Chapter 124). A feeding tube or a chronic nasogastric tube and a history of gastroesophageal reflux disease raise the suspicion for severe erosive esophagitis (Chapter 124).

The physician should check the vital signs with attention to signs of hypovolemia, such as hypotension, tachycardia, and orthostasis. The patient's skin should be examined for petechiae (see Fig. 158-2), purpura (see Fig. 406-10), spider angiomas, and palmar erythema (see Fig. 132-2), and the abdomen should be assessed for ascites (see Fig. 132-4), hepatomegaly, or splenomegaly, which may indicate portal hypertension. Tenderness or a mass may indicate an intra-abdominal tumor.

Routine placement of a nasogastric or orogastric tube is not recommended for patients with upper GI hemorrhage. Such a tube may, however, potentially be useful in selected patients to localize bleeding to the upper GI tract in patients with hematochezia, hemodynamic instability, and absence of overt

†Other lesions were surgical anastomoses, Cameron ulcers, aortoenteric fistulas, and hemobilia.
‡No cause found in esophagus, stomach, or duodenum, but 2% had mouth, nose, or pharyngeal bleeding sites.

ABSTRACT

Acute gastrointestinal bleeding is a common clinical problem associated with significant morbidity and mortality. This chapter reviews the important etiologies for upper, lower, and obscure gastrointestinal hemorrhage. The optimal diagnostic and management modalities are highlighted. Specific endoscopic therapeutic techniques to improve evaluation, prognosis, and treatment of gastrointestinal hemorrhage are detailed.

signs of upper GI bleeding; help clear gastric blood for better endoscopic visualization; and minimize the risk of aspiration.

Peripheral blood should be sent for standard hematology, chemistry, liver, and coagulation studies as well as for typing and crossmatching for packed red blood cells (Chapter 162). Hemoglobin concentration and hematocrit may not accurately reflect blood loss because equilibration with extravascular fluid requires 24 to 72 hours. A low platelet count suggests chronic liver disease, dilution, drug reaction, or a hematologic disorder. In upper GI bleeding, the blood urea nitrogen level typically increases to a greater extent than the creatinine level owing to increased intestinal absorption of urea after the breakdown of blood proteins. However, this phenomenon can be misleading in the setting of renal insufficiency or rapid transit of blood. An elevated international normalized ratio can be observed in chronic liver disease and in patients who are taking warfarin.

TREATMENT

Acute Management

Resuscitation efforts should be initiated simultaneously with assessment in the emergency department and continue during the hospitalization.[2] Large-bore (14- or 16-gauge) intravenous catheters are recommended, with normal saline infused as fast as necessary to maintain hemodynamic stability. A restrictive transfusion strategy (red blood cell transfusions given only at hemoglobin level <7 g/dL, with a post-transfusion target of 7 to 9 g/dL) is better than a liberal strategy for reducing 45-day mortality and further bleeding in patients with acute upper GI hemorrhage.[3] These results can be generalized to patients with nonexsanguinating upper GI bleeding[A1] but not to patients who are hypotensive due to severe hemorrhage or have associated cardiovascular disease, in whom a hemoglobin target of 9 to 10 g/dL is recommended.[4] Guidelines also advocate platelet transfusion for patients with active bleeding and a low platelet count (<50,000/μL), but there is no benefit from platelet transfusions in patients who are on antiplatelet agents but have normal platelet levels. For patients who develop upper GI hemorrhage while taking anticoagulants, such as a vitamin K antagonist or a direct-acting oral anticoagulant, it is reasonable to proceed to upper endoscopy before correcting the medication effects. To prevent aspiration, which can cause considerable morbidity and mortality, endotracheal intubation should be considered in patients with active hematemesis or altered mental status.

Nonvariceal Hemorrhage

Endoscopic Therapy

Endoscopy can identify the site of bleeding and provide therapeutic hemostasis in most patients.[5] Patients with evidence of active bleeding (hematemesis, red blood by nasogastric lavage, or hemodynamic instability) should undergo emergency endoscopy as soon as possible (within 12 hours) after medical resuscitation. An intravenous prokinetic agent (either erythromycin 250 mg or metoclopramide 10 mg) 30 to 60 minutes before endoscopy may help move blood out of the stomach and into the small intestine, thereby improving endoscopic visualization. In other patients, endoscopy between 6 and 24 hours after presentation appears to be as safe and effective as emergent endoscopy.[A2,A3]

In addition to localization of the bleeding source, endoscopic evaluation can provide prognostic information and stratify the risk of rebleeding on the basis of the presence or absence of stigmata of recent hemorrhage (Table 121-2).[6] In addition to endoscopic stigmata, other clinical and laboratory factors that predict a poor prognosis include older age, bleeding onset in the hospital, medical comorbidities (especially hepatic, renal, and malignant disease), shock, coagulopathy, fresh blood in the nasogastric lavage, and the need for multiple blood transfusions. Risk stratification using clinical scoring systems, such as the Glasgow-Blatchford score (Table 121-3), may also identify patients at very low risk (score = 0 to 1) of rebleeding or mortality and thereby allow safe, early discharge from the emergency department with outpatient follow-up.

The goal of endoscopic therapy is to stop acute bleeding and to reduce the risk of recurrent bleeding. Most endoscopic therapies were designed for peptic ulcer hemorrhage, but they can be used for other causes of nonvariceal upper GI bleeding, in which underlying arteries are the source of bleeding. Available treatments include injection (epinephrine or sclerosants such as absolute ethanol), thermal coagulation (with multipolar/bipolar or heater probe), and mechanical compression (hemostatic clips). Injection therapy is effective, safe, and inexpensive, but it is sometimes inadequate for definitive hemostasis when it is used alone. When epinephrine injection is combined with either thermal coagulation or hemoclips, hemostasis is achieved in more than 95% of patients with active bleeding, and rebleeding rates are decreased by more than 50%. A device with a larger, over-the-scope clip may be useful for re-treating patients who rebleed after initial hemostasis.[A4,A5]

Endoscopic therapy is reserved for lesions that have high-risk stigmata for rebleeding (e.g., active arterial bleeding, nonbleeding visible vessel, or adherent clot) or moderate-risk stigmata, such as oozing, bleeding without associated clot, or nonbleeding visible vessel.[7] It is not warranted for low-risk stigmata (clean-based ulcer or flat pigmented spot, unless arterial blood flow is underneath the flat spot), which have the lowest risk of rebleeding (Fig. 121-3). Some causes of upper GI bleeding, such as gastric or duodenal erosions and neoplasms, generally are not amenable to endoscopic treatment and require appropriate medical or surgical therapy.

Recurrent bleeding after endoscopic treatment directly increases mortality, raises transfusion requirements, and prolongs hospitalization. Independent

TABLE 121-2 ENDOSCOPIC STIGMATA OF RECENT HEMORRHAGE FOR PEPTIC ULCER BLEEDS

STIGMATA	PREVALENCE (%)	RISK OF REBLEEDING ON MEDICAL TREATMENT (%)	REBLEED RISK AFTER ENDOSCOPIC HEMOSTASIS (%)*
Active spurting bleeding	12	80-90	15-30

predictors of recurrent hemorrhage after successful endoscopic therapy include hemodynamic instability, comorbid illness, posterior duodenal location, and large ulcer size. Patients with these high-risk ulcer features may benefit from more aggressive posthemostasis triage and management.

Use of a Doppler endoscopic probe to detect blood flow underneath stigmata of a recent nonvariceal upper GI hemorrhage provides a more objective way to stratify the risk of patients with ulcer hemorrhage as well as a safe and effective method to improve outcomes. Persistence of a positive Doppler signal after endoscopic treatment correlates with rebleeding, and Doppler probe–guided endoscopic hemostasis significantly reduces 30-day rebleeding rates compared with standard, visually guided hemostasis.[A6] Patients who have residual arterial blood flow after endoscopic hemostasis have significantly higher rebleeding rates than do patients in whom arterial blood flow is successfully obliterated.

Medical Therapy

The most common cause of upper GI bleeding is peptic ulcer disease, and the most common cause of peptic ulcer disease in developed countries is NSAID use. Aspirin and other NSAIDs should be discontinued in patients with bleeding peptic ulcers, unless there is a contraindication to do so (e.g., secondary prophylaxis for stroke). Patients with documented *Helicobacter pylori* infection should be treated with combination antibiotics and a proton pump inhibitor (Chapter 125). After documentation of *H. pylori* eradication, maintenance antisecretory treatment is not needed unless the patient also requires NSAIDs or anticoagulation therapy.

Proton pump inhibitors (see Table 124-1) are the mainstay of medical therapy for hemostasis and healing of peptic lesions. Acid suppression can promote platelet aggregation and clot formation as well as reduce the risk of rebleeding. High-dose intravenous proton pump inhibitors (bolus followed by continuous infusion [e.g., pantoprazole 80 mg followed by 8 mg/hour for 72 hours]) after successful endoscopic hemostasis reduce rebleeding rates and mortality in patients with high-risk stigmata of recent hemorrhage. For patients with high-risk stigmata, either this same regimen or intermittent high-dose proton pump inhibitor therapy may be equally effective.[8] Patients with low-risk or no stigmata can be treated with an oral proton pump inhibitor (e.g., esomeprazole or pantoprazole 40 mg twice daily) and considered for early discharge. Pre-endoscopic proton pump inhibitor treatment is controversial since it does not alter clinical outcomes, but it may downstage the severity of the stigmata of recent hemorrhage and decrease the need for endoscopic intervention. Therefore, in patients with suspected ulcer bleeding, proton pump inhibitors given as an intravenous bolus may be used while waiting for the endoscopy, but this therapy cannot substitute for endoscopy and should not delay it.

The optimal management approach for patients who develop peptic ulcer–related GI bleeding while receiving antiplatelet or anticoagulant therapy is controversial, but rapid reversal of antithrombotic treatments is generally important (Chapter 70).[9] In patients who have a bleeding peptic ulcer while receiving low-dose aspirin therapy followed by successful endoscopic hemostasis and high-dose intravenous proton pump inhibitor therapy, the incidence of recurrent ulcer bleeding at 30 days is twice as high (10% vs. 5%) in patients who continue low-dose aspirin compared with those who did not. However, patients who continue low-dose aspirin have a significantly lower mortality rate compared with the placebo group because of lower rates of cardiovascular and cerebrovascular complications. Current recommendations[10] suggest that patients with upper GI hemorrhage who need secondary cardiovascular prophylaxis should resume low-dose aspirin treatment as soon as the cardiovascular risks outweigh the gastrointestinal risks, usually within 7 days, while continuing proton pump inhibitors (e.g., esomeprazole or pantoprazole 40 mg daily). Such a policy increases the risk of recurrent bleeding by about 65% but also decreases the risk of thromboembolism by about 65% and all-cause mortality by about 50%.[11] Among the direct-acting oral anticoagulants, apixaban (Chapter 70) may be associated with the lowest risk of major GI bleeding.[12]

Patients with idiopathic (non–*H. pylori*, non-NSAID) peptic ulcers should receive long-term acid suppression therapy. For this purpose, limited data suggest that proton pump inhibitors and histamine 2 receptor antagonists are about equally effective, although the former may be slightly better.[A7]

Variceal Bleeding

The treatment of variceal bleeding is discussed in Chapter 139.

LOWER GASTROINTESTINAL BLEEDING

DEFINITION AND EPIDEMIOLOGY

Lower GI hemorrhage generally refers to bleeding from the colon and anorectum. Severe lower GI bleeding occurs with an annual incidence of 20 per 100,000 population, much less frequently than upper GI bleeding. Patients are usually older and present with painless hematochezia, typically without orthostasis. If orthostasis is present, a brisk upper GI bleed, which occurs in 15 to 20% of cases of severe hematochezia, should be considered. The most common cause of severe colorectal hemorrhage is from diverticulosis (Chapter 128). Other frequent causes include internal hemorrhoids (Chapter 131), ischemic colitis (Chapter 129), rectal ulcer (Chapter 131), and delayed bleeding from postpolypectomy ulcers at a median of 8 days (range, 5 hours to 17 days) after the procedure (Table 121-4). In most patients, the bleeding stops and does not recur. The overall mortality rate from lower GI bleeding is 2 to 4%.

DIAGNOSIS

Patients with hematochezia should have a careful history, physical examination, and laboratory evaluation, analogous to the evaluation for upper GI bleeding.[13] The history may help in the differential diagnosis. A history of diverticulosis (see Figs. 128-5 and 128-6) may raise the suspicion for a diverticular bleed (Chapter 128). Abdominal cramping followed by bloody diarrhea suggests ischemic colitis (see Fig. 129-2). A recent polypectomy makes a postpolypectomy bleed more likely.

After medical resuscitation, most patients will need to undergo colonoscopy, although a flexible sigmoidoscopy or anoscopy may be an alternative in cases in which it is highly likely that the bleeding source is from the anorectum or distal colon (Fig. 121-4). Colonoscopy is critical for identifying a luminal source of bleeding as well as for potential hemostasis of amenable lesions.[14] Urgent colonoscopy within 12 hours of admission improves diagnostic yield but has not been shown to reduce either the rate of rebleeding or transfusion requirements.[A8] To cleanse the colon adequately and to visualize the colonic mucosa, a bowel purge with 6 L or more of a polyethylene glycol solution should be administered before the procedure. Colonoscopic treatment (Fig. 121-4) of focal bleeding sources with stigmata of hemorrhage (Fig. 121-5) uses the same methods (epinephrine and either thermocoagulation or hemoclips) as for upper GI bleeding. In addition, coagulation of angiectasias and bleeding biopsy sites is feasible during colonoscopy.[15]

If colonoscopy does not reveal the source of bleeding, an upper endoscopic evaluation should be performed. If both are negative, capsule endoscopy (Chapter 120), if it is locally available, may be the preferred way to look for a small intestinal source of bleeding. Alternatively, if bleeding persists or is too rapid for a colonoscopy to be performed, a tagged red blood cell nuclear scan or angiography may be performed to localize the bleeding. The red blood cell scan can help localize bleeding if it occurs at a rate of at least 0.1 mL/minute. However, a positive scan localizes bleeding to a general region of the abdomen but not to a specific anatomic site. CT angiography, which can detect bleeding rates of 0.3 to 0.5 mL/minute, is a more useful imaging test to identify the anatomic source of hemorrhage. Angiography has the advantage that it can treat the bleeding source with embolization of the bleeding vessel. However, it requires a faster bleeding rate (at least 0.5 mL/minute). These imaging studies cannot identify nonbleeding stigmata and usually do not yield an etiologic diagnosis.

TABLE 121-4 MOST COMMON COLONIC SOURCES OF SEVERE HEMATOCHEZIA IN A SERIES OF 486 CASES (EXPRESSED AS PERCENTAGE OF COLONIC SOURCES)*

Diverticulosis	32%
Internal hemorrhoids	13%
Ischemic colitis	12%
Rectal ulcers	8%
Colonic angiodysplasia, angiectasia, angiomas, or radiation proctopathy	7%
Ulcerative colitis, Crohn disease, other colitis	6%
Postpolypectomy ulcer	5%
Other lower gastrointestinal tract sources	6%

*Less common causes include surgical anastomotic ulcers or sutures, nonsteroidal anti-inflammatory agent colopathy, metastases, portal hypertensive colopathy, lymphoma, and endometriosis.

TREATMENT

Surgical management rarely is needed for hemostasis of lower GI bleeding because most bleeding is either self-limited or easily managed with medical or endoscopic therapy.[16] The main indications for surgery are malignant lesions (Chapters 131 and 179), diffusely bleeding lesions that fail to respond to medical therapy (such as ischemia; Chapter 129), and recurrent diverticular hemorrhage (Chapter 128). If the bleeding source can be localized preoperatively to a particular area of the colon, a segmental resection can be performed rather than a subtotal colectomy. In patients who have lower GI bleeding while on aspirin, the continuation of aspirin is associated with higher risk of recurrent lower GI bleeding but a lower risk of serious cardiovascular events and death.[17] Patients who develop GI bleeding while on antithrombotic medications for atherosclerotic conditions (e.g., coronary, peripheral vascular, or cerebrovascular artery disease) have a 20-fold increase in the likelihood of a new gastrointestinal cancer[18] and require the same aggressive evaluation as patients who bleed without using such medication.

OBSCURE AND OCCULT GASTROINTESTINAL BLEEDING

DEFINITION AND EPIDEMIOLOGY

Obscure GI bleeding is persistent or recurrent bleeding, despite negative initial GI evaluation—including upper endoscopy, push enteroscopy (which reaches farther into the small intestine), and colonoscopy, as well as radiologic evaluation of the small intestine, such as small bowel follow-through or CT or MR

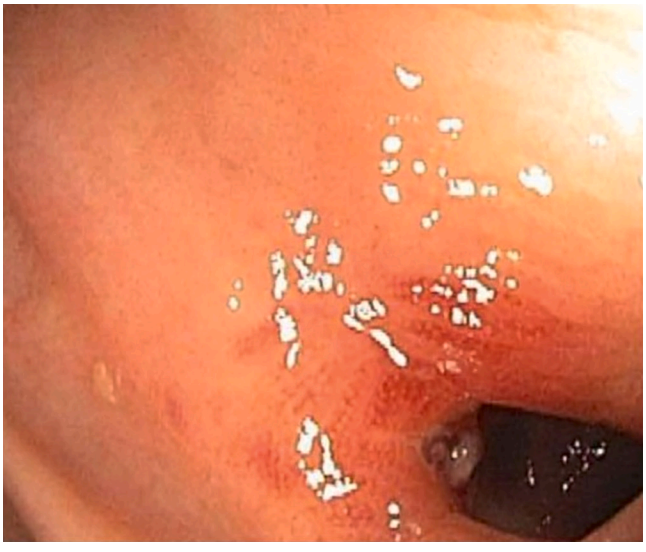

FIGURE 121-5. Colon diverticulum with a visible vessel.

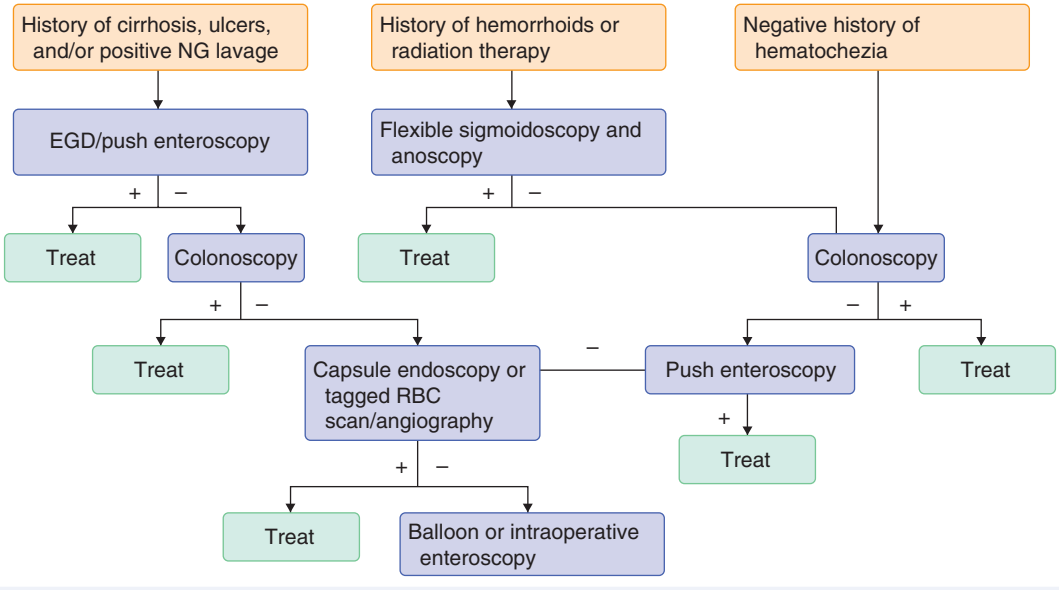

FIGURE 121-4. Management algorithm for severe hematochezia. EGD = esophagogastroduodenoscopy; NG = nasogastric; RBC = red blood cell; + = diagnostic findings; – = no diagnostic findings.

TABLE 121-5 SMALL INTESTINAL LESIONS FOUND IN 488 PATIENTS DURING DOUBLE-BALLOON ENTEROSCOPY FOR OBSCURE GASTROINTESTINAL BLEEDING

LESION	FREQUENCY (RANGE)
None	40% (0-57)
Angiectasias	31% (6-55)
Ulcerations	13% (2-35)
Malignancy	8% (3-26)
Other	6% (2-22)

enterography.[19] Obscure GI bleeding can be classified as either overt (melena, maroon stool, or hematochezia) or occult bleeding (positive result of fecal occult blood testing, usually in the setting of iron deficiency anemia).

In most large series of hospitalized patients, 5% of overt GI bleeding cases are considered to be obscure, and 75% of these patients have bleeding from the small intestine that is beyond the reach of an upper endoscope or colonoscope. Angiectasias (see Fig. 120-5) are the most common source of small intestinal bleeding, followed by ulcers and tumors (Table 121-5). Other causes for obscure GI bleeding include lesions that are within reach of standard endoscopes but that were not recognized as the bleeding site (e.g., a large hiatal hernia with lesions known as Cameron ulcers on endoscopy or internal hemorrhoids on colonoscopy) and intermittently bleeding lesions such as a Dieulafoy lesion (Fig. 121-5),[20] which is an aberrant submucosal vessel without an ulcer.

Iron deficiency (Chapter 145) has a prevalence of 2 to 5% among adult men and postmenopausal women. It can occur from overt or occult blood loss (e.g., GI tract lesions, menorrhagia), iron malabsorption (celiac disease, atrophic gastritis), and red blood cell destruction (hemolysis). It should be suspected in patients with low mean corpuscular volume, low ferritin level, or low transferrin saturation.

DIAGNOSIS

The approaches to overt and occult obscure GI bleeding are similar (Fig. 121-6). In the case of recurrent overt bleeding, upper endoscopy, push enteroscopy, and colonoscopy should be repeated, with the type of bleeding dictating which endoscopic procedure to do first. Colonoscopy with anoscopy should be done first if there is hematochezia. If there is melena, a push small bowel enteroscopy should be performed. If the first procedure is unremarkable, evaluation should be undertaken from the opposite end. If the second test result is negative, capsule endoscopy should be performed (Chapter 120).[21] If bleeding from the small intestine is seen on capsule endoscopy, further attempts to diagnose and to treat the bleeding should be performed with either deep enteroscopy (using a balloon overtube to slide much farther along into the small intestine) or intraoperative enteroscopy. All of these long enteroscopes facilitate diagnosis and hemostasis. If the capsule endoscopy is negative and rapid rebleeding recurs, a tagged red blood cell scan or angiography may be used to localize the bleeding site and assist with subsequent intraoperative enteroscopy.

For occult GI bleeding, colonoscopy should be performed first because fecal occult blood testing was designed to screen for colorectal cancer (Chapter 179). Upper endoscopy and push enteroscopy should follow if the colonoscopy is unremarkable. Afterward, the algorithm is the same as for overt bleeding; however, if the capsule endoscopy is negative, efforts should be focused toward providing supportive care rather than further evaluation.

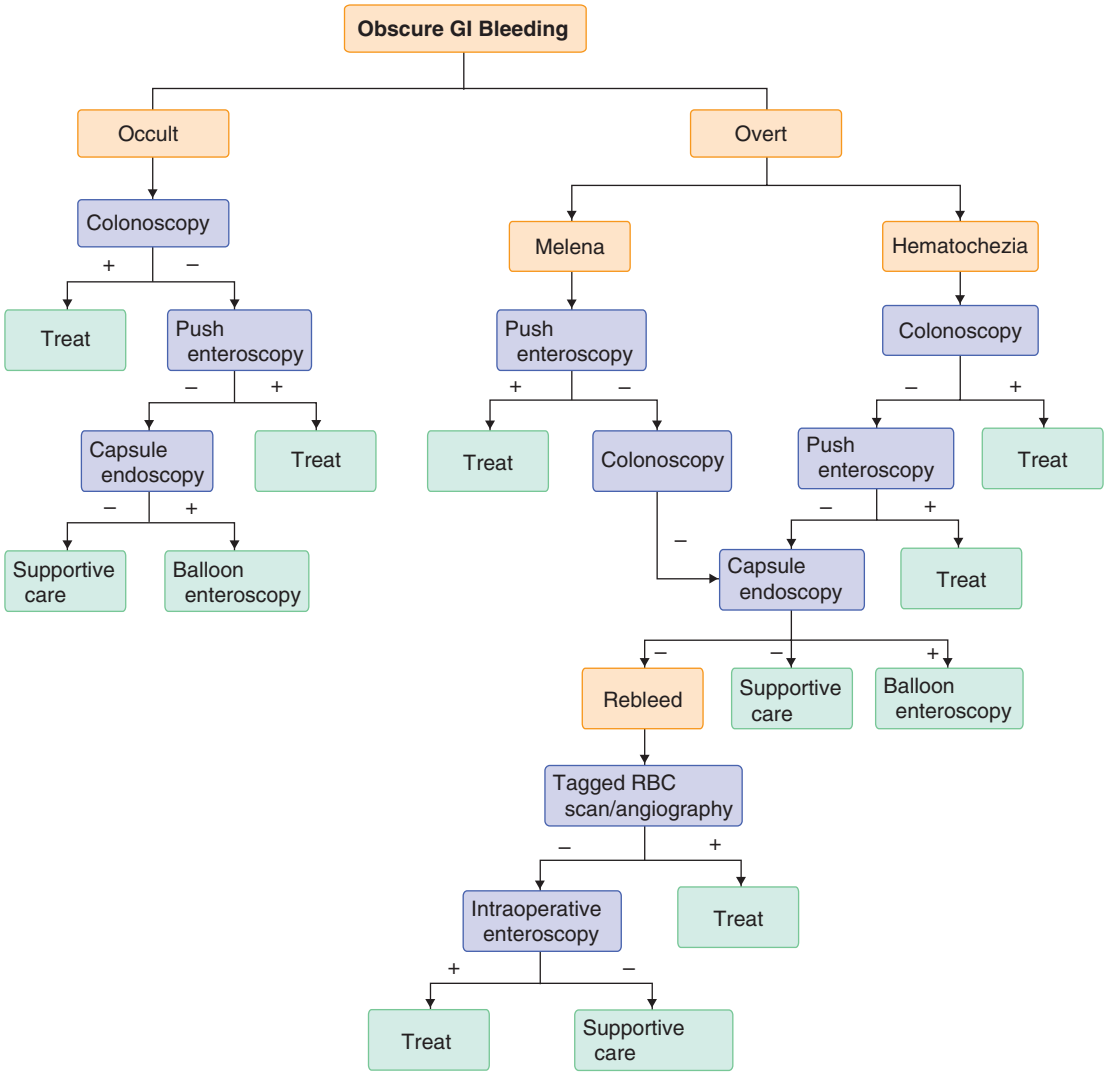

FIGURE 121-6. **Management algorithm for obscure gastrointestinal bleeding.** GI = gastrointestinal; RBC = red blood cell; + = diagnostic findings; – = no diagnostic findings.

Iron Deficiency Anemia

GI evaluation of iron deficiency anemia (Chapter 145) is indicated in adult men, regardless of age, and postmenopausal women. Women who have not reached menopause may warrant a GI evaluation after obvious or potential causes of iron deficiency and blood loss, such as chronic menorrhagia, have been excluded. Colonoscopy should be performed first, followed by upper endoscopy and push enteroscopy if the colonoscopy is negative.[22] Duodenal biopsy specimens should be taken to look for evidence of celiac disease (Chapter 126). In the absence of other potential sources of iron deficiency anemia, *H. pylori* should be treated, if present, because *H. pylori* infection decreases iron absorption and may produce microerosions that bleed. If all three of these endoscopic procedures are unrevealing, capsule endoscopy should be performed. If the capsule study is negative, investigation into non-GI causes of iron deficiency (Chapter 145) may be pursued.

122 DISORDERS OF GASTROINTESTINAL MOTILITY

MICHAEL CAMILLERI

DEFINITION

Motility disorders result from impaired control of the neuromuscular apparatus of the gastrointestinal tract. Associated symptoms include recurrent or chronic nausea, vomiting, bloating, abdominal discomfort, and constipation or diarrhea in the absence of intestinal obstruction.

PATHOBIOLOGY

Normal Physiology

Neuroenteric Control

Motor function of the gastrointestinal tract depends on the contraction of smooth muscle cells and their integration and modulation by enteric and extrinsic nerves as well as pacemaker cells, such as the interstitial cells of Cajal. Extrinsic neural control consists of cranial and sacral parasympathetic nerves (excitatory to nonsphincteric muscle) and the thoracolumbar sympathetic supply (excitatory to sphincters, inhibitory to nonsphincteric muscle). The vagus nerve innervates from the stomach to the right colon. Parasympathetic innervation of the distal colon arises from sacral segments S2 to S4. Sympathetic fibers to proximal and mid-gut and to the colon arise from the intermediolateral column of the spinal cord (T5 to T10 and T11 to L3, respectively). The prevertebral ganglia integrate afferent impulses from the gut and mediate reflex control of abdominal viscera.

The enteric nervous system, which is capable of autonomous control of the gut, comprises about 100 million neurons organized in ganglionated plexuses. The larger myenteric or Auerbach plexus, between the longitudinal and circular muscle layers, is responsible for motility, and the submucosal or Meissner plexus controls absorption, secretion, and mucosal blood flow. The enteric nervous system also plays an important role in visceral afferent function.

Pacemaker cells, which coordinate muscle contraction and sense distortion, serve as intermediaries between the enteric nerves and the smooth muscle cells. Electrical control activity spreads through interneurons in the contiguous segments of the gut via neurochemical activation by transmitters that may be excitatory (e.g., acetylcholine, substance P) or inhibitory (e.g., nitric oxide, somatostatin).

Gastric and Small Bowel Motility

The motor functions of the stomach and small intestine are characterized by distinct patterns of motor activity in the fasting and postprandial periods (E-Fig. 122-1). The fasting period is characterized by a cyclic motor phenomenon, the interdigestive migrating motor complex. In healthy individuals, one cycle of this complex is completed every 60 to 90 minutes. The complex has three phases: quiescence (phase I), intermittent pressure activity (phase II), and an activity front (phase III) during which the stomach and small intestine contract at their highest frequencies (3 per minute in the stomach, 12 per minute in the duodenum, 8 per minute in the ileum). Another characteristic motor pattern in the distal small intestine is prolonged propagated contraction, which empties residue from the ileum into the colon in bolus transfers.

In response to the ingestion of food, the proximal stomach accommodates the food by a vagally mediated reduction in tone, thereby facilitating the ingestion of food without an increase in pressure. Liquids empty from the stomach in an exponential manner, and the rate of emptying varies with calorie content and viscosity. The half-emptying time for non-nutrient liquids in healthy individuals is usually less than 20 minutes. Solids are retained selectively in the stomach, where they undergo acid and peptic digestion as well as "churning" or trituration by high liquid shearing forces in the antrum. Digestible food particles are emptied after their size is reduced by trituration to less than 2 mm. Gastric emptying of solids is characterized by an initial lag period followed by a linear post-lag emptying phase. Secretion of hormones that mediate the motor and digestive process (e.g., gastrin for acid secretion; cholecystokinin for gallbladder contraction and bile and pancreatic secretion; and insulin, glucagon, and incretins such as glucagon-like peptide 1 for glucose regulation) is integrated with the arrival of food or chyme at different levels of the gut to ensure optimal digestion and signal satiation.

The small intestine transports solids and liquids at approximately the same rate. As a result of the lag phase for the transport of solids from the stomach, liquids typically arrive in the colon before solids. Chyme moves from ileum to colon intermittently in boluses propelled by contractions. In the postprandial period, the interdigestive migrating motor complex is replaced by an irregular pattern of contractile activity that persists for about 1 hour for each 200 kcal ingested.

Vomiting is characterized by a stereotypic sequence of motor events, including contractions of the stomach, abdominal muscles, and diaphragm. This sequence is followed immediately in the proximal small bowel by a propagated, rhythmic contractile response similar to the migrating motor complex.

Colonic Motility

The normal colon displays short-duration (phasic) contractions and a background contractility or tone. Nonpropagated phasic contractions segment the colon and facilitate mixing, retention of residue, and formation of solid stool. High-amplitude propagated contractions, which exceed 75 mm Hg, propagate over a distance of at least 15 cm at a propagation velocity of 0.15 to 2.2 cm/second and contribute to the movement of feces in the colon. In health, these contractions occur on average five or six times per day, most often postprandially and between 6 am and 2 pm.

Colonic transit is slow most of the time but rapid at other times. Residue may be retained for prolonged periods in the ascending and transverse colon; alternatively, a mass movement may deliver the contents to the sigmoid colon in seconds. Feeding stimulates movement of colonic content (a gastrocolonic response). In health, the average mouth-to-cecum transit time is about 6 hours, and transit times through the right colon, left colon, and sigmoid colon are about 12 hours each. Decreased calorie intake slows colonic transit, whereas

Iron Deficiency Anemia

GI evaluation of iron deficiency anemia (Chapter 145) is indicated in adult men, regardless of age, and postmenopausal women. Women who have not reached menopause may warrant a GI evaluation after obvious or potential causes of iron deficiency and blood loss, such as chronic menorrhagia, have been excluded. Colonoscopy should be performed first, followed by upper endoscopy and push enteroscopy if the colonoscopy is negative.[22] Duodenal biopsy specimens should be taken to look for evidence of celiac disease (Chapter 126). In the absence of other potential sources of iron deficiency anemia, *H. pylori* should be treated, if present, because *H. pylori* infection decreases iron absorption and may produce microerosions that bleed. If all three of these endoscopic procedures are unrevealing, capsule endoscopy should be performed. If the capsule study is negative, investigation into non-GI causes of iron deficiency (Chapter 145) may be pursued.

122 DISORDERS OF GASTROINTESTINAL MOTILITY

MICHAEL CAMILLERI

DEFINITION

Motility disorders result from impaired control of the neuromuscular apparatus of the gastrointestinal tract. Associated symptoms include recurrent or chronic nausea, vomiting, bloating, abdominal discomfort, and constipation or diarrhea in the absence of intestinal obstruction.

PATHOBIOLOGY

Normal Physiology

Neuroenteric Control

Motor function of the gastrointestinal tract depends on the contraction of smooth muscle cells and their integration and modulation by enteric and extrinsic nerves as well as pacemaker cells, such as the interstitial cells of Cajal. Extrinsic neural control consists of cranial and sacral parasympathetic nerves (excitatory to nonsphincteric muscle) and the thoracolumbar sympathetic supply (excitatory to sphincters, inhibitory to nonsphincteric muscle). The vagus nerve innervates from the stomach to the right colon. Parasympathetic innervation of the distal colon arises from sacral segments S2 to S4. Sympathetic fibers to proximal and mid-gut and to the colon arise from the intermediolateral column of the spinal cord (T5 to T10 and T11 to L3, respectively). The prevertebral ganglia integrate afferent impulses from the gut and mediate reflex control of abdominal viscera.

The enteric nervous system, which is capable of autonomous control of the gut, comprises about 100 million neurons organized in ganglionated plexuses. The larger myenteric or Auerbach plexus, between the longitudinal and circular muscle layers, is responsible for motility, and the submucosal or Meissner plexus controls absorption, secretion, and mucosal blood flow. The enteric nervous system also plays an important role in visceral afferent function.

Pacemaker cells, which coordinate muscle contraction and sense distortion, serve as intermediaries between the enteric nerves and the smooth muscle cells. Electrical control activity spreads through interneurons in the contiguous segments of the gut via neurochemical activation by transmitters that may be excitatory (e.g., acetylcholine, substance P) or inhibitory (e.g., nitric oxide, somatostatin).

Gastric and Small Bowel Motility

The motor functions of the stomach and small intestine are characterized by distinct patterns of motor activity in the fasting and postprandial periods (E-Fig. 122-1). The fasting period is characterized by a cyclic motor phenomenon, the interdigestive migrating motor complex. In healthy individuals, one cycle of this complex is completed every 60 to 90 minutes. The complex has three phases: quiescence (phase I), intermittent pressure activity (phase II), and an activity front (phase III) during which the stomach and small intestine contract at their highest frequencies (3 per minute in the stomach, 12 per minute in the duodenum, 8 per minute in the ileum). Another characteristic motor pattern in the distal small intestine is prolonged propagated contraction, which empties residue from the ileum into the colon in bolus transfers.

In response to the ingestion of food, the proximal stomach accommodates the food by a vagally mediated reduction in tone, thereby facilitating the ingestion of food without an increase in pressure. Liquids empty from the stomach in an exponential manner, and the rate of emptying varies with calorie content and viscosity. The half-emptying time for non-nutrient liquids in healthy individuals is usually less than 20 minutes. Solids are retained selectively in the stomach, where they undergo acid and peptic digestion as well as "churning" or trituration by high liquid shearing forces in the antrum. Digestible food particles are emptied after their size is reduced by trituration to less than 2 mm. Gastric emptying of solids is characterized by an initial lag period followed by a linear post-lag emptying phase. Secretion of hormones that mediate the motor and digestive process (e.g., gastrin for acid secretion; cholecystokinin for gallbladder contraction and bile and pancreatic secretion; and insulin, glucagon, and incretins such as glucagon-like peptide 1 for glucose regulation) is integrated with the arrival of food or chyme at different levels of the gut to ensure optimal digestion and signal satiation.

The small intestine transports solids and liquids at approximately the same rate. As a result of the lag phase for the transport of solids from the stomach, liquids typically arrive in the colon before solids. Chyme moves from ileum to colon intermittently in boluses propelled by contractions. In the postprandial period, the interdigestive migrating motor complex is replaced by an irregular pattern of contractile activity that persists for about 1 hour for each 200 kcal ingested.

Vomiting is characterized by a stereotypic sequence of motor events, including contractions of the stomach, abdominal muscles, and diaphragm. This sequence is followed immediately in the proximal small bowel by a propagated, rhythmic contractile response similar to the migrating motor complex.

Colonic Motility

The normal colon displays short-duration (phasic) contractions and a background contractility or tone. Nonpropagated phasic contractions segment the colon and facilitate mixing, retention of residue, and formation of solid stool. High-amplitude propagated contractions, which exceed 75 mm Hg, propagate over a distance of at least 15 cm at a propagation velocity of 0.15 to 2.2 cm/second and contribute to the movement of feces in the colon. In health, these contractions occur on average five or six times per day, most often postprandially and between 6 am and 2 pm.

Colonic transit is slow most of the time but rapid at other times. Residue may be retained for prolonged periods in the ascending and transverse colon; alternatively, a mass movement may deliver the contents to the sigmoid colon in seconds. Feeding stimulates movement of colonic content (a gastrocolonic response). In health, the average mouth-to-cecum transit time is about 6 hours, and transit times through the right colon, left colon, and sigmoid colon are about 12 hours each. Decreased calorie intake slows colonic transit, whereas

ABSTRACT

Disorders of gastrointestinal motility comprise at least 25% of all gastroenterology practice. The manifestations of disordered neuromuscular function include gastroparesis, chronic intestinal pseudo-obstruction, chronic constipation, dumping syndrome, and diarrhea. Rectal evacuation disorders may present with constipation, abdominal discomfort, bloating, or nausea. Motility disorders result from abnormal neuroenteric, muscle, transmitter, or hormonal functions. Algorithms are provided for evaluation of patients with retardation of gastric or small bowel transit and for the very common clinical presentation of chronic constipation. The principles of treatment are based on accurate diagnosis, correction of dehydration and malnutrition, use of prokinetic or anti-motility agents, and symptomatic remedies such as antiemetics for nausea or vomiting and laxatives for constipation.

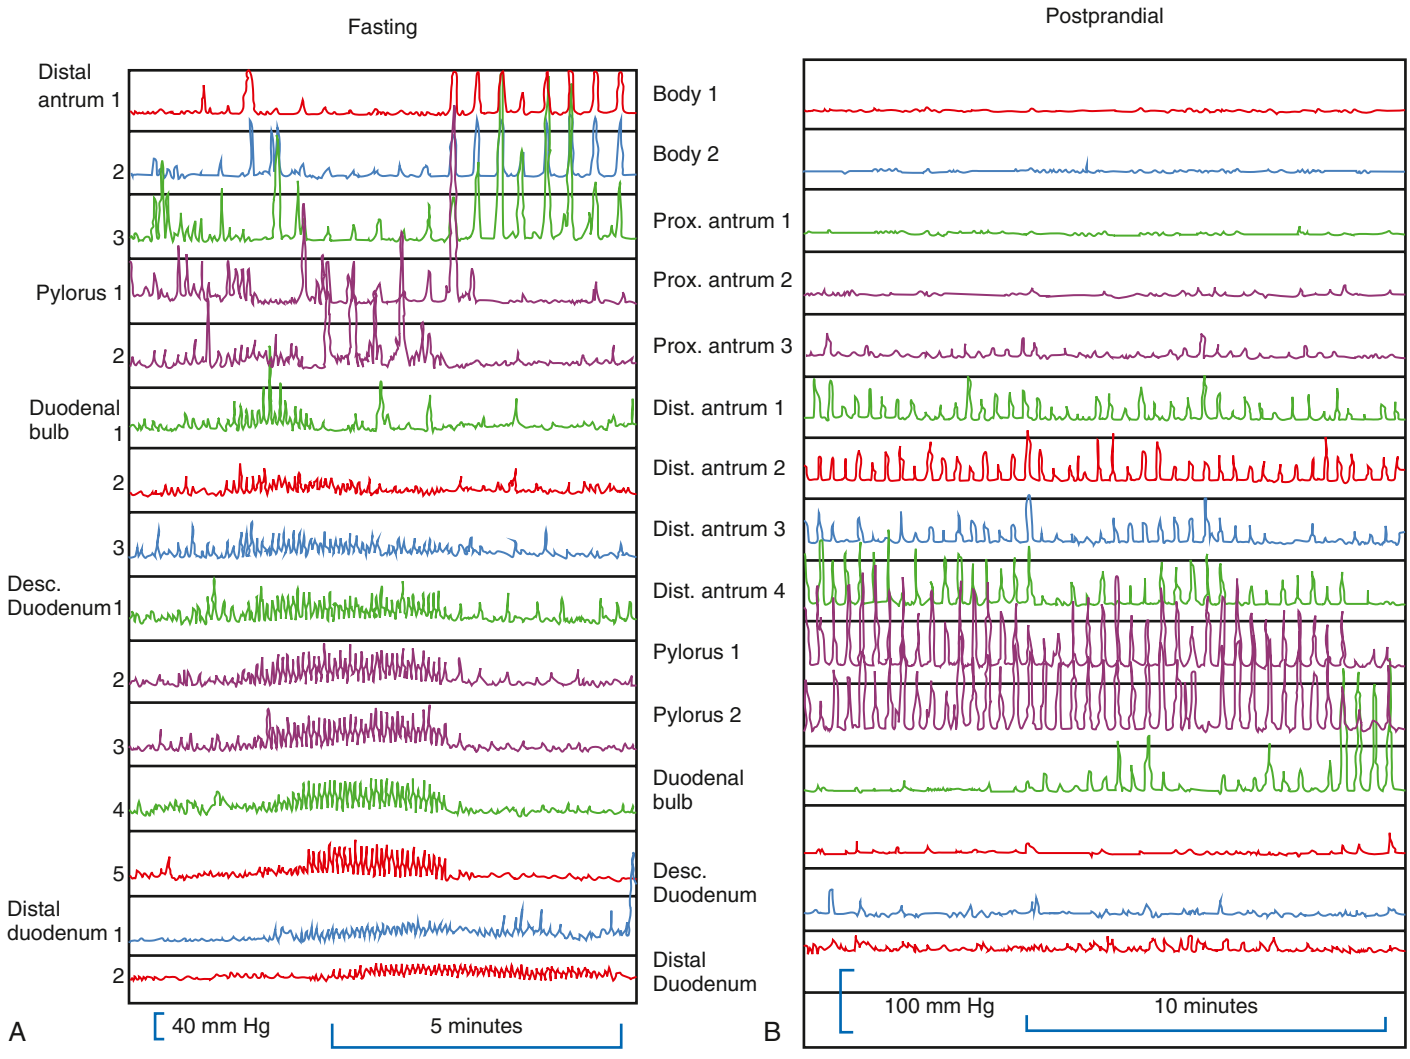
pseudo-obstruction



E-FIGURE 122-1. **A,** The migrating motor complex (MMC) in the gastric and small intestinal motor pattern of the interdigestive state. The interdigestive motility begins after digestion and absorption of nutrients are complete, 2 to 3 hours after a meal. Sensors in the stomach show that the MMC starts as large amplitude contractions at 3 per minute in the distal stomach. Activity in the stomach migrates into the small intestine to the ileum. (From Camilleri M. Physiological fundamentals of neurogastroenterology: motility, absorption, sensation. In: *Neurogastroenterology and Gastrointestinal Motility in Clinical Practice*. Mexico City, Mexico: Permanyer Publishers, 2017.) **B,** Gastroduodenal manometry in healthy subject showing contractions in the postprandial period from the gastric body to the duodenum. Desc. = descending; Dist. = distal; Prox. = proximal. (From Nelson AD, Camilleri M, Acosta A, et al. Effects of ghrelin receptor agonist, relamorelin, on gastric motor functions and satiation in healthy volunteers. *Neurogastroenterol Motil*. 2016;28:1705-1713.)

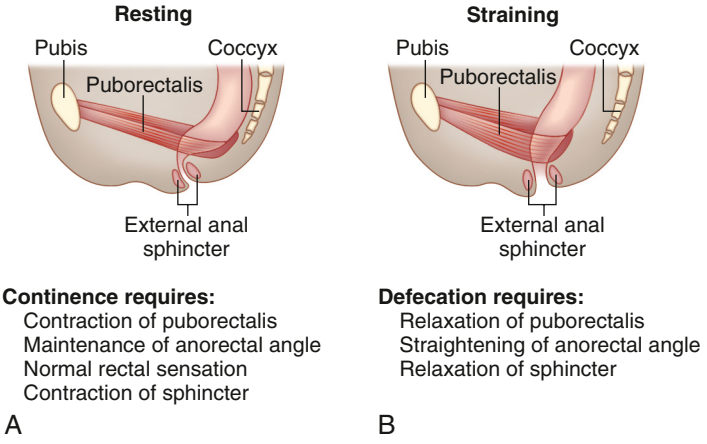


FIGURE 122-1. **Pelvic floor and anorectal functions during continence and defecation.** Sagittal view through the pelvis in the resting (A) and straining (B) postures. Coordinated functions of pelvic floor (puborectalis) and anal sphincter are essential for continence and defecation.

meals greater than 500 kcal, especially if fat-rich, stimulate colonic motility and propulsion. Outlet obstruction in patients with pelvic floor dysfunction or voluntary suppression of defecation often slow colonic transit and decrease the motor response to feeding.

Fluid reabsorption influences gastrointestinal transit. Approximately 9 L of fluid enters the gut from oral intake and endogenous secretions. The small intestine delivers about 1.5 L of fluid to the colon, where most is reabsorbed, leaving a maximum of 200 mL of water excreted in normal stool. Up to 3 L of fluid can be reabsorbed by the colon over 24 hours, unless the ileocolonic flow rate or colonic motility overwhelm the colon's capacity or reabsorption.

Defecation and Continence

Normal defecation requires a series of coordinated actions of the colon, rectum, pelvic floor, and anal sphincter muscles (Fig. 122-1). Distention of the rectum results in the relaxation of the internal anal sphincter (rectoanal inhibitory reflex) and simultaneous contraction of the external anal sphincter to maintain continence. The anal transition zone can sense the difference between solid or liquid stool and gas.

DISEASES OF SLOW TRANSIT THROUGH THE STOMACH AND SMALL BOWEL

PATHOBIOLOGY

Gastrointestinal motility disturbances (Table 122-1) result from disorders of the extrinsic nervous system, enteric nervous system, intestinal pacemakers or smooth muscle. Neuropathic patterns are characterized by normal amplitude but incoordinated contractions, whereas myopathies are characterized by low-amplitude contractions (average <40 mm Hg in the antrum and <10 mm Hg in the small bowel).

Genetic defects that result in congenital dysmotility include abnormalities of *RET*, the gene that encodes the tyrosine kinase receptor, and abnormalities in the endothelin B system. Neural crest cells migrate from the vagal and sacral crest to the developing gut and, over time, colonize the entire developing alimentary canal and its appendages. Endothelin B serves to retard maturation of migrating neural crest cells, thus facilitating colonization of the entire gut with nerve cells.

EXTRINSIC NEUROPATHIC DISORDERS

Extrinsic neuropathic processes include vagotomy, trauma, Parkinson disease (Chapter 378), diabetes (Chapter 210), amyloidosis (Chapter 174), a paraneoplastic syndrome usually associated with small cell carcinoma of the lung (Chapter 177), and effect of medications, such as α_2-adrenergic agonists, glucagon-like peptide 1 analogues, opiates, and anticholinergics, on neural control.

Damage to the autonomic nerves may lead to motor, secretory, and sensory disturbances, most frequently resulting in constipation. Fasting colonic motility and tone remain normal, but a reduced left colon response to feeding as well as decreased rectal tone and sensitivity may lead to colorectal dilation and fecal impaction.

ENTERIC AND INTRINSIC NEUROPATHIC DISORDERS

Disorders of the enteric nervous system or interstitial cells of Cajal are usually the result of an infectious (e.g., viral), degenerative, immune, or inflammatory process associated with infiltration of the myenteric plexus with inflammatory cells.

TABLE 122-1 CLASSIFICATION OF GASTROPARESIS AND PSEUDO-OBSTRUCTION

TYPE	NEUROPATHIC	MYOPATHIC
Infiltrative	Progressive systemic sclerosis Amyloidosis	Progressive systemic sclerosis Amyloidosis Systemic lupus erythematosus Ehlers-Danlos syndrome Dermatomyositis
Familial	Familial visceral neuropathies	Familial visceral myopathies Metabolic myopathies
Idiopathic	Idiopathic intestinal pseudo-obstruction	Sporadic hollow visceral myopathy
Neurologic	Porphyria Heavy metal poisoning Brain stem tumor Parkinson disease Multiple sclerosis Spinal cord transection	Myotonia Other dystrophies
Infectious	Chagas disease Cytomegalovirus Norwalk virus Epstein-Barr virus	
Drug induced	Tricyclic antidepressants Narcotic agents Anticholinergic agents Antihypertensives Dopaminergic agents Vincristine Laxatives	
Paraneoplastic	Small cell lung cancer Carcinoid syndrome	
Postsurgical/ Injury	Postvagotomy with or without pyloroplasty or gastric resection Spinal cord injury	
Endocrine	Diabetes mellitus Hypothyroidism or hyperthyroidism Hypoparathyroidism	

SMOOTH MUSCLE DISORDERS

Disturbances of smooth muscle may result in significant disorders of gastric emptying and of transit through the small bowel and colon. Motility disturbances may be the result of metabolic disorders, such as hypothyroidism (Chapter 207) and hyperparathyroidism (Chapter 227), but these patients more commonly present with constipation. Scleroderma may result in focal or general dilation, wide-mouthed diverticula, and delayed transit in the stomach, small bowel, and colon. The amplitude of contractions is reduced, and bacterial overgrowth may result in steatorrhea or pneumatosis intestinalis. Mitochondrial neurogastrointestinal encephalomyopathy is an autosomal recessive condition that may be manifested with hepatic failure in neonates, seizures or diarrhea in infants, and hepatic failure or chronic intestinal pseudo-obstruction in adults.

CLINICAL MANIFESTATIONS

The clinical features of gastroparesis[1,2] and chronic intestinal pseudo-obstruction[3] are similar and include nausea, vomiting, early satiety, abdominal discomfort, distention, bloating, and anorexia. Severe cases, which occur mostly in patients with disorders of smooth muscle, may be accompanied by dilation, weight loss, depletion of mineral and vitamin stores. Diarrhea and constipation indicate that the motility disorder extends beyond the stomach. Vomiting may result in aspiration pneumonia (Chapter 82) or Mallory-Weiss esophageal tears (Chapters 121 and 124), and patients with a generalized motility disorder may have abnormal swallowing or delayed colonic transit.

A careful family and medication history is essential. Review of systems may reveal an underlying collagen vascular disease (e.g., scleroderma) or disturbances of extrinsic autonomic neural control, including orthostatic dizziness, difficulties with erection or ejaculation, recurrent urinary tract infections, dry mouth, dry eyes, dry vagina, difficulties with visual accommodation in bright lights, and absence of sweating.

On physical examination, a succussion splash indicates stasis, typically in the stomach. The hands and mouth may reveal signs of Raynaud phenomenon or

scleroderma (Chapter 246). Testing of pupillary responses (to light and accommodation), external ocular movements, blood pressure in the lying and standing positions, and general features of a peripheral neuropathy can identify patients with an associated neurologic disturbance (e.g., diabetic neuropathy) or mitochondrial cytopathies (see under the Smooth Muscle Disorders section in this chapter).

The differential diagnosis includes mechanical obstruction, functional gastrointestinal disorders, anorexia nervosa, and the rumination syndrome. The rumination syndrome is a relatively common, underdiagnosed condition that is manifested with early (0 to 30 minutes) postprandial, effortless regurgitation of undigested food after virtually every meal.

DIAGNOSIS

Diagnosis requires documentation of delayed gastric emptying of a digestible solid meal. The clinician should assess the acuity of symptoms and the patient's state of hydration and nutrition. The goals of the evaluation are to determine what regions of the digestive tract are malfunctioning and whether the symptoms are due to a neuropathy or a myopathy (Fig. 122-2). Key steps include the following:

1. *Suspect and exclude mechanical obstruction* by upper gastrointestinal endoscopy and small bowel imaging studies, including a small bowel follow-through, computed tomographic enterography, and magnetic resonance enteroclysis. Capsule endoscopy should be avoided because of the potential risk of retention of the capsule. These studies rarely identify the cause, however, except for systemic sclerosis and mitochondrial cytopathy, which are characterized by megaduodenum, multiple small bowel diverticula, and pneumatosis intestinalis.
2. *Assess gastric and small bowel motility*. After mechanical obstruction and alternative diagnoses such as Crohn disease (Chapter 127) have been excluded, a transit profile of the stomach should be performed using a radiolabeled solid meal followed by scintigraphy at 0, 1, 2, 3, 4, and 6 hours, or a stable isotope breath test. Delayed gastric emptying is associated with symptoms of gastroparesis.[4] If the underlying cause of the motility disturbance is known, it is usually unnecessary to pursue further diagnostic testing. If the cause is unclear, gastroduodenal manometry by use of a multilumen tube with sensors in the distal stomach and proximal small intestine can differentiate a neuropathic process (normal-amplitude contractions but abnormal patterns of contractility) from a myopathic process (low-amplitude contractions in the affected segments, typically <10 mm Hg in the small intestine). A wireless motility capsule also can assess contraction amplitude if the intestine is not dilated to more than 5 cm. Manometry may also identify pylorospasm, which may respond to per-oral endoscopic myotomy.
3. *Identify the pathogenesis* (see Table 122-1). Other tests for neuropathic causes assess autonomic dysfunction (Chapter 389), autoantibodies associated with paraneoplastic syndromes, and brain stem function. In patients with a myopathic disorder of unclear cause, the evaluation should consider amyloidosis (immunoglobulin electrophoresis, fat aspirate, or rectal biopsy; Chapter 174), systemic sclerosis (topoisomerase I; Chapter 246), and thyroid disease (Chapter 207). In appropriate settings, porphyria (Chapter 194) and Chagas disease (Chapter 318) may need to be excluded. Diabetes mellitus (Chapter 210) is associated with gastroparesis, pylorospasm, intestinal pseudo-obstruction, diarrhea, constipation, and fecal incontinence.[5] In refractory cases, genetic testing or full-thickness biopsy of the small intestine (E-Fig. 122-2) may be required to identify metabolic muscle disorders and mitochondrial cytopathies (Chapter 389).
4. *Identify complications of the motility disorder, including bacterial overgrowth, dehydration, and malnutrition*. In patients presenting with diarrhea, it is important to assess nutritional status and to exclude bacterial overgrowth by culture of small bowel aspirates or glucose-hydrogen breath test (Chapter 126). Bacterial overgrowth is relatively uncommon in neuropathic disorders but is found more often in myopathic conditions, such as scleroderma, that are associated more often with dilation or low-amplitude contractions. An empirical trial of antibiotics (see later) often is used instead of formal testing.

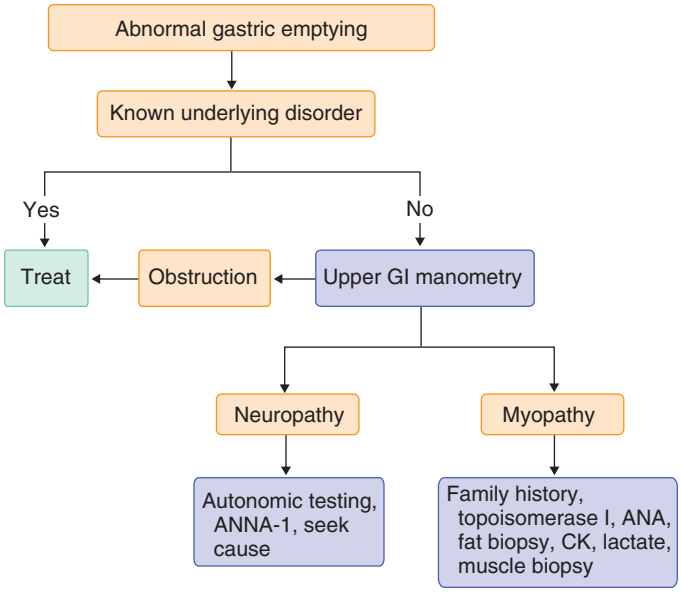

FIGURE 122-2. Flow diagram outlines steps in diagnosis of idiopathic gastroparesis and intestinal pseudo-obstruction. ANA = antinuclear antibody; ANNA-1 = type 1 antineuronal nuclear antibody; CK = creatine kinase; GI = gastrointestinal.

TREATMENT

Rehydration, electrolyte repletion, and nutritional supplementation are particularly important during acute exacerbations of gastroparesis and chronic intestinal pseudo-obstruction. Initial nutritional measures include small solid particle meals (blenderized solids) or low-fiber liquid food supplements with the addition of iron, folate, calcium, and vitamins D, K, and B_{12} at the usually recommended daily levels. In patients with more severe symptoms, enteral or parenteral supplementation may be required.[6] If it is anticipated that enteral supplementation may be needed for more than 3 months, a jejunostomy feeding tube is recommended. These tubes may be placed with the aid of endoscopy. Gastrostomy tubes should be avoided in patients with gastroparesis except for venting purposes.

Medical Therapy

Prokinetic Agents

Medications often can enhance gastric emptying and improve symptoms in patients with neuromuscular motility disorders.[A1] Tradipitant (an experimental antagonist of tachykinin receptor 1 given orally at 85 mg twice daily) can significantly reduce nausea and vomiting in patients with diabetic or idiopathic gastroparesis.[A2] Aprepitant (125 mg/day for 4 weeks) also appears to be efficacious for gastroparesis and related disorders.[A3]

Erythromycin, a macrolide antibiotic that stimulates motilin receptors at higher doses (250 to 500 mg) and cholinergic mechanisms at lower doses (40 to 80 mg) accelerates gastric emptying in gastroparesis. Erythromycin is most effective when it is used intravenously (3 mg/kg every 8 hours by slow infusion) during acute exacerbations of gastroparesis. Efficacy wanes over 14 days because of tachyphylaxis. Pyridostigmine (30 to 60 mg every 6 hours tablet or liquid formulation) is also sometimes used. In patients who do not respond to other treatments, metoclopramide (a dopamine antagonist with mild prokinetic and antiemetic properties) can be useful for up to 3 months as a rapid oral disintegrating tablet, intranasal spray, elixir, or parenteral preparation. It should be taken orally (15 to 30 minutes before meals and at bedtime). Usual doses are 5 to 10 mg four times daily, but patients may experience side effects (changes in affect, anxiety) at relatively low doses (even 30 to 40 mg/day).

Domperidone (10 to 20 mg, three times per day before meals) is another dopamine antagonist available through an investigational drug application to the U.S. Food and Drug Administration and local Institutional Review Board. Its efficacy appears similar to metoclopramide, with lower risk of involuntary movements. Domperidone-induced cardiac arrhythmias may occur in patients with specific polymorphisms in the cytochrome P-450 3A4 gene, which encodes the enzyme that metabolizes domperidone (Chapter 25). Genetic screening is not recommended in any guidelines.

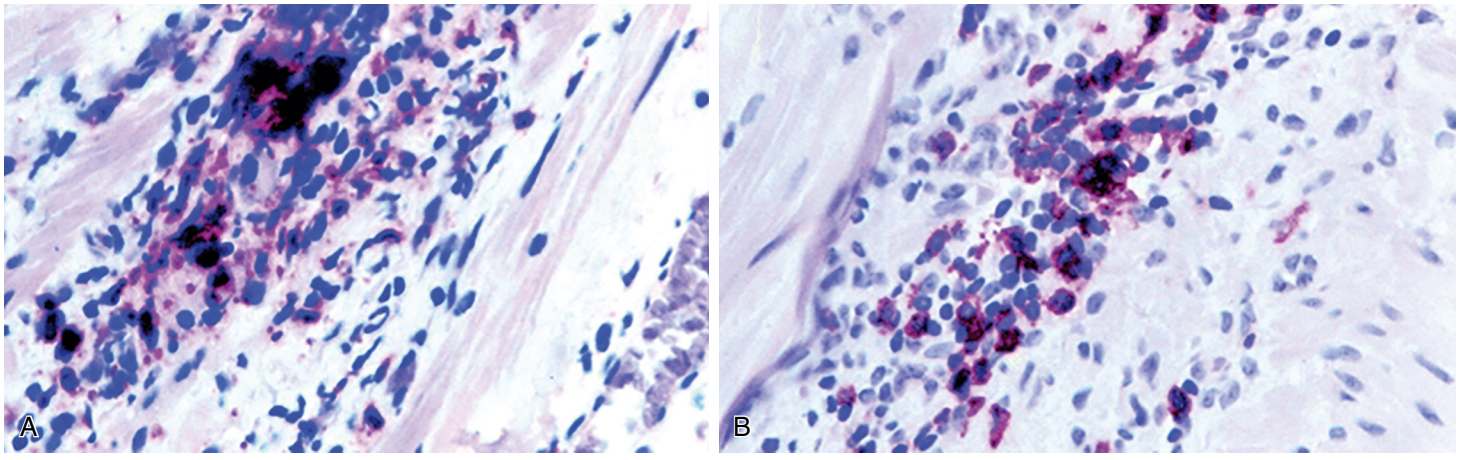
Experimental medications for gastroparesis include relamorelin, an agonist of ghrelin receptor (given subcutaneously once or twice daily), which can speed gastric emptying and improve the symptoms of gastroparesis in diabetic patients,[A4] and felcisetrag, an intravenous 5-HT4 receptor agonist, which accelerates gastric emptying in idiopathic and diabetic gastroparesis.[A5]

Antiemetic Agents

Antiemetics (Table 118-5), including diphenhydramine (25 mg orally up to two times per day for up to 3 months) and promethazine (orally or by suppository, 25 mg up to two times per day) can treat nausea and vomiting in patients with gastroparesis and intestinal pseudo-obstruction. The serotonin 5-HT_3 antagonists (e.g., ondansetron, 4 or 8 mg tablet or oral dissolution tablet; or granisetron which is available as a transdermal patch) also may be used.

Other Approaches

Octreotide (50 μg subcutaneously at bedtime), a cyclized analogue of somatostatin, induces small intestinal activity that mimics phase III of the interdigestive migrating motor complex. It actually retards gastric emptying and small



E-FIGURE 122-2. Micrographs showing both types of T lymphocytes, CD4 (A) and CD8 (B), detectable within the myenteric plexus of the small intestine (proximal ileum) of a 20-year-old man with chronic intestinal pseudo-obstruction. Note the intense CD4 and CD8 immunoreactivities that represent the predominant component of the immune infiltrate observed in cases of lymphocytic ganglionitis. Alkaline phosphatase anti–alkaline phosphatase immunohistochemical technique (×120) in A and B. (From De Giorgio R, Camilleri M. Human enteric neuropathies: morphology and molecular pathology. *Neurogastroenterol Motil*. 2004;16:515-531.)

bowel transit. Octreotide may be used before sleep to sweep residue toward the colon and to avoid bacterial overgrowth.

Antibiotic therapy, typically using different antibiotics for 7 to 10 days each month in an attempt to avoid bacterial resistance, is indicated in patients with documented, symptomatic bacterial overgrowth. Common antibiotics include doxycycline (50 to 100 mg twice daily), metronidazole (250 mg three times daily), and double-strength trimethoprim-sulfamethoxazole (two tablets twice daily). Use of antibiotics in patients with diarrhea and fat malabsorption secondary to bacterial overgrowth results in significant symptomatic relief.

Surgical and Endoscopic Therapy

Surgical decompression is rarely necessary in patients with chronic pseudo-obstruction. Venting enterostomy (jejunostomy) is effective, however, in relieving abdominal distention and bloating and in reducing the frequency with which nasogastric intubations and hospitalizations are required for acute exacerbations compared with the period before vent placement. Access to the small intestine by enterostomy also provides a means to deliver nutrients and should be considered in patients with intermittent symptoms. Surgical treatment should be considered whenever the motility disorder is localized to a resectable portion of the gut: completion gastrectomy for patients with post–gastric surgical stasis syndrome, and colectomy with ileorectostomy for intractable constipation associated with chronic colonic pseudo-obstruction.

Gastric electrical stimulation may improve symptoms in some patients with severe gastroparesis.[A6] Botulinum injection of the pylorus, followed if successful by gastric per-oral endoscopic myotomy or pyloric surgery, is a promising therapy for troublesome cases.[7]

Small bowel transplantation currently is limited to patients who have intestinal failure and reversible liver disease induced by total parenteral nutrition or who have life-threatening or recurrent catheter-related sepsis. Isolated transplantation of the small intestine is associated with higher graft and patient survival and fewer complications related to rejection and infection.

DISEASES OF RAPID TRANSIT THROUGH STOMACH AND SMALL BOWEL

DUMPING SYNDROME AND ACCELERATED GASTRIC EMPTYING

Dumping syndrome and accelerated gastric emptying typically follow truncal vagotomy and gastric drainage procedures (Chapter 125), fundoplication for gastric esophageal reflux disease (Chapter 124), or bariatric procedures such as sleeve gastrectomy or Roux-en-Y gastric bypass. A high calorie (usually carbohydrate) content of the liquid phase of the meal evokes a rapid insulin response with secondary hypoglycemia.

The management of dumping syndrome and accelerated gastric emptying emphasizes dietary maneuvers, such as avoidance of high-nutrient liquid drinks and possibly addition of guar gum or pectin to retard gastric emptying of liquids. Pharmacologic treatment with octreotide, 25 to 100 µg subcutaneously before meals, retards intestinal transit and inhibits the hormonal responses that lead to hypoglycemia.

RAPID TRANSIT DYSMOTILITY OF THE SMALL BOWEL

Rapid transit of material through the small bowel may occur in postvagotomy diarrhea (Chapter 126), short bowel syndrome (Chapter 126), diabetic diarrhea (Chapter 126), and carcinoid diarrhea (Chapter 213) and result in significant losses of fluid and electrolytes. Ileal resection or disease and idiopathic bile acid malabsorption may induce colonic secretion and secondary diarrhea. Accelerated transit may be confirmed by scintigraphic studies.

Treatment goals are to restore hydration and nutrition and to slow small bowel transit by avoiding hyperosmolar drinks and replacing with iso-osmolar or hypo-osmolar oral rehydration solutions. The fat content in the diet should be reduced to approximately 50 g/day to avoid delivery of unabsorbed fat to the colon. All electrolyte and nutritional deficiencies of calcium, magnesium, potassium, and water-soluble and fat-soluble vitamins should be corrected. In patients with less than 1 m of residual small bowel, it may be impossible to maintain fluid and electrolyte homeostasis without parenteral support. In patients with a longer residual intestinal segment, oral nutrition, pharmacotherapy, and supplements are almost always effective.

The opioid agent loperamide (2 to 4 mg 30 minutes before meals and at bedtime for a total dose of 16 mg/day) suppresses the motor response to feeding and improves symptoms. Bile acid binding, such as with cholestyramine (4 g three times daily) or colesevelam (1.875 g twice daily), is indicated for patients with suspected or proven bile acid malabsorption.[8] Clonidine (0.1 mg daily as oral tablet or dermal patch) or a 5-HT_3 antagonist (e.g., ondansetron, 4 to 8 mg three times daily) is used rarely in addition to loperamide. Octreotide (50 µg subcutaneously three times daily, 5 minutes before meals) may be used in patients for whom the oral agents are ineffective or poorly tolerated.

COLONIC MOTILITY DISORDERS

Constipation

EPIDEMIOLOGY

Constipation is a common clinical problem, reported by about 20% of the population, and 40% of Americans report needing to strain excessively to pass their bowel movements.[9]

PATHOBIOLOGY

In functional constipation, transit is normal, and there is no evacuation disorder. These patients may have pain in association with constipation, and there is overlap with constipation-predominant irritable bowel syndrome (Chapter 123). In patients with acquired slow-transit constipation, unassociated with colonic dilation, the number of interstitial cells of Cajal in the different layers of the colon is reduced compared with controls.

Idiopathic megarectum and megacolon can be either congenital or acquired; an enteric nervous system defect is suspected. In megacolon, the dilated segment shows normal phasic contractility but decreased colonic tone, with smooth muscle hypertrophy and fibrosis of the muscularis mucosa, circular muscle, and longitudinal muscle layers.

Acquired defects in the enteric nervous system may result in constipation in Chagas disease (Chapter 318), which is caused by infection with *Trypanosoma cruzi* and results in the destruction of myenteric neurons.

DIAGNOSIS

It is essential to distinguish an evacuation disorder, also called functional outlet obstruction (Table 122-2), from constipation resulting from slow transit or other causes.[10] In a tertiary center, about 25% of patients presenting with constipation have impaired evacuation, and the remainder have constipation associated with either normal transit (also called functional constipation) or delayed colonic transit (also called slow-transit constipation). Characterization of constipated patients without rectal evacuation disorders (Fig. 122-3) relies on the measurement of transit with radiopaque markers or scintigraphy.

TABLE 122-2 CLINICAL CLUES SUGGESTIVE OF AN EVACUATION DISORDER

HISTORY
Prolonged straining to expel stool
Taking up unusual postures on the toilet to facilitate stool expulsion
Support of perineum or digitation of rectum or vagina to facilitate rectal emptying
Inability to expel enema fluid
Constipation after subtotal colectomy for constipation
RECTAL EXAMINATION (WITH PATIENT IN LEFT LATERAL POSITION)
Inspection
Anus "pulled" forward during attempts to simulate strain during defecation
Anal verge descends <1 cm or >4 cm during attempts to simulate strain during defecation
Perineum balloons down during straining, and rectal mucosa prolapses through anus
Palpation
High anal sphincter tone at rest precludes easy entry of examining finger (in absence of painful perianal condition, e.g., anal fissure)
Anal sphincter pressure during voluntary squeeze is minimally higher than tone at rest
Perineum descends <1 cm or >4 cm during attempts to simulate strain during defecation
Puborectalis muscle palpable through posterior rectal wall is tender
Palpable mucosal prolapse during straining
"Defect" in anterior wall of the rectum, suggestive of rectocele
ANORECTAL MANOMETRY AND BALLOON EXPULSION (WITH PATIENT IN LEFT LATERAL POSITION)
Average anal sphincter resting tone >80 cm H_2O or squeeze pressure >240 cm H_2O
Failure of balloon expulsion despite addition of 200 g weight
ABDOMINO-PELVIC RADIOGRAPH
Rectal gas area >9 cm^2

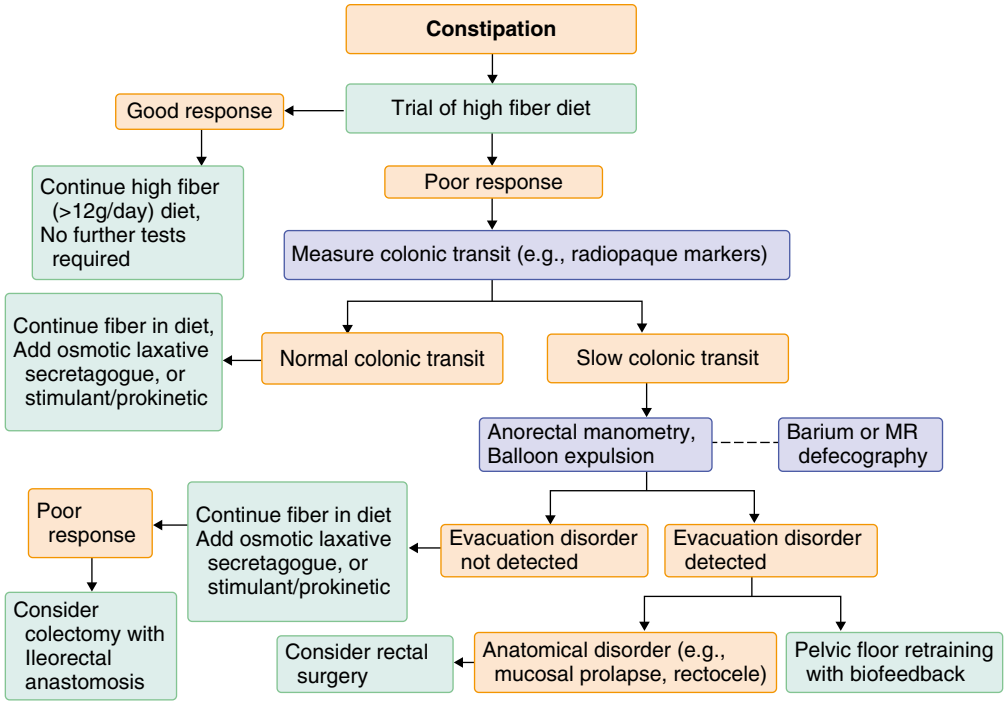


FIGURE 122-3. Algorithm in the management of constipation.

TREATMENT

The average daily fiber intake is around 12 g/day. In patients with normal-transit constipation, 20 to 30 g/day is effective to relieve constipation. In patients with slow-transit constipation, drug-induced constipation, or evacuation disorders, however, supplementation of 30 g of fiber per day does not result in any improvement in constipation. A second step is to add an osmotic laxative, such as a magnesium salt[A7] or polyethylene glycol solution, to enhance the retention of fluid within the lumen by osmotic forces, to increase fluidity, and to facilitate aboral transport of colonic contents. If these measures do not suffice, a prokinetic or stimulant agent,[11] such as bisacodyl (5 to 10 mg every 1 to 2 days) may be added (Table 122-3).[A8]

In more difficult-to-treat cases, prucalopride (1 to 2 mg daily) accelerates colonic transit and is beneficial in chronic constipation.[A9] Other pharmacologic approaches include lubiprostone (24 μg twice daily); linaclotide (72 μg, 145 μg, or 290 μg daily), or plecanatide (3 mg). These drugs as well as naloxegol (a peripheral μ-opioid antagonist at 12.5 or 25 mg daily), methylnaltrexone (0.15 mg/kg subcutaneously every other day for 2 weeks or 450 mg/day orally), naldemedine (0.2 mg daily), and the combination of oxycodone with naloxone (the latter displaces oxycodone from μ-opioid receptors in the gut) are effective in patients with opiate-induced constipation as a complication of advanced illness or noncancer pain.[A10]

When these approaches do not work, the patient should be reassessed to exclude an evacuation disorder (Chapter 131). For evacuation disorders, a biofeedback treatment program with muscle relaxation of the anal sphincters and pelvic floor results in a 70% or greater cure rate for the constipation.

Surgical Therapy

In patients whose constipation is not associated with an evacuation disorder and does not respond to aggressive medical therapies (including combinations described earlier), laparoscopic colectomy with ileorectostomy is effective in relieving constipation.

TABLE 122-3 TREATMENTS FOR CHRONIC CONSTIPATION

IDIOPATHIC CONSTIPATION
Bulk Agents
Psyllium (10 g daily), methylcellulose, calcium polycarbophil, wheat dextrin
Nonabsorbed Substances
PEG 3350 (17 g daily) Lactulose (20 g daily) Magnesium hydroxide (1 g daily)
Stimulants
Bisacodyl (5-10 mg daily) Senna (8.6 mg, 2 to 4 tabs daily) Prucalopride (1-2 mg daily)
Secretory Drugs
Lubiprostone (24 μg twice daily)* Linaclotide (72 μg, 145 μg, or 290 μg daily) Plecanatide (3 mg daily)
OPIOID-INDUCED CONSTIPATION
Opioid Receptor Antagonists
Naloxegol (12.5-25 mg daily) Naloxone/oxycodone (20 mg/40 mg) Methylnaltrexone (0.15 mg/kg subcutaneously every other day for 2 weeks or 450 mg orally per day) Naldemedine (0.2 mg daily)

*Also indicated for opioid-induced constipation.
PEG 3350 = polyethylene glycol-electrolyte.

HIRSCHSPRUNG DISEASE

DEFINITION

Hirschsprung disease occurs in 1 in 5000 live births. It is characterized by a localized segment of narrowing of the distal colon as a result of failure of local development of intrinsic nerves in the myenteric plexus.[12]

PATHOBIOLOGY

A relative deficiency of *KIT*-positive interstitial cells of Cajal has been reported in Hirschsprung disease and chronic intestinal pseudo-obstruction. The majority of familial and sporadic Hirschsprung disease is associated with *RET* oncogene mutations, but mutations in *EDNRB, GDNF*, and *EDN3* have been reported as well. Hirschsprung disease is well characterized histologically by the absence of ganglion cells in the myenteric and submucosal plexus and the presence of hypertrophied nerve trunks in the space normally occupied by the ganglion cells. In the muscle layers of the colon involved with Hirschsprung disease, deficiency of nerve growth factor receptors also contributes to the dysfunction. The narrowing and failure of relaxation in the aganglionic segment are thought to be due to the lack of neurons containing nitric oxide synthase.

CLINICAL MANIFESTATIONS

Hirschsprung disease is usually diagnosed at birth because of failure to pass meconium or the presence of megacolon, although it may be identified in

childhood as a result of fecal retention, constipation, or abdominal distention. Onset of symptoms or diagnosis after the age of 10 years is rare.

DIAGNOSIS

Diagnosis is based on the typical focal narrowing of the colon, the absence of the rectoanal inhibitory reflex (relaxation of anal sphincter pressure at rest during distention of a balloon in the rectum depends on natural preservation and maturation of intrinsic nerves in the distal bowel), and a deep rectal biopsy specimen showing absence of submucosal neurons with hypertrophied nerve trunks.

TREATMENT

Treatment involves excision of the affected bowel segment or a pull-through procedure by which normal bowel is anastomosed to the cuff of the lower rectum, just above the anal sphincters.

123 IRRITABLE BOWEL AND FUNCTIONAL UPPER GASTROINTESTINAL SYNDROMES

LIN CHANG

Functional gastrointestinal disorders are a spectrum of chronic gastrointestinal disorders that are characterized by specific symptoms depending on the region that is involved.[1] Functional gastrointestinal disorders have been traditionally known to be syndromes without a structural or biochemical basis to explain their clinical features. However, alterations in the bidirectional communication between the brain and the gut are increasingly being implicated in their motility disturbances, visceral hypersensitivity, altered mucosal and immune function, altered gut microbiota, and altered central nervous system (CNS) processing, all of which may vary among individuals or even in the same individual over time. As a result, these conditions are now referred to as disorders of gut-brain interaction.

The most current and widely used classification system is the Rome IV diagnostic criteria, which has defined a number of functional gastrointestinal disorders, by far the most common of which are irritable bowel syndrome, functional dyspepsia, and functional heartburn. Based on these criteria, the worldwide prevalence of functional gastrointestinal disorders is estimated to be as high as 40%.[2]

IRRITABLE BOWEL SYNDROME

DEFINITION

Irritable bowel syndrome is characterized by chronic or recurrent abdominal pain associated with alterations in stool form and/or frequency (i.e., diarrhea and/or constipation). Irritable bowel syndrome, which is frequently diagnosed in primary care and referral practices, is a functional bowel disorder attributable to the middle or lower gastrointestinal tract. It also includes functional constipation (also known as chronic idiopathic constipation), functional diarrhea, and functional abdominal bloating/distention. Functional bowel disorders are a spectrum of syndromes that can transition to another over time because of their natural history, response to therapy, or both. For example, a patient may initially present with symptoms of functional constipation, such as hard and infrequent stools and straining without abdominal pain, but later develop abdominal pain associated with constipation and meet criteria for irritable bowel syndrome with predominant constipation.

EPIDEMIOLOGY

Irritable bowel syndrome is seen worldwide, but its prevalence varies based on geographic region, diagnostic criteria, and population studied. In the United States, Canada, and the United Kingdom, the estimated prevalence of irritable bowel syndrome based on the current Rome IV diagnostic criteria is 4.6%,[3] but the prevalence was higher using older, less restrictive criteria. In a global epidemiology study in 33 countries on six continents, the worldwide prevalence of irritable bowel syndrome was 4.1% based upon Rome IV criteria, but it was more common in women (5.2%) than in men (2.9%).[4] Using predominantly a physician's diagnosis of irritable bowel syndrome, the estimated incidence is about 38 per 10,000 person-years.

The three main subtypes of irritable bowel syndrome are based upon the usual stool form (i.e., irritable bowel syndrome with predominant constipation, irritable bowel syndrome with predominant diarrhea, and irritable bowel syndrome with mixed bowel habits). Patients who have irritable bowel syndrome but whose stool form pattern does not meet criteria for one of these three bowel habit subtypes is defined as having irritable bowel syndrome unclassified. Using Rome IV criteria, irritable bowel syndrome with predominant diarrhea and irritable bowel syndrome with mixed bowel habits each accounted for 35 to 40% of irritable bowel patients, irritable bowel syndrome with predominant constipation accounted for about 25%, and less than 5% were irritable bowel syndrome unclassified. However, the subtypes of irritable syndrome can transition over time in the same patient.

Up to 50% of individuals with symptoms of irritable bowel syndrome do not seek health care, but functional bowel disorders are nevertheless estimated to generate about 4.4 million annual physician visits.[5] When they do seek health care, patients with irritable bowel syndrome are more likely to have diagnostic tests and abdominal or pelvic surgeries compared with other patients, although many of these interventions are neither necessary nor recommended by professional society guidelines. Health care–seeking about irritable bowel syndrome symptoms is associated with older age, a higher level of concern about bowel function, bloating, and a greater impact on social activities. Patients with irritable bowel syndrome also have increased health care visits and costs associated with nongastrointestinal symptoms as well as a significant comorbidity from other somatic and psychological disorders. In addition to increased direct medical expenses, irritable bowel syndrome is associated with absenteeism from work and impaired work productivity.

PATHOBIOLOGY

Irritable bowel syndrome is a multifactorial disorder that results from a dysregulation of gut-brain interactions, thereby resulting in alterations of intestinal motility, visceral perception, autonomic nervous system function, stress responsiveness, mucosal and immune function, gut microbiota, and CNS modulation of viscerosensory input. Risk factors that increase the risk of developing irritable bowel syndrome and of triggering symptomatic flares include genetic predisposition, environmental factors (e.g., adverse childhood experiences and infectious gastroenteritis), food, and stress.

Familial and Genetic Factors

Irritable bowel syndrome clusters in families, and the odds of having affected relatives are 1.75-fold to 2.75-fold higher than among relatives of unaffected persons. However, compelling evidence shows that environmental factors also

childhood as a result of fecal retention, constipation, or abdominal distention. Onset of symptoms or diagnosis after the age of 10 years is rare.

DIAGNOSIS

Diagnosis is based on the typical focal narrowing of the colon, the absence of the rectoanal inhibitory reflex (relaxation of anal sphincter pressure at rest during distention of a balloon in the rectum depends on natural preservation and maturation of intrinsic nerves in the distal bowel), and a deep rectal biopsy specimen showing absence of submucosal neurons with hypertrophied nerve trunks.

TREATMENT

Treatment involves excision of the affected bowel segment or a pull-through procedure by which normal bowel is anastomosed to the cuff of the lower rectum, just above the anal sphincters.

Irritable bowel syndrome clusters in families, and the odds of having affected relatives are 1.75-fold to 2.75-fold higher than among relatives of unaffected persons. However, compelling evidence shows that environmental factors also

ABSTRACT

Functional gastrointestinal disorders comprise a spectrum of chronic gastrointestinal disorders that are prevalent worldwide. These disorders, which are related to bidirectional communication between the brain and the gut, can cause a wide range of symptoms: motility disturbances, visceral hypersensitivity, altered mucosal and immune function, altered gut microbiota, and altered central nervous system processing. From a clinician's perspective, the conditions include irritable bowel syndrome, functional dyspepsia, and functional heartburn, each of which has its own epidemiology, pathobiology, clinical manifestations, and treatments.

KEYWORDS

irritable bowel syndrome
functional dyspepsia
functional heartburn

influence the presence of irritable bowel syndrome, potentially to a greater degree than genetic heritability.

Large genome-wide association studies have found that polymorphisms on chromosome 9q31.2 are significantly more common in women but not men with irritable bowel syndrome compared with controls. Another large study found six independent susceptibility loci. Four of these six loci also have been associated with mood and anxiety disorders and/or genes expressed in the nervous system, thereby suggesting a key role for neuronal pathways within the brain-gut axis.

About 2 to 3% of patients with irritable bowel syndrome have rare genetic variants that may result in a functional abnormality at the level of the gastrointestinal tract.[6] These variants include functional polymorphisms of the voltage-gated channel $Na_v1.5$ (*SCN5A*) causing a channelopathy and potentially a loss of function in voltage dependence or mechanosensitivity and sucrase-isomaltase gene variants indicative of reduced levels of a disaccharide enzyme that may protect against chronic diarrhea. Other associations include a homozygous short allele of the serotonin transporter gene (*5-HTTLPR*) and polymorphisms in the genes that encode for serotonin type 3 receptors. However, all these findings must be interpreted cautiously until treatment studies validate their causality.

Postinfection Irritable Bowel Syndrome

The strongest risk factor for irritable bowel syndrome, especially irritable bowel syndrome with predominant diarrhea, is an acute gastrointestinal infection, which increases the risk of irritable bowel syndrome at 12 months by about four-fold regardless of whether the infection was bacterial, protozoal/parasitic, or viral in nature.[7] The risk is especially increased in individuals who are younger, female, or have a history of gastroesophageal reflux disease, dyspepsia, more severe diarrheal illness, anxiety, or depression.

Stressful Life Events

An important risk factor for the development and exacerbations of irritable bowel syndrome is stressful life events.[8] Implicated stressful life events include physical, sexual, or emotional/verbal abuse; history of severe illness; death or mental illness of a parent; incarceration of an individual in the household; and exposure to wartime conditions.

Increased Visceral Perception

The perception of gut stimuli is influenced by the integrated activity and communication among the gut lumen, mucosa, submucosa, enteric nervous system, and CNS.[9,10] Stimuli within the gut (e.g., contractile activity, distension) are detected and transmitted via primary afferent nerves that project to the dorsal horn of the spinal cord, with neurons located in the dorsal root ganglia. This sensory input ascends along the dorsal column and then to the contralateral ventroposterolateral nucleus of the thalamus, brainstem nuclei, and cortical regions. Visceral stimuli are assessed by the salience network and insula, which assess the importance of these signals and whether they are perceived as normal gut sensations, abdominal discomfort, or pain. The two main brain output systems to the gut are the autonomic nervous system and descending pain modulatory pathways. The autonomic nervous system regulates and modulates gut motility, immune responses, and sensation, whereas the pain facilitatory and inhibitory pathways regulate pain sensitivity at the level of the spinal cord's dorsal neurons, which receive afferent visceral input.

Increased perception of visceral stimuli and symptoms of irritable bowel syndrome develop from either greater sensitivity of visceral afferent pathways (peripheral sensitization) or central amplification of visceral afferent input at the level of the brain and spinal cord (central sensitization). Peripheral sensitization of sensory nerves occurs when nerves are activated by mediators released from immune and/or epithelial cells, such as occurs in inflammation or infection.

Patients with irritable bowel syndrome have overall lowered thresholds for pain or discomfort when exposed to rectal or colonic balloon distension (i.e., visceral hypersensitivity) compared with healthy individuals. However, this hypersensitivity typically is seen only in a subset of patients with irritable bowel syndrome and only modestly correlates with the severity of their symptoms.

Altered CNS Processing and Modulation

Multimodal brain imaging studies have demonstrated both structural and functional alterations in task-related brain networks in patients with irritable bowel syndrome. Neuroimaging findings associated with irritable bowel syndrome include greater volume and cortical thickness of the sensorimotor cortex that correlates with the severity of symptoms; alterations in resting state functional connectivity of the anterior insula and amygdala; greater engagement of the salience detection and emotional arousal networks in response to rectal balloon distension; decreased corticolimbic inhibitory feedback; and increased activation of the central autonomic network that regulates autonomic nervous system response. These findings support the role of the CNS and brain-gut interactions in irritable bowel syndrome pathophysiology.

Gut Transit and Motility

Alterations in small intestinal and colonic motility in irritable bowel syndrome include increased colonic motility during fasting, in the postprandial state, and with psychological or physical stressors. A subset of patients with irritable bowel syndrome with predominant diarrhea have a more rapid intestinal transit time that can be induced by psychological and physical stress. About 50% of patients with irritable bowel syndrome with predominant diarrhea have accelerated colon transit times.

Peripheral Gastrointestinal Factors

The gut is composed of a network of cells and mediators that affect gastrointestinal function and contribute to the symptoms of irritable bowel syndrome. This peripheral gut network can communicate with the brain via multiple routes, including neural, endocrine, and inflammatory pathways. The brain-to-gut communication is mainly mediated via the autonomic nervous system pathways to the gut.

Patients with irritable bowel syndrome have an increase in colonic mucosal nerves that express substance P, transient receptor potential vanilloid type 1 cannabinoid, and protease-activated receptors. Some patients with irritable bowel syndrome have altered mucosal barrier function and decreased expression of tight junction proteins in the jejunum and colon. Increased permeability has been associated with greater severity of abdominal pain, visceral hyperalgesia, and altered bowel habits. Immune activation involving mast cells and T lymphocytes may mediate dysfunction of the intestinal barrier, abnormalities in motility, and visceral pain in irritable bowel syndromes.

Increased immune activation has been demonstrated in the colonic mucosa of patients with irritable bowel syndromes, including increased numbers of mast cells adjacent to sensory neurons in the colonic mucosa. Mast cells release mediators such as histamine that may activate afferent nerves and result in peripheral sensitization and increased abdominal pain. Disruption of the mucosal barrier associated with changes in expression of tight junction proteins in response to food allergens suggests that patients with irritable bowel syndrome have nonclassical food allergies that may contribute to postprandial symptoms.

The fecal microbiota of patients with irritable bowel syndrome often shows an abundance of Enterobacteriaceae, family Lactobacillaceae, and genus *Bacteroides*, as well as decreased amount of Clostridiales I, genus *Faecalibacterium*, and genus *Bifidobacterium*.[11] These findings have biologic plausibility because the microbes that are increased in irritable bowel syndrome produce organic acids (e.g., lactic acid), reduce mucosal glycoproteins, or contain pathogenic bacteria. The microbes that are decreased in irritable bowel syndrome produce butyrate, which is an energy source for epithelial cells, have anti-inflammatory effects, and are thought to maintain gut health. About 25% patients with irritable bowel syndrome have bile acid diarrhea.

Dysregulated Stress Responsiveness

Growing evidence supports that irritable bowel syndrome is a stress-sensitive disorder. The stress of the hypothalamic-pituitary-adrenal axis is dysregulated in response to experimental stress or hormone challenge in patients with irritable bowel syndrome compared with healthy controls. This stress can increase visceral sensitivity, gut motility and permeability, and immune responses.

CLINICAL MANIFESTATIONS

The hallmark feature of irritable bowel syndrome is chronic or recurrent pain that is associated with diarrhea, constipation, or both.[12] Postprandial symptoms, which are reported by about two thirds of patients, include abdominal pain, bloating, and flatulence. Meal-related symptoms are often triggered by larger meals, foods rich in carbohydrates or fats, coffee, alcohol, and spicy foods.

Women with irritable bowel syndrome are more likely to have constipation and less likely to have diarrhea compared with men. Symptoms can worsen just prior to menses, when estrogen and progesterone levels decline. Irritable bowel syndrome is also more commonly diagnosed in patients under age 50 years.

Extraintestinal symptoms and conditions that may coexist with irritable bowel syndrome include temporomandibular joint disorder, interstitial cystitis/painful bladder syndrome, dysmenorrhea (Chapter 218), migraine headaches (Chapter 367), fibromyalgia (Chapter 253), chronic fatigue syndrome (Chapter 253), anxiety (Chapter 362), depression (Chapter 362), and somatization. Patients with irritable bowel syndrome also are more likely to report subjective sleep disturbances (Chapter 374), especially when they have more severe gastrointestinal symptoms.

In about one third of patients, irritable bowel syndrome can coexist with other functional gastrointestinal disorders, such as functional dyspepsia and functional heartburn.[13] Most patients note a decreased quality of life because of gastrointestinal symptoms, abdominal pain, and psychological stress. For example, patients often report difficulty concentrating; feeling self-conscious; and having a fear of leaving the house, traveling, or being in places without bathrooms.

TABLE 123-1 DIAGNOSTIC CRITERIA FOR IRRITABLE BOWEL SYNDROME

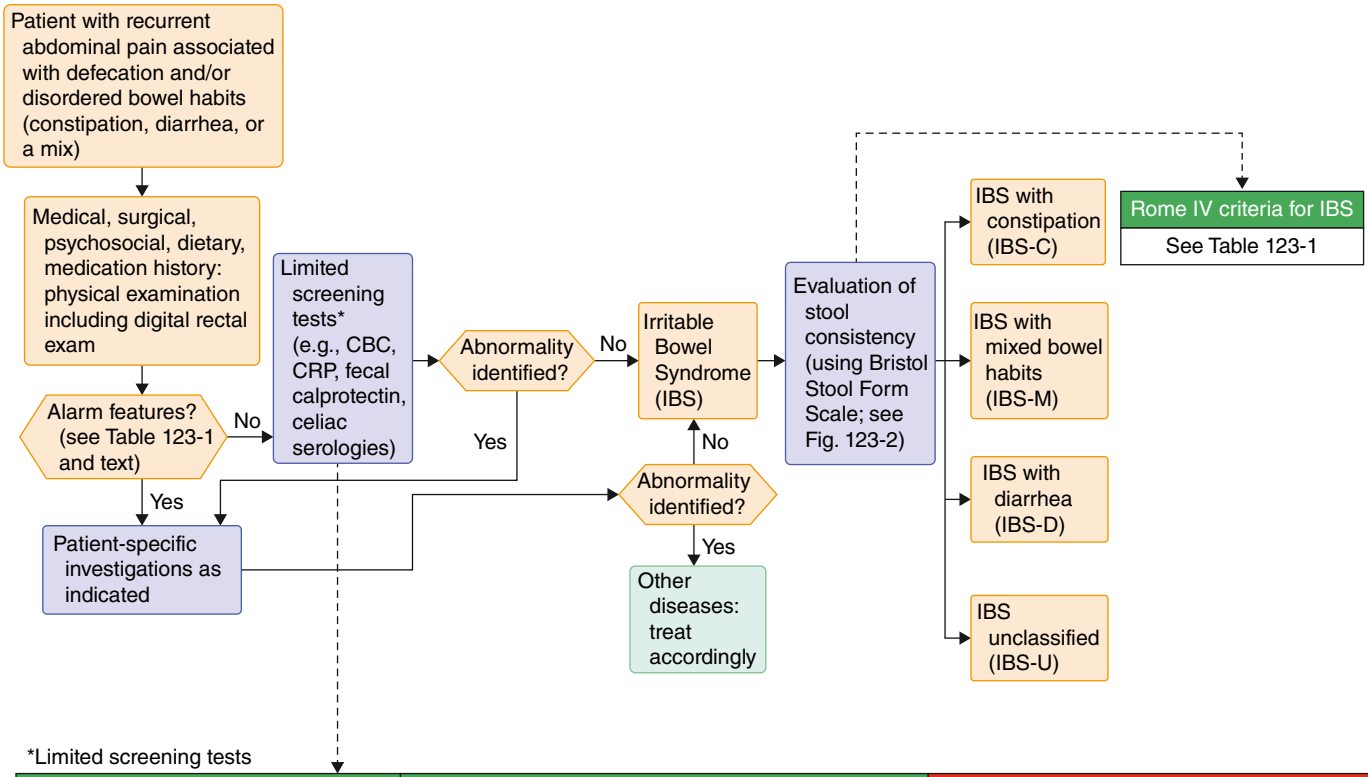
1. Symptoms:
   - A. Recurrent abdominal pain (at least 1 day per week, on average, in the last 3 months) with symptoms for at least 6 months and associated with two or more of the following:
     - Related to defecation
     - Associated with a change in frequency of stool
     - Associated with a change in form (appearance) of stool
   - B. Symptoms that cumulatively support the diagnosis of irritable bowel syndrome:
     - Abnormal stool frequency: ≤3 bowel movements per week or >3 bowel movements per day
     - Abnormal stool form: lumpy/hard stool or loose/watery stool
     - Defecation straining
     - Urgency
     - Feeling of incomplete bowel movement
     - Passing mucus
     - Bloating or feeling of abdominal distention
2. Absence of alarm symptoms, such as:
   - New-onset symptoms at age ≥50 years
   - Unintentional weight loss
   - Hematochezia or melena not related to hemorrhoids
   - Nocturnal diarrhea
   - Anemia
   - Palpable abdominal mass or lymphadenopathy
   - Family history of colorectal cancer, inflammatory bowel disease, or celiac disease

Adapted from Mearin F, Lacy BE, Chang L, et al. Bowel disorders. *Gastroenterology*. 2016;150:1393-1407 and Mayer EA. Functional gastrointestinal disorders: irritable bowel syndrome, dyspepsia, esophageal chest pain, and heartburn. In: Goldman L, Schafer A, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Elsevier; 2020:852-859.

DIAGNOSIS

Symptom-Based Criteria

A systematic approach with limited diagnostic testing typically is sufficient to make the diagnosis of irritable bowel syndrome (Fig. 123-1), using the symptom-based Rome IV criteria (Table 123-1).[14] The Rome criteria also can classify irritable bowel syndrome into subtypes based on the most frequent



*Limited screening tests

Recommended	IBS population	Not recommended
Positive diagnostic strategy vs. diagnosis of exclusion	All IBS	Routine stool testing
Celiac serologies	IBS-D	Routine colonoscopy <45 yrs
Fecal calprotectin/lactoferrin	IBS-D	Food allergy or insensitivities testing
C-reactive protein	IBS-D	Lactulose or glucose hydrogen breath testing
Bile acid diarrhea testing	IBS-D where bile acid diarrhea is suspected	
Giardia stool antigen	IBS-D if giardia is endemic	
Anorectal physiology testing	IBS with suspected pelvic floor dysfunction and/or refractory constipation	

FIGURE 123-1. Diagnostic algorithm for irritable bowel syndrome. The recommendations for limited diagnostic testing are summarized from society guidelines. Rome IV diagnostic criteria for irritable bowel syndrome shown. CBC = complete blood count; CRP = C-reactive protein; IBS = irritable bowel syndrome. (From Chang L. How to Approach a Patient with Difficult to Treat IBS. Invited review, Gastroenterology, Mentoring, Education and Training section. *Gastroenterology* 2021;161[4]:1092-1098.)

stool form (Fig. 123-2) at a time when the patient is not taking medications to treat diarrhea or constipation.

The differential diagnosis for symptoms consistent with irritable bowel syndrome includes celiac disease (Chapter 126), inflammatory bowel disease (i.e., ulcerative colitis and Crohn disease; Chapter 127), microscopic or collagenous colitis (Chapter 126), colon cancer (Chapter 127), bile acid diarrhea (Chapter 126), and food intolerances. Alarm features or "red flags" that suggest these alternative diagnoses include the new onset of symptoms after age 50 years; rectal bleeding; weight loss; iron deficiency anemia; nocturnal diarrhea; and a family history of colon cancer, inflammatory bowel disease, or celiac disease. The presence of an alarm feature should prompt a targeted diagnostic evaluation of the clinical symptoms. However, testing often does not reveal another cause of the patient's symptoms, and many patients with red flag symptoms are ultimately diagnosed with irritable bowel syndrome.

Diagnostic Testing

Since irritable bowel syndrome is a diagnosis of exclusion, diagnostic testing (Fig. 123-1; Table 123-2) is targeted to exclude other potential causes of the patient's symptoms.[15] Guidelines recommend a serum IgA anti-tissue transglutaminase to assess for celiac disease, with a duodenal biopsy if the serologic test is positive. Since IgA deficiency is not uncommon in the general population, however, this test can be falsely negative and should be combined with a total IgA level. In IgA-deficient patients, a serum IgG anti-tissue transglutaminase level and/or an IgG deaminated gliadin peptide level should be used to screen for celiac disease.

Most guidelines do not recommend a routine colonoscopy in patients who are under the age of 45 to 50 years without alarm features.[16] If a colonoscopy is performed, random colon biopsies should be taken in patients with diarrheal symptoms to examine for microscopic or collagenous colitis.

TABLE 123-2 DIAGNOSTIC TESTING IN THE EVALUATION OF SUSPECTED IRRITABLE BOWEL SYNDROME

1.	Generally recommended tests
	Complete blood count
	C-reactive protein
	Fecal calprotectin/lactoferrin
	Celiac serologies (IgA anti-tissue transglutaminase level and IgA level)
	Colonoscopy in new-onset irritable bowel syndrome symptoms at age ≥50 years
	Stool *Giardia* test (antigen or PCR) in endemic areas
	Stool testing for bacteria and parasites if a relevant travel history
2.	Tests generally NOT recommended
	Colonoscopy if age <50 years without alarm features
	Stool studies for infection without a history of travel to high-risk regions
	Food allergy or intolerance testing
	Lactose or glucose hydrogen breath tests

Ig = immunoglobulin; PCR = polymerase chain reaction.

TREATMENT

Overall Approach

A prompt and clear diagnosis can facilitate appropriate treatment in a timely manner. The patient's acceptance of the diagnosis, ability to recognize fluctuating symptom patterns, and knowledge regarding how to prevent flares and treat symptoms when they arise aids in an increased perceived sense of control over them. Providing educational resources validates irritable bowel syndrome as a real condition and empowers patients to learn how to manage their symptoms.

Treatment should consider the most bothersome symptoms, the severity of symptoms, the impact of symptoms on quality of life, the presence of comorbid conditions, psychological impact, prior treatment history, and the patient's preferences.[17–19] A clinician-patient relationship founded on effective communication is of utmost importance in providing effective care and improving patient outcomes.[20]

Mild symptoms of irritable bowel syndrome have little or no impact on the patient's quality of life and may require nothing more than a positive diagnosis of irritable bowel syndrome, education, reassurance, dietary advice, and over-the-counter medications. Moderate symptoms that affect daily activities commonly also require pharmacotherapy. Severe symptoms, which have a significant impact on quality of life, coexist with psychological distress or extraintestinal symptoms, or have failed to respond to prior treatments, require an integrated approach, usually with both pharmacologic and behavioral treatment.[21] Strategies to prevent flares include avoidance of dietary triggers and stressors that can exacerbate symptoms. For irritable bowel syndrome with predominant diarrhea (Fig. 123-2) and irritable bowel syndrome with predominant constipation (Fig. 123-3), treatments typically focus on interventions to normalize bowel habits and reduce abdominal pain.

Therapies for Multiple Types of Irritable Bowel Syndrome

Diet

Dietary treatment is a first-line treatment for irritable bowel syndrome. A 1- to 2-week food and symptom diary can help determine if symptoms are triggered by specific foods that should be avoided.[22] A diet that is low in fermentable oligosaccharides, disaccharides, monosaccharides, and polyols (FODMAPs) can improve global irritable bowel symptoms, especially in patients with predominant diarrhea, and also can reduce abdominal pain, abdominal bloating, and abnormal bowel habits.[A1,A2] This diet is best explained and supervised by a trained dietitian, who can also guide the gradual reintroduction of foods if the strict elimination diet is succesful. By comparison, a gluten-free diet is of less clear benefit, though it may be tried in patients in whom gluten products consistently exacerbate symptoms.

Soluble Fiber

Fiber supplementation (up to 25 to 35 g of psyllium fiber daily) can be beneficial, especially in patients who have predominant constipation, and can be tried in other patients as well. However, fiber may cause abdominal discomfort and gas, so lower doses should be used initially, followed by a gradual increase.[A3] Guidelines specifically recommend soluble (e.g., psyllium) but not insoluble fiber (e.g., wheat bran). Although psyllium is less likely to improve overall symptoms compared with medications, it is also less likely to cause adverse events.

Medications

Medications can help relieve the spasms, constipation, diarrhea, and pain of irritable bowel syndrome (Table 123-3).[23]

Antispasmodics and Peppermint Oil

Antispasmodic agents, which exert their potential benefits via a direct effect on intestinal smooth muscle or via anticholinergic or antimuscarinic properties, are generally efficacious for improving symptoms of irritable bowel syndrome.[24] The most common adverse events are dry mouth, dizziness, and blurred vision. Peppermint oil also is useful to relieve abdominal pain and global symptoms of irritable bowel syndrome.

Probiotics

Combination probiotic products can reduce global symptoms of irritable bowel syndrome by about 20%,[25] but data from randomized trials are mixed and so are the recommendations of various professional societies. Probiotics may be most useful in patients who have persistent bloating.

Central Brain-Gut Neuromodulators

Centrally acting brain-gut neuromodulators can be used to treat irritable bowel symptoms and not necessarily anxiety or depression. These agents, which

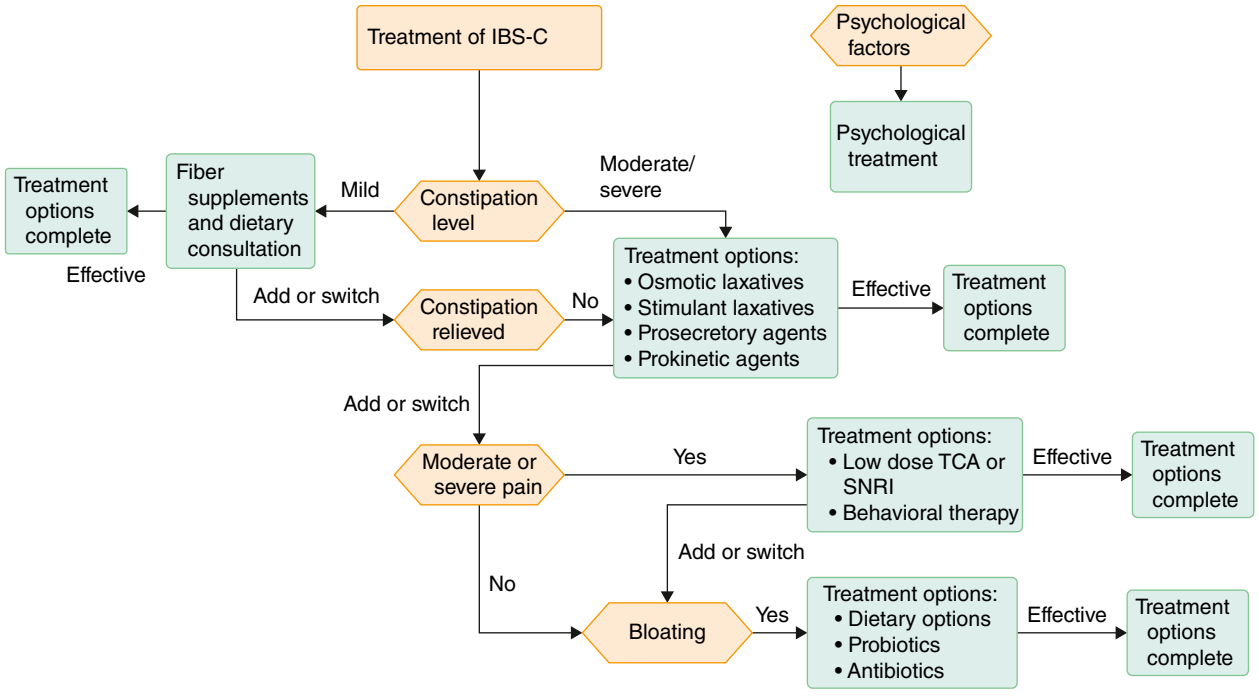

FIGURE 123-3. **Treatment algorithm for irritable bowel syndrome with constipation predominance (IBS-C).** SNRI = serotonin-norepinephrine reuptake inhibitor; TCA = tricyclic antidepressants. (Adapted with permission obtained from the Rome Foundation.)

TABLE 123-3 EVIDENCE-BASED ORAL TREATMENTS FOR IRRITABLE BOWEL SYNDROME

SYMPTOMS AND MEDICATION	DOSE	COMMON OR SERIOUS SIDE EFFECTS
PAIN AND SPASM		
Antispasmodics		
Peppermint oil	1 to 2 capsules three times daily or as needed	Heartburn, nausea, vomiting
Hyoscyamine	0.125 mg three to four times daily or as needed	Dry mouth, blurred vision, dizziness, constipation
Dicyclomine	10 mg three to four times daily or as needed	Dry mouth, blurred vision, dizziness
Central Neuromodulators		
Amitriptyline (TCA)	10 to 25 mg at bedtime, can increase gradually up to 100 mg at bedtime	Sedation, dry mouth, constipation
Desipramine (TCA)	10 to 25 mg at bedtime, can increase gradually up to 100 mg at bedtime	Dry mouth, dizziness
Nortriptyline (TCA)	10 to 25 mg at bedtime, can increase gradually up to 100 mg at bedtime	
Citalopram (SSRI)	5 to 20 mg daily	Sexual dysfunction, headache, nausea, sedation, insomnia, dizziness, sweating, withdrawal symptoms
Fluoxetine (SSRI)	20 to 40 mg daily	
Paroxetine (SSRI)	10 to 50 mg daily	
Sertraline (SSRI)	25 to 150 mg daily	
CONSTIPATION		
Laxatives and Secretory Modulators		
Polyethylene glycol 3350	17 g in 125 mL water daily	Nausea, bloating
Lactulose	10 g daily, can increase to 20 to 40 g daily	Diarrhea, bloating, cramping
Lubiprostone	8 µg twice daily	Nausea, diarrhea, headache, abdominal pain and discomfort
Linaclotide	290 µg daily	Diarrhea, abdominal pain, flatulence
Plecanatide	3 mg daily	Diarrhea, flatulence
Tenapanor	50 mg twice daily	Diarrhea, abdominal distension, flatulence
Prokinetic		
Tegaserod (5-HT4 agonist)	6 mg twice daily in women under age 65 years without a history of cardiovascular ischemic events	Diarrhea, headache, nausea, flatulence
DIARRHEA		
Opioid Receptor Agents		
Loperamide	2 mg, can increase up to 4 mg four times daily	Constipation
Eluxadoline	75 to 100 mg twice daily	Constipation, nausea, sphincter of Oddi dysfunction, pancreatitis
5HT3 Antagonists		
Alosetron	0.5 to 1.0 mg twice daily	Constipation, ischemic colitis (rare)

TABLE 123-3 EVIDENCE-BASED TREATMENTS FOR IRRITABLE BOWEL SYNDROME—cont'd

SYMPTOMS AND MEDICATION	DOSE	COMMON OR SERIOUS SIDE EFFECTS
Bile Acid Sequestrants		
Bile acid sequestrants (cholestyramine, colesevelam)	Cholestyramine: start at 2 to 4 g/day and titrate up to 24 g/day to response Colesevelam: two 625-mg tablets twice daily Colestipol: 1 g twice daily, can increase by 1 g/day every other day up to 16 g daily depending on response	Abdominal cramps, constipation
BLOATING		
Antibiotics		
Rifaximin	550 mg three times daily for 14 days	Abdominal pain, nausea
Probiotics		
Bifidobacterium infantis 35624	1 capsule per day	None
Activia	1 container twice daily	None

SSRI = selective serotonin reuptake inhibitor; TCA = tricyclic antidepressant.

Adapted from Mayer EA. Functional gastrointestinal disorders: irritable bowel syndrome, dyspepsia, esophageal chest pain, and heartburn. In: Goldman L, Schafer A, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Elsevier; 2020:852-859.

include tricyclic antidepressants, selective serotonin reuptake inhibitors, and serotonin-norepinephrine reuptake inhibitors (see Table 362-5), may decrease pain perception by modulating the CNS processing of visceral stimuli, enhancing descending pain inhibitory pathways, decreasing the firing of primary sensory afferent nerves, altering gastrointestinal transit, and treating comorbid psychological symptoms.

Pooled data suggest that tricyclic antidepressants (Table 362-5) can improve global symptoms of irritable bowel syndrome in about 35% of patients[A4] and may be especially useful for abdominal pain. Preferred formulations are desipramine or nortriptyline (10 to 25 mg at bedtime), which are less likely to cause sedation, constipation, and dry mouth.

Selective serotonin reuptake inhibitors appear to have a similar efficacy for improving global symptoms, with fewer side effects than tricyclic antidepressants, but they do not seem to be as efficacious for reducing abdominal pain. Serotonin-norepinephrine reuptake inhibitors also can reduce chronic pain, particularly in patients who cannot tolerate or take tricyclic antidepressants.

Pharmacotherapy for Irritable Bowel Syndrome with Predominant Constipation (See Fig.123-2)

Medications should be used in patients who have at least moderately severe symptoms despite dietary interventions and over-the-counter remedies.[26] Medications generally should be tried sequentially for 8 to 12 weeks since their maximal effects for reducing abdominal pain, discomfort, and bloating can require at least 6 to 8 weeks of therapy. Combination therapy has not been evaluated in randomized clinical trials but can be used in clinical practice if patients have a partial response to a single treatment.

Over-the-Counter Laxatives

Osmotic laxatives, such as polyethylene glycol, are commonly used, over-the-counter, relatively inexpensive agents that are safe and well tolerated in patients with irritable bowel syndrome with predominant constipation. Polyethylene glycol is efficacious for improving the frequency and form of stools but not for reducing abdominal pain or global symptoms. Side effects include abdominal pain, diarrhea, nausea, and flatulence, all of which occur in a dose-dependent manner.

Lubiprostone

Lubiprostone (8 μg twice daily), which is a peripherally acting chloride channel activator that increases intestinal chloride secretion, can improve symptoms of constipation, stool consistency, straining, abdominal pain, bloating, and discomfort in patients with irritable bowel syndrome with predominant constipation.[A5,A6] The most common side effects of lubiprostone are nausea, which may be reduced by taking the drug with meals, and diarrhea.

Linaclotide and Plecanatide

Linaclotide and plecanatide are minimally absorbed peptides that activate guanylate cyclase C receptors on the luminal side of the intestinal epithelium, increase levels of cyclic guanosine monophosphate, and result in enhanced luminal secretion of chloride and bicarbonate. Linaclotide also may decrease firing of visceral sensory nerves, thereby reducing abdominal pain. Linaclotide (290 μg daily) can reduce abdominal pain and increase spontaneous bowel movements.[A7] Plecanatide (3 mg daily) has similar benefits.[A8] The most common side effect of both of these agents is diarrhea, which may remit if lower doses are used.

Tenapanor

Tenapanor is a minimally absorbed, small molecule inhibitor of the gastrointestinal sodium/hydrogen exchanger isoform 3, which is a transporter that is involved in the reabsorption of sodium and water. Tenapanor (50 mg twice daily) is effective for treating constipation and abdominal pain,[A9] with diarrhea as its most common adverse event.

Pharmacologic Therapies for Irritable Bowel Syndrome with Predominant Diarrhea (See Fig. 123-4)

μ-Opioid Receptor Agonists

Loperamide, which is a peripheral opioid agonist, is efficacious in reducing the frequency of stools in patients who have irritable bowel syndrome with predominant diarrhea, but it does not improve global irritable bowel syndrome symptoms or abdominal pain.[27] Because of the lack of effect on global symptoms, loperamide is a first-line treatment predominately for patients with mild abdominal pain.

Eluxadoline (starting at 100 mg twice daily but reducing the dose to 75 mg twice daily if the higher dose is not tolerated) is a μ- and a κ-opioid receptor agonist and a δ-opioid receptor antagonist that is efficacious for reducing diarrhea and abdominal pain in patients with irritable bowel syndrome with predominant diarrhea.[A10] Contraindications include mild or moderate hepatic impairment, the lack of a gallbladder, known or suspected biliary duct obstruction, pancreatic disease, sphincter of Oddi dysfunction, and alcohol use disorder. The most common side effects are nausea and constipation.

Rifaximin

Rifaximin is a broad-spectrum, minimally absorbed antibiotic that is approved for the treatment of irritable bowel syndrome with diarrhea at a dose of 550 mg three times daily for 14 days.[A11] Subsequent retreatment with up to three courses of rifaximin can also be effective. Rifaximin is generally well tolerated, but the most common side effects are nausea and abdominal pain.

Alosetron

Alosteron is a 5-HT_3 receptor antagonist that influences the brain-gut axis to slow gastrointestinal transit and reduce visceral hypersensitivity. Because alosetron can cause ischemic colitis (rate of 1.1 per 1000 patient years) and serious complications of constipation (0.66 per 1000 patient years), it is available in the United States only under a risk evaluation and mitigation strategy under expert oversight for women with severe irritable bowel syndrome with predominant diarrhea who have failed traditional treatment.

Bile Acid Sequestrants

Some patients with irritable bowel syndrome with predominant diarrhea are thought to have bile acid diarrhea (Chapter 141), which can be confirmed by fecal bile acid levels. If confirmed, bile acid diarrhea can be treated with a bile acid sequestrant (see Table 123-3), but an empiric trial of a bile acid sequestrant also may be considered.

Psychological Interventions

Psychological therapies that reduce stress-sensitive symptoms of irritable bowel syndrome include standard and minimal contact cognitive-behavioral therapy, gut-directed hypnotherapy, relaxation training/therapy, psychotherapy, mindfulness meditation, stress management, and training in emotional awareness and expression.[A12] Cognitive-behavioral therapy aims to reduce maladaptive

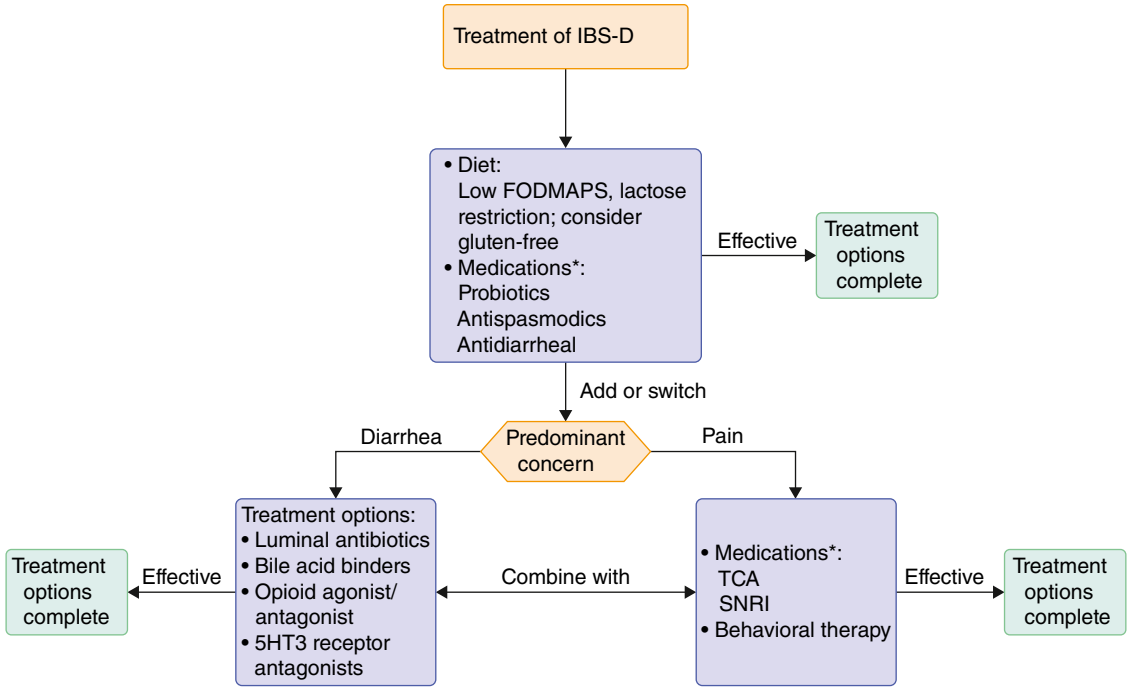

FIGURE 123-4. **Treatment algorithm for irritable bowel syndrome with diarrhea predominance (IBS-D).** *See Table 123-3. FODMAPS = fermentable oligosaccharides, disaccharides, monosaccharides, and polyols; SNRI = serotonin-norepinephrine reuptake inhibitor; TCA = tricyclic antidepressants. (Adapted with permission from the Rome Foundation.)

thoughts that can influence behaviors and emotional responses, thereby exacerbating physical symptoms. Gut-directed hypnotherapy focuses on relaxation and repeated suggestions focused on improving gut-brain communication and on reinterpretating visceral signals arising from the gut during routine activities such as digestion as being natural, comfortable, and unimportant. For patients with persistent bothersome symptoms despite standard care, an integrated care model of physicians working synergistically with dietitians, health psychologists, and even pelvic floor therapists, in person or using Internet-based programs, can improve quality of life.[28] Compared with usual care and education, psychological therapies are associated with about a 30% reduction of the symptoms of irritable bowel syndrome and are recommended for selected patients who understand the role of brain-gut behavioral therapy for irritable bowel syndrome, have the time and motivation to make behavioral changes, and experience avoidance and significant distress regarding symptoms and/or respond poorly to other therapies (see Figs. 123-2 and 123-3).

TABLE 123-4 ROME IV DIAGNOSTIC CRITERIA FOR FUNCTIONAL DYSPEPSIA*

1. One or more of the following bothersome symptoms:
   - Postprandial fullness
   - Early satiation
   - Epigastric pain
   - Epigastric burning

and

2. No evidence of structural disease (including at upper endoscopy) that is likely to explain the symptoms

*The criteria must be fulfilled for the last 3 months with onset of symptoms at least 6 months before diagnosis.

Adapted from Stanghellini V, Chan FK, Hasler WL, et al. Gastroduodenal disorders. *Gastroenterology*. 2016;150:1380-1392.

PROGNOSIS

About 30 to 45% of patients with irritable bowel syndrome have persistent symptoms for up to 12 years. Psychological symptoms, particularly anxiety and a negative perception of stressful life events, are associated with persistent symptoms. Other risk factors for persistent symptoms include female gender, younger age, and prior anxiety or depression.

FUNCTIONAL DYSPEPSIA

DEFINITION AND EPIDEMIOLOGY

Functional dyspepsia is the most common functional gastrointestinal disorder, with a prevalence of about 7%. The Rome IV diagnostic criteria for functional dyspepsia comprises bothersome (i.e., impacts usual activities) postprandial fullness, early satiety, epigastric pain, and/or epigastric burning in the absence of structural disease to explain these symptoms (Table 123-4). Heartburn, which is excluded from the definition of functional dyspepsia, may nevertheless coexist with it. Epigastric pain syndrome and postprandial distress syndrome are the two subtypes of functional dyspepsia (Table 123-5). Epigastric pain syndrome is characterized as bothersome epigastric pain or burning on one or more days per week in the past 3 months. Postprandial distress syndrome is defined as bothersome early satiety or postprandial fullness on 3 or more days per week in the previous 3 months. Almost two thirds of patients with functional dyspepsia have postprandial distress syndrome, over 15% have epigastric pain syndrome, and the remainder have symptoms that overlap both postprandial distress syndrome and epigastric pain syndrome.

Risk factors for functional dyspepsia include female sex, smoking, use of nonsteroidal anti-inflammatory drugs, acute gastroenteritis, psychological disorders (particularly anxiety), and *Helicobacter pylori* infection (Chapter 125).[29] Eradication of *H. pylori* has a statistically significant but unfortunately small likelihood of relieving symptoms of functional dyspepsia. If a patient who has symptoms of functional dyspepsia also has *H. pylori* infection and if eradication of *H. pylori* resolves these symptoms, the patient is classified as having *H. pylori* gastritis and not functional dyspepsia.

PATHOBIOLOGY

The pathobiology of functional dyspepsia includes delayed or rapid gastric emptying, visceral hypersensitivity, and impaired gastric accommodation, as well as gastric and duodenal hypersensitivity to distention, acid, low-grade inflammation (e.g., eosinophilia), mucosal permeability, and food antigens. About 30% of patients with functional dyspepsia have delayed gastric emptying time, which prompts the ongoing debate as to whether these patients should be diagnosed as having functional dyspepsia with delayed gastric emptying or as having gastroparesis (Chapter 122). However, symptoms other than severe nausea do not correlate well with gastric emptying time.[30]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The initial diagnostic evaluation of functional dyspepsia is based on the assessment of symptoms and alarm features (Fig. 123-5).[31] The presence of alarm features (Table 123-6) warrants an upper endoscopy to exclude conditions such as gastric cancer (Chapter 178) or serious esophageal disease (Chapter 124) as well as to perform a biopsy to detect *H. pylori*. If alarm features are absent and the patient is younger than age 60 years (or under age 55 years in regions with a high prevalence of gastric cancer), endoscopy is not required, but noninvasive testing for *H. pylori* (e.g., a stool antigen test [Table 125-3; Fig. 125-5]) is indicated.

TABLE 123-5 ROME IV DIAGNOSTIC CRITERIA FOR SUBGROUPS OF PATIENTS WITH FUNCTIONAL DYSPEPSIA*

POSTPRANDIAL DISTRESS SYNDROME

One or both of the following bothersome symptoms at least 3 days per week:
1. Postprandial fullness (severe enough to impact usual activities)
2. Early satiation

Supportive Criteria

1. Postprandial epigastric pain or burning, epigastric bloating, excessive belching, and nausea can also be present.
2. Vomiting warrants consideration for another diagnosis.
3. Heartburn is not a dyspeptic symptom but may often coexist.
4. Symptoms that are relieved by evacuation of feces or gas should generally not be considered as part of dyspepsia.

EPIGASTRIC PAIN SYNDROME

Must include at least one of the following bothersome symptoms at least 1 day a week:
1. Epigastric pain (i.e., severe enough to impact on usual activities)
2. Epigastric burning (i.e., severe enough to impact on usual activities)

Supportive Criteria

1. Pain may be induced by ingestion of a meal, relieved by ingestion of a meal, or may occur while fasting.
2. Postprandial epigastric bloating, belching, and nausea can also be present.
3. Persistent vomiting likely suggests another disorder.
4. Heartburn is not a dyspeptic symptom but may often coexist.
5. The pain does not fulfill biliary pain criteria.
6. Symptoms that are relieved by evacuation of feces or gas generally should not be considered as part of dyspepsia.

*The criteria must be fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis.

Adapted from Stanghellini V, Chan FK, Hasler WL, et al. Gastroduodenal disorders. *Gastroenterology*. 2016;150:1380-1392.

TABLE 123-6 ALARM SYMPTOMS ASSOCIATED WITH AN UNDERLYING UPPER GASTROINTESTINAL MALIGNANCY

Unintentional weight loss
New-onset dyspepsia after age 55 years
Dysphagia
Persistent vomiting
Any overt gastrointestinal bleeding, hematemesis, or melena
Family history of esophageal or gastric cancer
Iron deficiency anemia
Palpable abdominal mass or lymph node

From Mayer EA. Functional gastrointestinal disorders: irritable bowel syndrome, dyspepsia, esophageal chest pain, and heartburn. In: Goldman L, Schafer A, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Elsevier; 2020:852-859.

TREATMENT

If *H. pylori* is not detected, empiric therapy with a proton pump inhibitor (see Table 124-1) is typically recommended.[A13] If symptoms persist, additional treatment is based on the subtype of functional dyspepsia. In patients with postprandial distress syndrome, buspirone (10 mg three times daily) and mirtazapine (15 mg at bedtime) have demonstrated efficacy. Tricyclic antidepressants (see Table 362-5) can relieve symptoms compared with placebo, particularly in patients who have abdominal pain and a normal gastric emptying time.

PROGNOSIS

The long-term prognosis for functional dyspepsia is favorable in the majority of patients, and life expectancy is similar to that of the general population.

FUNCTIONAL HEARTBURN

Functional heartburn is retrosternal burning discomfort or pain that radiates retrosternally, is unresponsive to optimal antisecretory therapy, and is not

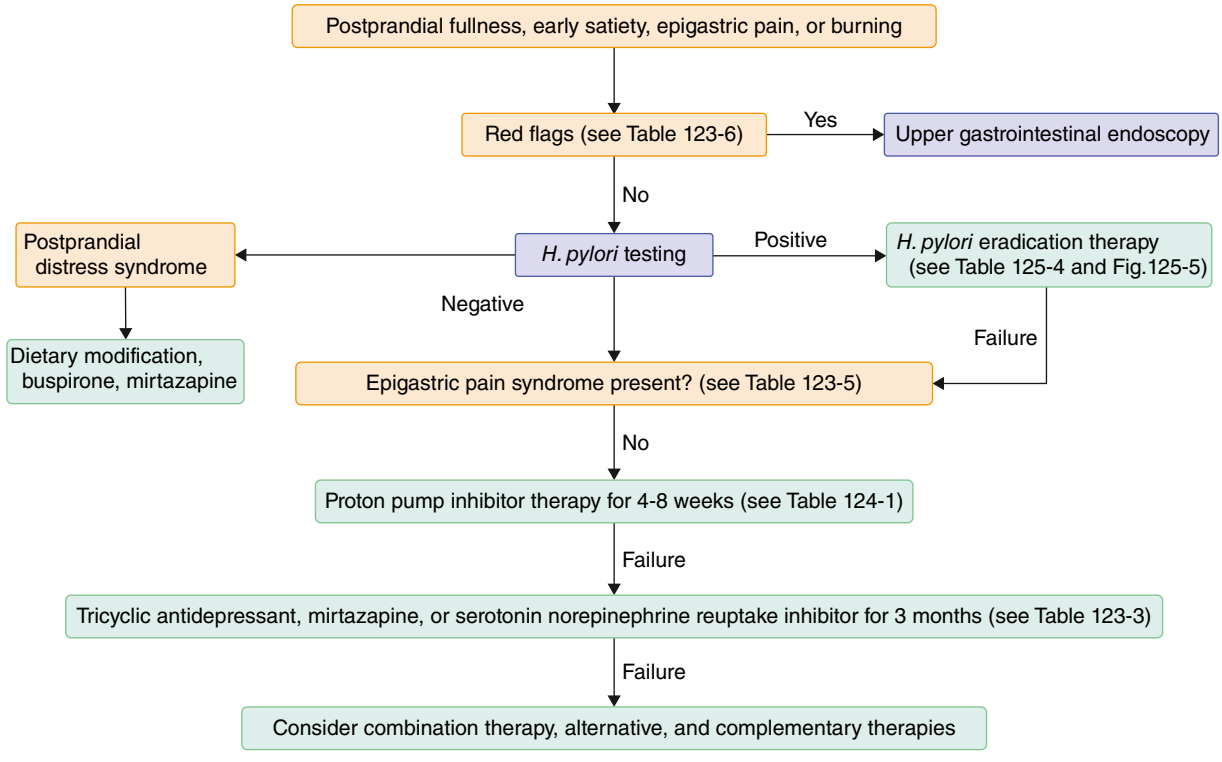

FIGURE 123-5. Algorithm for functional dyspepsia. A recommended approach to patients who present with epigastric pain, postprandial fullness, and early satiety, who meet the Rome IV diagnostic criteria for functional dyspepsia (see Table 123-4), and who lack any alarm features (see Table 123-6). In the setting of treatment failure, the physician should re-evaluate all clinical and laboratory findings to determine whether further diagnostic testing might be beneficial to assess the patients for alternative causes of the symptoms. (From Mayer EA. Functional gastrointestinal disorders: irritable bowel syndrome, dyspepsia, esophageal chest pain, and heartburn. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Elsevier; 2020:852-859.)

accompanied by gastroesophageal reflux disease or esophageal mucosal, motility, or structural abnormalities to explain the symptoms. Even if some gastroesophageal reflux is detected, symptoms are not correlated with it. Although patients may have some degree of epigastric discomfort, the chest symptoms predominate.

EPIDEMIOLOGY

Functional heartburn is very common. The global prevalence of functional heartburn is about 1%, but it is approximately 25% in patients whose heartburn responds to a proton pump inhibitor and 50% in patients whose heartburn does not respond to a proton pump inhibitor. The presence of coexistent irritable bowel syndrome is a strong predictor of functional heartburn.

PATHOBIOLOGY

The pathobiology of functional heartburn is likely related to visceral hypersensitivity to antral and esophageal distention, altered esophageal motility in the absence of a clinically detectable motility disorder, and psychological factors.

CLINICAL MANIFESTATIONS

Patients with functional heartburn, which unlike dyspepsia is felt in the chest rather than the abdomen, complain of typical heartburn symptoms that usually are triggered by food intake and psychosocial stress but are refractory to acid-suppressive therapy with proton pump inhibitors. By definition, they also have negative endoscopic and acid monitoring evaluations of the esophagus.

DIAGNOSIS

An endoscopy with biopsies is performed in patients whose heartburn symptoms do not respond to an adequate trial of empirical proton pump inhibitor therapy in order to exclude other esophageal or gastric diseases, such as eosinophilic esophagitis, pill-induced esophagitis, stricture, Barrett esophagus, and malignancy (Chapter 124). If endoscopy is normal, ambulatory pH monitoring alone or with impedence should be conducted without acid suppression in patients who do not have proven gastroesophageal reflux and with acid suppression in patients who have proven gastroesophageal reflux. If esophageal acid (pH <4) exposure time is less than 4% of the time of a complete study, high-resolution esophageal manometry should be performed to exclude a major esophageal motility disorder such as achalasia (Chapter 124).

Based on the Rome IV criteria (Table 123-7), functional heartburn is diagnosed if heartburn is present at least twice per week with all of the following criteria: no relief of symptoms with optimal antisecretory therapy; absence of gastroesophageal reflux, eosinophilic esophagitis, or major esophageal motor disorders (e.g., achalasia, diffuse esophageal spasm); and symptoms that are present for the past 3 months with an onset of symptoms at least 6 months prior to the diagnosis.

TREATMENT

Treatment of functional heartburn consists of lifestyle modifications, pharmacotherapy with neuromodulators, and behavioral therapy.[32] Lifestyle modifications include identifying and managing triggers such as foods, stress, or physical activities that precipitate symptoms. Antisecretory medications such as standard- or double-dose proton pump inhibitors (e.g., omeprazole 20 mg once to twice daily; see Table 124-1) can be helpful, especially if gastroesophageal reflux coexists.[33] Low doses of tricyclic antidepressants (e.g., imipramine; starting at 10 to 20 mg at bedtime) or selective serotonin reuptake inhibitors (e.g., fluoxetine 10 to 20 mg daily) are considered the mainstay of treatment for functional heartburn. For truly refractory heartburn caused by reflux, laparoscopic Nissen fundoplication is better than continued medical treatment (see Chapter 124). Cognitive-behavioral therapy may be helpful. Acupuncture and esophageal-directed hypnotherapy (Chapter 30) are reserved for refractory cases.

PROGNOSIS

The prognosis and long-term natural history of functional heartburn are not completely known. Up to two thirds of patients continue to have heartburn over 2 years of follow-up, whereas about 20% experience a reduction in symptoms.

FUNCTIONAL CHEST PAIN OF LIKELY ESOPHAGEAL ORIGIN

DEFINITION

Functional chest pain of presumed esophageal origin (Table 123-8) is a chronic midline chest pain that is not explained by cardiac causes, gastroesophageal reflux, or esophageal motility disorders (Chapters 39 and 124).

TABLE 123-7 ROME IV DIAGNOSTIC CRITERIA FOR FUNCTIONAL HEARTBURN

Must include all of the following:

- Burning retrosternal discomfort or pain
- No relief of symptoms despite optimal antisecretory therapy
- Absence of evidence that gastroesophageal reflux (abnormal acid exposure and symptoms) or eosinophilic esophagitis is the cause of symptoms
- Absence of major esophageal motor disorders (e.g., achalasia/esophagogastric junction outflow obstruction, diffuse esophageal spasm, jackhammer esophagus, absent peristalsis)

*The criteria must be fulfilled for the last 3 months with the onset of symptoms at least 6 months before diagnosis, with a frequency of at least twice per week.

Aziz Q, Fass R, Gyawali CP, et al. Functional esophageal disorders. *Gastroenterology*. 2016;150:1368-1379.

TABLE 123-8 ROME IV DIAGNOSTIC CRITERIA FOR FUNCTIONAL CHEST PAIN OF PRESUMED ESOPHAGEAL ORIGIN*

Must include all of the following:

- Retrosternal chest pain or discomfort; cardiac causes should be excluded
- Absence of associated esophageal symptoms, such as heartburn and dysphagia
- Absence of evidence that gastroesophageal reflux or eosinophilic esophagitis are the cause of the symptoms
- Absence of major esophageal motor disorders (e.g., achalasia/esophageal-gastric outflow obstruction, diffuse esophageal spasm, jackhammer esophagus, absent peristalsis)

*The criteria must be fulfilled for the last 3 months with the onset of symptoms at least 6 months before diagnosis, with a frequency of at least once a week.

From Mayer EA. Functional gastrointestinal disorders: irritable bowel syndrome, dyspepsia, esophageal chest pain, and heartburn. In: Goldman L, Schafer A, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Elsevier; 2020:852-859.

EPIDEMIOLOGY AND PATHOBIOLOGY

Functional chest pain has a prevalence rate as high as 25% and is a leading cause of acute chest pain (see Table 39-2), especially in younger patients. Men and women are equally affected, and it is more commonly reported in younger individuals, perhaps because repeated reassurance decreases the complaint in other individuals. Nevertheless, many patients undergo repeated and unnecessary diagnostic cardiac evaluations. Patients with functional chest pain often have anxiety or panic attacks (Chapter 362), thereby suggesting a link between functional chest pain and psychological issues.

The pathobiology of esophageal chest pain is thought to be similar to that of functional heartburn. In addition, however, increased esophageal muscle contraction has been implicated.

CLINICAL MANIFESTATIONS

Functional chest pain is often indistinguishable from the pain of acute myocardial ischemia or myocardial infarction (Chapters 57 and 58). Although the pain is typically substernal, it can radiate to the arm and neck. The pain is unrelated to exercise and can persist for hours.

DIAGNOSIS

Patients who present with chest pain (see Table 39-2) suspicious for angina or acute myocardial infarction (Chapters 56 to 58) should undergo prompt cardiac evaluation. A trial of nitroglycerin is not helpful diagnostically because it can relieve esophageal spasm as well as myocardial ischemia. If the cardiac evaluation is negative, other causes of functional chest pain should be evaluated (Table 123-9), but repeated cardiac evaluations for recurrent symptoms usually are not helpful (Chapter 39). Chest wall pain, tenderness on palpation, or changes in pain with movement usually are musculoskeletal in origin (Chapter 39).

An association with certain foods or concurrent heartburn or dyspepsia can sometimes differentiate between acid-induced versus non–acid-related causes. In patients with alarm symptoms (see Table 123-6), such as weight loss, progressive dysphagia, or anemia, upper endoscopy is required. Testing for esophageal motility disorders (Chapter 124) is useful for severe or recurrent symptoms.

TABLE 123-9 DIFFERENTIAL DIAGNOSIS OF FUNCTIONAL CHEST PAIN

ORGANIC ESOPHAGEAL CAUSES
Gastroesophageal reflux disease
Achalasia
Virus- or pill-induced esophagitis
Eosinophilic esophagitis
NONGASTROINTESTINAL CAUSES
Cardiac chest pain
Chest wall pain
Pulmonary disease
Panic attack

From Mayer EA. Functional gastrointestinal disorders: irritable bowel syndrome, dyspepsia, esophageal chest pain, and heartburn. In: Goldman L, Schafer A, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Elsevier; 2020:852-859.

TREATMENT

Many patients with functional chest pain have atypical gastroesophageal reflux disorder (Chapter 124) and benefit from a therapeutic trial with a proton pump inhibitor (e.g., omeprazole 20 mg daily). The optimal duration of treatment is unclear, but an attempt should be made to discontinue proton pump inhibitors after several months of successful therapy. If the patient's response is equivocal, 24-hour pH testing can be considered (Chapter 124). In patients who do not respond to a proton pump inhibitor, testing for esophageal motility disorders (Chapter 124) should be performed to look for conditions such as high-amplitude contractions, diffuse esophageal spasm, or achalasia. Fears regarding possible cardiac disease must be addresseed explicitly, and patients must be reassured by the negative results of the cardiac evaluation.

Low-dose tricyclic antidepressants (e.g., amitriptyline, imipramine, or desipramine 10 to 50 mg at bedtime) may be useful. For persistent symptoms, cognitive-behavioral therapy or mindfulness-based stress reduction may be beneficial.

PROGNOSIS

Functional chest pain has a benign prognosis, although many patients may request repeated cardiac evaluations if symptoms persist and diminish quality of life.

DISEASES OF THE ESOPHAGUS

GARY W. FALK AND DAVID A. KATZKA

NORMAL ANATOMY AND PHYSIOLOGY

The esophagus, which averages about 27 cm in length, is a hollow muscular tube consisting of the mucosa, submucosa, and muscularis layers, with the notable absence of a serosal layer. The mucosa is a stratified squamous nonkeratinized epithelium that transitions to a columnar epithelium at the gastroesophageal junction. The muscular layer of the esophagus is composed of striated muscle in the upper one third and smooth muscle in the lower two thirds. These muscular components are arranged as an inner circular and an outer longitudinal layer. Located between the circular and longitudinal muscle layers is Auerbach (myenteric) plexus, whereas Meissner plexus is located within the submucosa and innervates the muscularis mucosae. The esophagus is bound by an upper esophageal sphincter proximally and the lower esophageal sphincter distally. The upper esophageal sphincter contains functional contributions from the inferior pharyngeal constrictor proximally and the cricopharyngeus distally. By contrast, the lower esophageal sphincter is anatomically and histologically indistinguishable from the lower esophagus. Blood supply for the cervical portion is derived from branches of the inferior thyroid artery. The intrathoracic segment of the esophagus receives its blood supply from bronchial arteries and direct branches from the aorta, and the left gastric and the inferior phrenic arteries supply the abdominal portion of the esophagus. Venous drainage follows the arterial supply in the cervical and abdominal portions, whereas the thoracic esophagus drains into the azygous and hemiazygos system. Likewise, the lymphatic drainage of the esophagus is segmental, with the cervical portion draining into deep cervical lymph nodes, the thoracic portion into the superior and posterior mediastinal lymph nodes, and the abdominal portion into the gastric and celiac lymph nodes.

The motor functions of the esophagus are to transport a food bolus from the oropharynx into the stomach and then to keep food from returning to the esophagus after it has entered the stomach. The upper esophageal sphincter and the proximal third of the esophagus compose the first portion of the esophagus. The upper esophageal sphincter is approximately 2 to 4 cm in length. The recurrent laryngeal nerve inferiorly and a pharyngeal plexus superiorly supply the upper esophageal sphincter. The muscle layers close the esophageal lumen and shorten the esophagus to facilitate forward transport through the proximal esophagus. After food traverses the proximal esophagus, it moves into the distal two thirds of the esophagus, where peristalsis is achieved by sequential muscular contraction mediated through an interplay of inhibitory and excitatory neurotransmitters. Peristalsis may be primary, that is, initiated by a swallow, or secondary, that is, stimulated by refluxed gastric contents. Although local mechanisms control most esophageal motor function, vagal input is important in the distal esophagus, where smooth muscle myopathies and autonomic neuropathies can cause dysfunction. The distal esophagus is separated from the stomach by the lower esophageal sphincter, which is 4 to 5 cm in length and is functionally distinct because it maintains a tonic high-pressure zone. This sphincter relaxes nearly completely upon swallowing to allow the passage of food and then regains its tone to provide a barrier against reflux. It also relaxes transiently during normal functions, such as belching and vomiting. The vagus nerve, acetylcholine, and nitric oxide influence tone, but the lower esophageal sphincter tone is influenced by the crural diaphragm as the esophagus traverses the diaphragmatic hiatus.

Esophageal Functional Testing

Options for esophageal functional testing include barium esophagography, high-resolution esophageal manometry, and esophageal impedance testing. Barium esophagography (Chapter 119) reveals both anatomic and physiologic information about luminal lesions, such as malignancies, ulceration, diverticula, hiatal hernia, and strictures; intramural lesions, such as leiomyomas; and extrinsic lesions, such as occur from vascular (aorta, right atrium, subclavian artery) impingement or solid lesions (pulmonary malignancy, adenopathy) that compress the esophagus. Radiography is also an excellent tool for studying motility patterns, such as peristalsis with either liquid or solid contrast material, while precisely visualizing how the esophagus handles a bolus rather than by implying function from pressure or impedance changes.

TREATMENT

Many patients with functional chest pain have atypical gastroesophageal reflux disorder (Chapter 124) and benefit from a therapeutic trial with a proton pump inhibitor (e.g., omeprazole 20 mg daily). The optimal duration of treatment is unclear, but an attempt should be made to discontinue proton pump inhibitors after several months of successful therapy. If the patient's response is equivocal, 24-hour pH testing can be considered (Chapter 124). In patients who do not respond to a proton pump inhibitor, testing for esophageal motility disorders (Chapter 124) should be performed to look for conditions such as high-amplitude contractions, diffuse esophageal spasm, or achalasia. Fears regarding possible cardiac disease must be addresseed explicitly, and patients must be reassured by the negative results of the cardiac evaluation.

Low-dose tricyclic antidepressants (e.g., amitriptyline, imipramine, or desipramine 10 to 50 mg at bedtime) may be useful. For persistent symptoms, cognitive-behavioral therapy or mindfulness-based stress reduction may be beneficial.

PROGNOSIS

Functional chest pain has a benign prognosis, although many patients may request repeated cardiac evaluations if symptoms persist and diminish quality of life.

DISEASES OF THE ESOPHAGUS

GARY W. FALK AND DAVID A. KATZKA

NORMAL ANATOMY AND PHYSIOLOGY

The esophagus, which averages about 27 cm in length, is a hollow muscular tube consisting of the mucosa, submucosa, and muscularis layers, with the notable absence of a serosal layer. The mucosa is a stratified squamous nonkeratinized epithelium that transitions to a columnar epithelium at the gastroesophageal junction. The muscular layer of the esophagus is composed of striated muscle in the upper one third and smooth muscle in the lower two thirds. These muscular components are arranged as an inner circular and an outer longitudinal layer. Located between the circular and longitudinal muscle layers is Auerbach (myenteric) plexus, whereas Meissner plexus is located within the submucosa and innervates the muscularis mucosae. The esophagus is bound by an upper esophageal sphincter proximally and the lower esophageal sphincter distally. The upper esophageal sphincter contains functional contributions from the inferior pharyngeal constrictor proximally and the cricopharyngeus distally. By contrast, the lower esophageal sphincter is anatomically and histologically indistinguishable from the lower esophagus. Blood supply for the cervical portion is derived from branches of the inferior thyroid artery. The intrathoracic segment of the esophagus receives its blood supply from bronchial arteries and direct branches from the aorta, and the left gastric and the inferior phrenic arteries supply the abdominal portion of the esophagus. Venous drainage follows the arterial supply in the cervical and abdominal portions, whereas the thoracic esophagus drains into the azygous and hemiazygos system. Likewise, the lymphatic drainage of the esophagus is segmental, with the cervical portion draining into deep cervical lymph nodes, the thoracic portion into the superior and posterior mediastinal lymph nodes, and the abdominal portion into the gastric and celiac lymph nodes.

The motor functions of the esophagus are to transport a food bolus from the oropharynx into the stomach and then to keep food from returning to the esophagus after it has entered the stomach. The upper esophageal sphincter and the proximal third of the esophagus compose the first portion of the esophagus. The upper esophageal sphincter is approximately 2 to 4 cm in length. The recurrent laryngeal nerve inferiorly and a pharyngeal plexus superiorly supply the upper esophageal sphincter. The muscle layers close the esophageal lumen and shorten the esophagus to facilitate forward transport through the proximal esophagus. After food traverses the proximal esophagus, it moves into the distal two thirds of the esophagus, where peristalsis is achieved by sequential muscular contraction mediated through an interplay of inhibitory and excitatory neurotransmitters. Peristalsis may be primary, that is, initiated by a swallow, or secondary, that is, stimulated by refluxed gastric contents. Although local mechanisms control most esophageal motor function, vagal input is important in the distal esophagus, where smooth muscle myopathies and autonomic neuropathies can cause dysfunction. The distal esophagus is separated from the stomach by the lower esophageal sphincter, which is 4 to 5 cm in length and is functionally distinct because it maintains a tonic high-pressure zone. This sphincter relaxes nearly completely upon swallowing to allow the passage of food and then regains its tone to provide a barrier against reflux. It also relaxes transiently during normal functions, such as belching and vomiting. The vagus nerve, acetylcholine, and nitric oxide influence tone, but the lower esophageal sphincter tone is influenced by the crural diaphragm as the esophagus traverses the diaphragmatic hiatus.

Esophageal Functional Testing

Options for esophageal functional testing include barium esophagography, high-resolution esophageal manometry, and esophageal impedance testing. Barium esophagography (Chapter 119) reveals both anatomic and physiologic information about luminal lesions, such as malignancies, ulceration, diverticula, hiatal hernia, and strictures; intramural lesions, such as leiomyomas; and extrinsic lesions, such as occur from vascular (aorta, right atrium, subclavian artery) impingement or solid lesions (pulmonary malignancy, adenopathy) that compress the esophagus. Radiography is also an excellent tool for studying motility patterns, such as peristalsis with either liquid or solid contrast material, while precisely visualizing how the esophagus handles a bolus rather than by implying function from pressure or impedance changes.

ABSTRACT

The esophagus is a muscular tube that facilitates the transport of a food bolus into the stomach. Classic symptoms of esophageal disease include dysphagia, heartburn, regurgitation, chest pain, and food impaction. Gastroesophageal reflux disease is perhaps the most common esophageal disease and is characterized by heartburn and acid regurgitation. Treatment focuses on simple lifestyle modifications, acid suppression therapy, and antireflux surgery in selected patients. Complications of reflux disease include peptic strictures, Barrett esophagus, and esophageal adenocarcinoma. Eosinophilic esophagitis is a relatively newly recognized disease caused when an aberrant immune response to food and aeroallergens leads to chronic inflammation and fibrosis of the esophagus. Treatments include elimination of common food allergens, topical steroids, proton pump inhibitors, and endoscopic dilation. Achalasia, which is the prototypic esophageal motility abnormality, is characterized by dysphagia to solids and liquids. Treatment focuses on disruption of the lower esophageal sphincter by pneumatic dilation or by surgical or endoscopic myotomy. A variety of structural and inflammatory abnormalities that may cause esophageal symptoms are also described in this chapter.

KEYWORDS

esophagus
esophagitis
Barrett esophagus
eosinophilic esophagitis
gastroesophageal reflux
achalasia
esophageal spasm
esophageal testing

High-resolution esophageal manometry measures pressure changes generated by esophageal wall contraction and changes in tone using multiple sensors that simultaneously measure pressure from the pharynx to the lower esophageal sphincter.[1] Esophageal impedance testing detects the movement of an intraluminal bolus by measuring conductance between catheter-based electrodes based on the substance that is in contact with each electrode. Air, which is a poor conductor of electric current, will yield high impedance, whereas swallowed or refluxed liquids, which are excellent conductors of electricity, will generate a low impedance signal. From these measurements, the direction and velocity of the transport of air and bolus can help assess peristaltic function and the reflux of acid and nonacid gastric contents. Impedance can also reflect site-specific esophageal mucosal permeability, thereby providing further insight into mucosal integrity and disease in inflammatory or metaplastic conditions.

A functional luminal imaging probe is a balloon-based device that measures pressures in response to controlled volumetric distentions. When used in the esophagus, it can measure the compliance of the esophageal wall and lower esophageal sphincter, as well as esophageal body motility. This procedure is increasingly being used to evaluate disorders such as eosinophilic esophagitis, achalasia, obstruction of the esophagogastric junction outlet, and unexplained dysphagia.

Symptoms of Esophageal Disease

The most common symptom of esophageal disease is heartburn, which is defined as a sensation of substernal burning. Chest pain without typical heartburn may occur in a variety of esophageal disorders, including gastroesophageal reflux and motor disorders such as in achalasia. However, esophageal pain and even heartburn can be indistinguishable from cardiac angina (Chapter 39), so care must be taken when a patient at risk for coronary artery disease complains of heartburn for the first time.

Dysphagia, or difficulty swallowing, is another cardinal symptom of esophageal disease. Dysphagia with only solid food tends to occur with structural lesions, which cause esophageal constriction, whereas dysphagia with both liquids and solids occurs more often with motility disorders. Patients with oropharyngeal dysphagia will commonly complain of a feeling of food "sticking" in the throat or the inability to propel the bolus from the mouth to the pharynx; they may also complain of the need for multiple swallowing motions to clear the bolus. Since the cranial nerves that generally control the initial phases of swallowing are responsible for other functions as well, symptoms that may be associated with oropharyngeal dysphagia include drooling, dysarthria (due to tongue dysfunction), nasal regurgitation (due to failure to seal off the nasal passage), or coughing and aspiration (due to failure to elevate and cover the laryngeal vestibule). Dysphagia that results from abnormalities in the body of the esophagus may be referred to the chest or the neck, so the location of dysphagia does not predict the location of the disease. Dysphagia may also lead to a variety of behavioral accommodations, including maneuvers such as slow eating, food aversion, avoidance of hard solid food, and drinking of large amounts of liquids with solid meals.

Regurgitation, which is another typical esophageal symptom, may be described as the feeling of food coming up into the chest or, more dramatically, into the mouth. When regurgitation occurs early in the meal, it suggests a proximal lesion. Regurgitation later in the meal suggests a motility abnormality such as achalasia.

Food impaction is an extreme esophageal symptom. When impaction occurs in the oropharynx, it may lead to tracheal impaction or compression. With more distal esophageal lesions, impaction may occur any time during the meal, almost always from a mechanical cause. Patients experience the sudden onset of chest pain and the sensation of food sticking, typically after solids such as meats, raw vegetables, and sticky rice. With complete impaction, patients who cannot handle secretions because of the obstructing bolus are at risk for aspiration, esophageal rupture, and perforation.

GASTROESOPHAGEAL REFLUX DISEASE

DEFINITION

Gastroesophageal reflux disease (GERD) develops when the reflux of stomach contents into the esophagus causes troublesome symptoms or complications.

EPIDEMIOLOGY

It is estimated that GERD, defined as at least weekly heartburn or acid regurgitation, has a prevalence ranging from 10 to 20% in the Western world and less than 5% in Asia. In the United States, estimates are that as many as 44% of people may have had GERD symptoms and 30% have had such symptoms in the prior week. The prevalence also tends to be higher in North America than Europe and higher in northern Europe than in southern Europe. Risk factors for developing GERD include obesity, particularly central obesity, and possibly increasing age. A genetic component may also play a role because GERD is more common in patients with a positive family history and in monozygotic twins than in dizygotic twins.

PATHOBIOLOGY

The esophagus is protected from the harmful effects of refluxed gastric contents by the antireflux barrier at the gastroesophageal junction, by esophageal clearance mechanisms, and by epithelial defensive factors. The antireflux barrier consists of the lower esophageal sphincter, crural diaphragm, phrenoesophageal ligament, and angle of His, which causes an oblique entrance of the esophagus into the stomach. The attachment of the lower esophageal sphincter to the crural diaphragm results in increased pressure during inspiration and when intra-abdominal pressure increases. Disruption of normal defense mechanisms leads to pathologic amounts of reflux.

Reflux of gastric contents from the stomach into the esophagus occurs in healthy individuals, but refluxed gastric contents are normally cleared in a two-step process: volume clearance by peristaltic function and neutralization of small amounts of residual acid by weakly alkaline swallowed saliva. In normal healthy individuals, physiologic reflux occurs primarily when the lower esophageal sphincter transiently relaxes in the absence of a swallow because of a vagally mediated reflex that is stimulated by gastric distention. In GERD patients, transient relaxation of the lower esophageal sphincter or a low resting lower esophageal sphincter pressure can result in regurgitation, especially when intra-abdominal pressure is increased. In some patients, a primary increase in intra-abdominal pressure overcomes normal lower esophageal sphincter pressure. These patients may have a rumination and/or supragastric belching variant of gastroesophageal reflux.[2]

A hiatal hernia, which results in axial and vertical spatial separation between the augmenting effects of the crural diaphragm and the lower esophageal sphincter, predisposes to reflux events by widening the opening of the gastroesophageal junction and decreasing the pressure of the lower esophageal sphincter. The result is an increased exposure of the esophagus to acid and gastric contents, with increased reflux events during transient physiologic relaxation of the lower esophageal sphincter and/or increased gastric pressure. Hernias also act as a reservoir for gastric contents when normal esophageal clearance mechanisms result in trapping of fluids in the hernia sac. These contents can reflux into the esophagus when the lower esophageal sphincter relaxes during subsequent swallowing.

Normal individuals also have an unbuffered acid pocket in the gastric cardia, which escapes the buffering effects of a meal in the postprandial period. This region is a source of postprandial reflux and may explain the chronic inflammation often seen in the cardia and distal esophagus. In reflux patients, the acid pocket is more common and longer in length than in normal individuals. Displacement of the acid pocket into a hiatal hernia also appears to increase acidic reflux in patients with GERD.

Increased intra-abdominal fat associated with obesity increases intragastric pressure, which increases the gastroesophageal pressure gradient and the frequency of transient lower esophageal sphincter relaxation, thereby predisposing gastric contents to migrate into the esophagus. In addition, obesity enhances the spatial separation of the crural diaphragm and the lower esophageal sphincter, thereby predisposing obese individuals to a hiatal hernia. The metabolic syndrome (Chapter 210) that is associated with obesity also may have an independent effect in promoting esophageal injury in GERD.

The normal defense mechanisms based on peristalsis and saliva also can be impaired. Peristaltic dysfunction is associated with an increasing severity of esophagitis, and ineffective peristaltic clearance may occur when the amplitude of esophageal contractions is less than 20 mm Hg. Saliva production may be impaired by a variety of mechanisms, such as smoking and Sjögren syndrome (Chapter 247).

The esophageal mucosa contains several lines of defense. A pre-epithelial barrier constitutes a small unstirred water layer combined with bicarbonate from swallowed saliva and from the secretions of submucosal glands. A second epithelial defense is composed of cell membranes and tight intercellular junctions, cellular and intercellular buffers, and cell membrane ion transporters. The postepithelial line of defense is composed of the blood supply to the esophagus. Acid and acidified pepsin in the refluxate are the key factors that damage the intercellular junctions, increase intracellular permeability, and dilate intercellular spaces. If sufficient quantities of refluxate diffuse into the intercellular spaces, cellular damage may occur. Signs and symptoms of GERD occur when defective epithelium comes into contact with refluxed acid, pepsin, or other noxious gastric contents. In addition to the direct noxious effects of refluxed acid, pepsin, and bile, refluxed gastric juice stimulates esophageal epithelial cells to secrete chemokines that attract inflammatory cells into the esophagus, thereby damaging the esophageal mucosa.

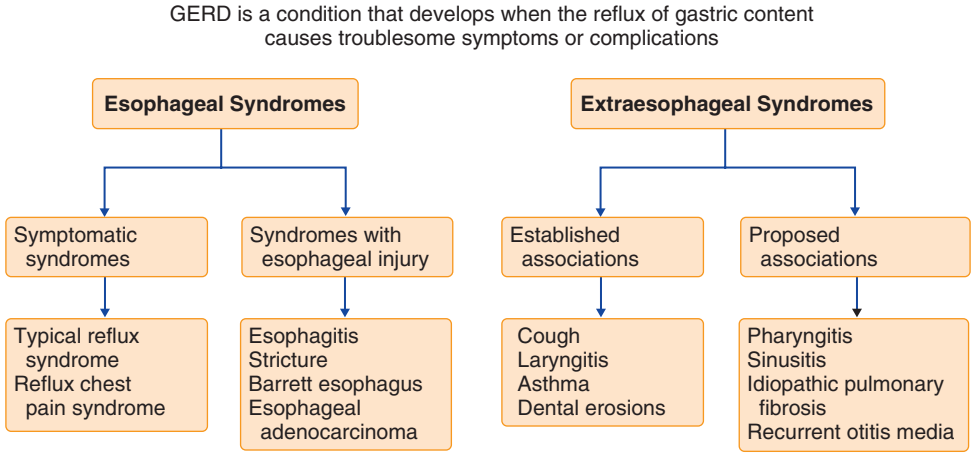

FIGURE 124-1. **Montreal classification of gastroesophageal reflux disease (GERD).** (From Vakil N, van Zanten S, Kahrilas P, et al. The Montreal definition and classification of gastroesophageal reflux disease: a global evidence-based consensus. *Am J Gastroenterol*. 2006;101:1900-1920.)

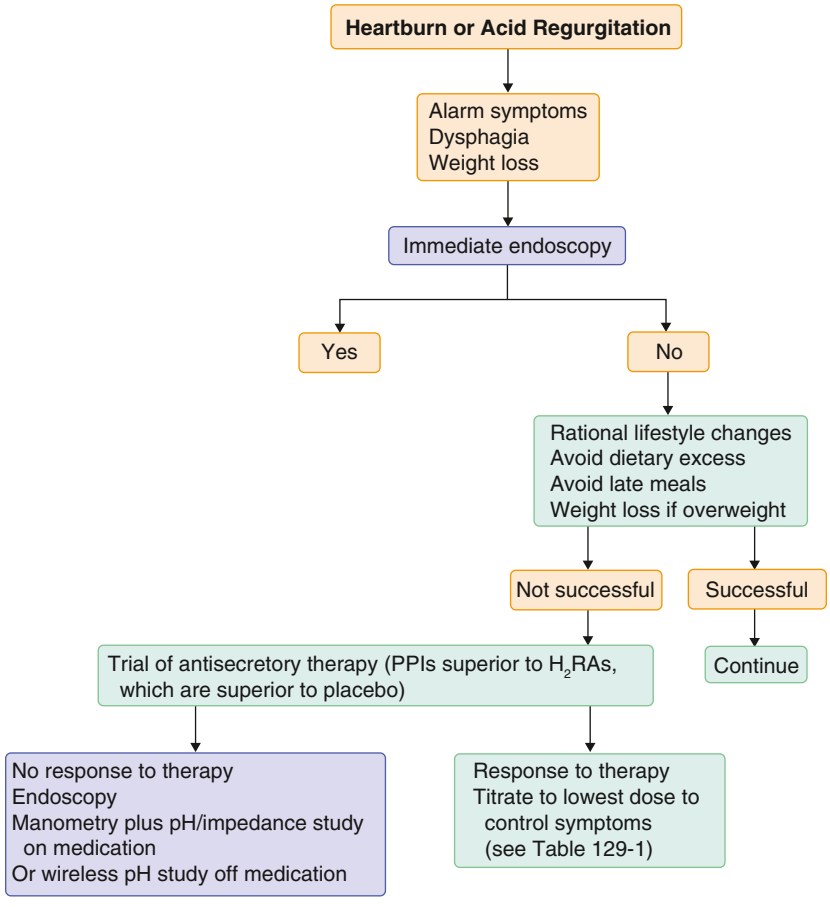

FIGURE 124-2. **Algorithm for the management of heartburn or regurgitation symptoms.** Surgery is indicated only for patients who are intolerant of antisecretory therapy or who have ongoing symptoms, especially regurgitation if reflux is well documented. H_2RA = histamine-2 receptor antagonist; PPI = proton pump inhibitor. (Based on Kahrilas PJ, Shaheen NJ, Vaezi MF. American Gastroenterological Association Institute technical review on the management of gastroesophageal reflux disease. *Gastroenterology*. 2008;135:1392-1413.)

CLINICAL MANIFESTATIONS

The classic symptoms of GERD are heartburn and acid regurgitation; atypical symptoms include chest pain, dysphagia, and odynophagia. Extraesophageal manifestations of reflux disease can include cough (Chapter 71), laryngitis (Chapter 397), asthma (Chapter 75), and dental erosions, but these symptoms are more easily attributable to GERD if accompanied by classic signs and symptoms of reflux disease and by objective testing that demonstrates increased reflux (Fig. 124-1). Other proposed associations that do not reliably respond to acid suppression and hence are not clearly related to GERD include pharyngitis, sinusitis, otitis media, throat clearing, and idiopathic pulmonary fibrosis.

When excessive gastric contents overwhelm the mucosal protective factors in the esophagus, esophagitis may be manifest as erosions or ulceration of the esophagus and may also lead to fibrosis with stricturing, columnar metaplasia (Barrett esophagus), or esophageal adenocarcinoma (Chapter 178). However, approximately two thirds of individuals with reflux symptoms have no evidence of esophageal damage by endoscopy.

DIAGNOSIS

When GERD is associated with typical signs and symptoms, such as heartburn or acid regurgitation, that are responsive to antisecretory therapy, no diagnostic evaluation is warranted,[3] except perhaps in patients who have high-risk characteristics for Barrett esophagus, such as smoking, older age, and absence of *H. pylori* infection.[4] However, recommendations on screening vary, and the cost-effectiveness of screening is uncertain.[5]

Diagnostic endoscopy is warranted in individuals who fail to respond to 4 to 8 weeks of therapy or have alarm symptoms or signs such as dysphagia, weight loss (Fig. 118-4), anemia, gastrointestinal bleeding, or persistent heartburn (Fig. 124-2). Endoscopy permits the detection of

erosive esophagitis and complications such as a peptic stricture (Fig. 124-3) and Barrett esophagus (Fig. 124-4); mucosal biopsy, which is crucial in these settings, also excludes conditions that can mimic GERD, such as eosinophilic esophagitis. However, most patients have no mucosal damage seen on endoscopy, regardless of whether they are on or off antisecretory therapy.

Esophageal manometry is useful to exclude achalasia in patients with suggestive symptoms. Esophageal reflux testing may be performed using 48- to 96-hour devices attached to the esophageal lumen, or 24-hour combined impedance and pH monitoring.[6] Testing of a patient who is not receiving antisecretory therapy can document abnormal esophageal acid exposure and establish the relationship between symptoms and reflux events. Testing of a patient who is on acid-suppression therapy should be considered only in individuals who have established GERD and in whom impedance pH monitoring can establish the relationship, if any, between refractory symptoms and reflux events, thereby permitting exclusion of GERD as the cause of persistent symptoms. Barium radiography has no role in the diagnostic evaluation of patients with uncomplicated reflux disease.

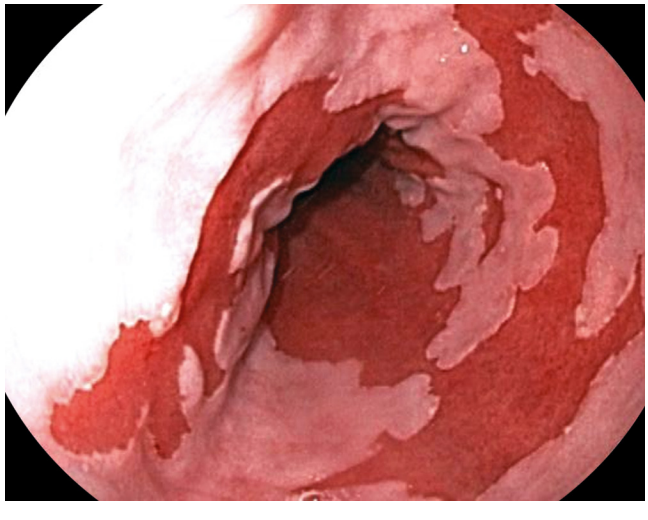

FIGURE 124-4. Endoscopic appearance of Barrett esophagus. Note the white-appearing normal squamous mucosa displaced above the true end of the esophagus. The intervening mucosa appears salmon pink.

TREATMENT

Although avoidance of foods or beverages that may provoke symptoms, such as alcohol, coffee, spicy foods, and late meals, makes physiologic sense, data from clinical trials to support these maneuvers are lacking. Elevation of the head of the bed, often with a wedge device, for patients with nocturnal regurgitation or heartburn also is logical. Given the association of obesity and GERD symptoms, weight loss should be part of any treatment program for obese patients.

Inhibition of gastric acid secretion (Table 124-1) is the cornerstone of the acute treatment of GERD,[7] and proton pump inhibitors are superior to histamine (H_2)–receptor antagonists for both the healing of esophagitis and the control of symptoms. For example, twice-daily proton pump inhibitor therapy results in more rapid endoscopic healing but not more rapid resolution of symptoms compared with once-daily treatment.[A1] However, the healing of esophagitis is more predictable than improvement in heartburn symptoms, even with proton pump inhibitors. There are no major differences in treatment efficacy among the various proton pump inhibitors.

Given the chronicity of reflux symptoms, long-term maintenance therapy with proton pump inhibitors is typically required, especially for patients with erosive esophagitis. Dosing should be titrated to the lowest dose necessary to control symptoms. Data to support the use of proton pump inhibitors in the management of extraesophageal GERD syndromes are weak, although selected patients, usually those with accompanying symptoms of classic heartburn and acid regurgitation, may benefit. The safety profile of proton pump inhibitors is excellent, but short-term adverse events such as headaches and diarrhea may occur. Long-term use of proton pump inhibitors has been associated with a variety of adverse consequences (vitamin B_{12} deficiency, *Clostridioides difficile* infection, community-acquired pneumonia, hip fracture, metabolic bone disease, diabetes mellitus, and small intestinal bacterial overgrowth), but the magnitude of any such risks is low enough that they do not offset their benefit.[8]

Although proton pump inhibitors are superior to H_2-receptor antagonists for long-term maintenance therapy as well as for short-term relief, H_2-receptor antagonists are superior to placebo and are useful in patients who cannot tolerate proton pump inhibitors. No high-quality data exist to support the common practice of using metoclopramide as either monotherapy or an adjunct to acid suppression therapy; furthermore, its potential adverse effects argue against the use of this drug in any GERD patients. In patients

TABLE 124-1 DRUG THERAPY FOR ESOPHAGEAL DISORDERS

AGENT	DOSE
ANTACIDS: LIQUID (TO BUFFER ACID AND INCREASE LESP)	
For example, Mylanta II/Maalox TC (acid-neutralizing capacity, 25 mEq/5 mL)*	15 mL qid 1 hr after meals and at bedtime or as needed
GAVISCON (TO DECREASE REFLUX VIA A VISCOUS MECHANICAL BARRIER AND BUFFER ACID)	
$Al(OH)_3$, $NaHCO_3$, Mg trisilicate, alginic acid	2-4 tablets qid and at bedtime or as needed
H_2-RECEPTOR ANTAGONISTS (TO DECREASE ACID SECRETION)	
Cimetidine	400 mg bid or 200 mg qid
Ranitidine	150 mg bid-qid or 10 mL qid; maintenance dose, 150 mg bid or 10 mL bid
Famotidine	20-40 mg bid or 2.5-5 mL bid
Nizatidine	150 mg bid
PROTON PUMP INHIBITORS (TO DECREASE ACID SECRETION AND GASTRIC VOLUME)†	
Omeprazole	20-40 mg/day; maintenance dose, 20 mg/day
Lansoprazole	15-30 mg/day; maintenance dose, 15 mg/day
Pantoprazole	40 mg/day; maintenance dose, 40 mg/day
Rabeprazole	20 mg/day; maintenance dose, 10-20 mg/day
Esomeprazole	20-40 mg/day; maintenance dose, 20 mg/day
Dexlansoprazole	30-60 mg/day; maintenance dose, 30 mg/day

*Patients with reflux are not generally hypersecretors of gastric acid, so the therapeutic doses of antacids are based on their capacity to buffer (normal) basal acid secretion rates of approximately 1 to 7 mEq/hr (mean, 2 mEq/hr) and peak meal-stimulated acid secretion rates of about 10 to 60 mEq/hr (mean, 30 mEq/hr).

†High-dose therapy is a twice-daily administration of the usually daily dose.

$Al(OH)_3$ = aluminum hydroxide; bid = twice daily; H_2 = histamine; LESP = lower esophageal sphincter pressure; Mg = magnesium; $NaHCO_3$ = sodium bicarbonate; qid = four times daily.

who have persistent symptoms despite proton pump inhibitor therapy, prolonged wireless monitoring off of proton pump therapy can identify patients whose symptoms are not acid-related and who can safely discontinue acid-suppression therapy.[A2]

If, however, patients have documented esophagitis, are intolerant of proton pump inhibitors or unresponsive to them, or regurgitate large volumes, an antireflux procedure should be considered.[9] Newer minimally invasive options in carefully selected patients (including full-thickness plication, various approaches to augment of the lower esophageal sphincter, and transoral incisionless fundoplication) can normalize esophageal acid exposure in about 50% of patients.

Antireflux surgery is an option for patients who have documented esophagitis, who are intolerant of proton pump inhibitors or unresponsive to them, or who regurgitate large volumes. Laparoscopic antireflux surgery is equivalent to continued proton pump inhibitor therapy for the healing of esophagitis and for the treatment of chronic GERD in patients who initially respond to proton pump inhibitors. In patients with persistent regurgitation despite proton pump inhibitor therapy, however, laparoscopic surgery is better than continued medical therapy for relieving symptoms,[A3,A4] even though about 15 to 20% of patients have recurrent symptoms severe enough to warrant another procedure. Surgery also has a number of serious complications that may affect quality of life, including dysphagia, vagal nerve injury, gas bloat syndrome, and diarrhea.

PROGNOSIS

Patients with GERD generally do well with conservative antireflux measures and proton pump inhibitor therapy. When surgery is required, the outcome is usually excellent.

PEPTIC STRICTURES

Esophageal strictures are a well-recognized complication of GERD, especially in older patients with long-standing reflux symptoms, but population-based studies suggest that the incidence of new and recurrent strictures is declining. Peptic strictures are thought to be a consequence of severe inflammation, which leads to fibrosis, scarring, esophageal shortening, and loss of compliance of the lumen.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms are typically dysphagia to solids with or without antecedent symptoms of heartburn or acid regurgitation. Strictures may be diagnosed by barium radiography or with upper endoscopy, but barium esophagograms (see Fig. 124-3) have a higher sensitivity for detecting subtle lesions, especially if performed with a solid challenge such as a barium-impregnated pill. However, peptic strictures must be distinguished from a wide variety of other causes of luminal narrowing, including pills, prior nasogastric tube intubation, neoplasia, infection, radiation, surgical anastomosis, some systemic diseases, caustic substances, eosinophilic esophagitis, lichen planus, and extrinsic compression. As a result, endoscopic biopsy and cytology are critical for distinguishing benign from malignant causes of strictures.

TREATMENT

Endoscopic dilation, which remains the cornerstone of therapy, should be done gradually to achieve a luminal diameter that is sufficiently large to relieve symptoms—typically a diameter of 13 mm or greater. After dilation is accomplished, patients should receive chronic proton pump inhibitor therapy (see Table 124-1). For recalcitrant peptic strictures, injection of triamcinolone into the stricture is superior to sham injection in patients who receive balloon dilation and post-procedure proton pump inhibitors.

PROGNOSIS

Endoscopic dilation will usually alleviate symptoms, but repetitive dilation is required in a significant minority of patients.

BARRETT ESOPHAGUS

Barrett esophagus, which is an acquired condition that results from severe esophageal mucosal injury, is a metaplastic change in the lining of the distal tubular esophagus, where the normal squamous epithelium is replaced by a columnar epithelium. Barrett esophagus would be of little importance if not for its well-recognized association with adenocarcinoma of the esophagus (Chapter 178). However, the risk for cancer in an individual patient with Barrett esophagus is low.

EPIDEMIOLOGY

Barrett esophagus is found in approximately 5 to 15% of patients who undergo endoscopy for symptoms of GERD.[10] Population-based studies suggest that the prevalence of Barrett esophagus is approximately 1.3 to 1.6%, but about 45% of affected patients do not have reflux symptoms. Barrett esophagus is predominantly a disease of middle-aged White men, but about 25% of patients are women or are younger than 50 years. The prevalence of Barrett esophagus increases until a plateau is reached between the seventh and ninth decades. Risk factors include frequent and long-standing reflux episodes, smoking, male sex, older age, and central male pattern obesity.

PATHOBIOLOGY

Barrett esophagus results from severe esophageal mucosal injury. Patients who develop Barrett esophagus typically have more esophageal acid and bile exposure, the former based on 24-hour pH monitoring, and almost always have a hiatal hernia, which is typically longer and associated with larger defects than in patients without Barrett esophagus. However, why some patients with GERD develop Barrett esophagus whereas others do not remains unclear, as does the cell of origin of columnar metaplasia. Candidates include dedifferentiation of squamous epithelium into columnar epithelium or stimulation of stem cells from either the basal layer of the esophageal epithelium, the esophageal submucosal glands, gastric cardia, residual embryonal stem cells at the gastroesophageal junction, or the bone marrow. The transcription factor CDX2, which can be induced by both acid and bile salts, appears to play a role in promoting the development of the columnar epithelium in the distal esophagus and gastroesophageal junction.[11] A small subset of patients may have an inherited predisposition to Barrett esophagus, although the genetics of the disease are incompletely understood.

CLINICAL MANIFESTATIONS

The development of reflux symptoms at an earlier age, an increased duration of reflux symptoms, an increased severity of nocturnal reflux symptoms, and prior complications of GERD such as esophagitis, ulceration, stricture, and bleeding may raise the likelihood of Barrett esophagus. Nevertheless, patients with Barrett esophagus are difficult to distinguish clinically from patients whose GERD is uncomplicated by a columnar-lined esophagus. Patients with Barrett esophagus may paradoxically have impaired sensitivity to esophageal acid perfusion and even lack symptoms of GERD.

DIAGNOSIS

Endoscopically, Barrett esophagus is characterized by displacement of the squamocolumnar junction so that it is now proximal to the gastroesophageal junction, which is defined by the proximal margin of gastric folds (see Fig. 124-4). The diagnosis of Barrett esophagus is established if the squamocolumnar junction is displaced 1 cm or more proximal to the gastroesophageal junction and if intestinal metaplasia, which is characterized in part by acid mucin-containing goblet cells, is detected by biopsy.[12]

The precise junction of the stomach and the esophagus may be difficult to determine endoscopically owing to the presence of a hiatal hernia, inflammation, and the dynamic nature of the gastroesophageal junction. If the squamocolumnar junction is above the level of the esophagogastric junction, as defined by the proximal margin of the gastric folds, biopsy specimens should be obtained for confirmation of columnar metaplasia.

Intestinal or columnar metaplasia may be seen in the cardia of normal individuals as well as in persons with chronic reflux disease, and the prevalence of intestinal metaplasia at a normal-appearing gastroesophageal junction varies from 5 to 36%. Dysplasia and an increased risk for carcinoma have been reported in patients who have intestinal metaplasia of the gastroesophageal junction or cardia, but the magnitude of that risk appears to be far less than that of Barrett esophagus and surveillance is not warranted.

Another potential approach to diagnosis is the cytosponge-trefoil factor 3, which is a non-endoscopic cell collection device coupled with an immunohistochemical biomarker. This small mesh sponge within a soluble gelatin capsule is attached to a string. The patient swallows the capsule, which is then retrieved about 5 minutes later. The mesh slightly abrades the esophageal mucosa, thereby collecting cells for analysis. In one randomized trial, this approach significantly increased the early diagnosis of Barrett esophagus.[A5]

TREATMENT

Patients who are diagnosed with Barrett esophagus require surveillance endoscopy at regular intervals (Fig. 124-5). They characteristically worry about cancer risk, which they may overestimate, face higher life insurance premiums, and may receive conflicting information on how best to treat their condition.

Proton pump inhibitors (see Table 124-1), which are the cornerstone of medical therapy for Barrett esophagus, consistently relieve symptoms and heal esophagitis. However, proton pump inhibitors, even at high doses, do not provide clear regression of Barrett histology, perhaps because alleviation of reflux symptoms is not necessarily equivalent to normalization of esophageal acid exposure. In fact, abnormal acid exposure persists in approximately 25% of Barrett esophagus patients despite twice-daily proton pump inhibitors. The precise importance of complete control of esophageal acid exposure in patients with Barrett esophagus remains unknown, but the combination of high-dose proton pump inhibitor therapy plus aspirin (300 to 325mg daily) can reduce the progression to high-grade dysplasia, adenocarcinoma, or death in patients with Barrett metaplasia.[A6] Antireflux surgery effectively alleviates GERD symptoms, and the indications for surgery are the same as those for patients with GERD without Barrett esophagus. Surgery should not, however, be viewed as a better cancer prevention tool.

Current practice guidelines, based on observational data, recommend endoscopic surveillance of patients with documented Barrett esophagus in an attempt to detect dysplasia and cancer at an early and potentially curable stage.[12] Before entering into a surveillance program, patients should be advised about risks and benefits, including the limitations of surveillance endoscopy as well as the importance of adhering to appropriate surveillance intervals. Other considerations include age, likelihood of survival over the next 5 years, and ability to tolerate either endoscopic or surgical interventions for early esophageal adenocarcinoma.

Systematic four-quadrant biopsies should be obtained at 2-cm intervals along the entire length of the Barrett segment after inflammation related to GERD is controlled with antisecretory therapy. Mucosal abnormalities, especially in the setting of high-grade dysplasia, should be resected endoscopically.

Surveillance intervals, determined by the presence and grade of dysplasia, are based on a limited understanding of the biology of esophageal adenocarcinoma. Surveillance for patients without dysplasia should occur every 3 to 5 years after an initial negative examination. If low-grade dysplasia is found, the diagnosis should first be confirmed by an expert gastrointestinal pathologist because of the marked interobserver variability in the interpretation of these biopsies. If confirmed, aggressive proton pump inhibitor therapy (see Table 124-1) is recommended to decrease inflammation and regeneration, which may make pathologic interpretation difficult. A repeat endoscopy should then be performed within 6 months of the initial diagnosis. If low-grade dysplasia is again confirmed, options include continued surveillance at 6- to 12-month intervals or radio frequency ablation, but ablation significantly reduces the risk for progression to high-grade dysplasia or to adenocarcinoma over the next 3 years.[A7]

If high-grade dysplasia is found, an experienced gastrointestinal pathologist should confirm the diagnosis. For patients with confirmed high-grade dysplasia, endoscopic ablation therapy with radio frequency ablation, endoscopic mucosal resection, or a combination is now recommended instead of surgery or continued surveillance.[13] For high-grade dysplasia patients with any visible abnormality, endoscopic mucosal resection is recommended for optimal diagnosis and staging. Surgery with esophagectomy is reserved only for patients who fail to respond to endoscopic ablation therapy or if the cancer is beyond stage T1a (intramucosal cancer).

PROGNOSIS

The risk that a patient with Barrett esophagus will develop esophageal adenocarcinoma is now estimated to be approximately 0.1 to 0.3% annually. With appropriate surveillance,[14] most patients with Barrett esophagus will never develop esophageal adenocarcinoma and will die of other causes.

ESOPHAGITIS

EOSINOPHILIC ESOPHAGITIS

Eosinophilic esophagitis is probably caused by an aberrant immune or antigenic response to food and aeroallergens that trigger chronic inflammation with dense eosinophilia in the esophageal mucosa. The disease is most common in children, adolescents, and young adults, but middle-aged adults are often affected as well. The estimated prevalence is about 0.5 to 1 case per 1000 population. Patients often have a personal and family history of other allergic disorders. A genetic predisposition is suggested by abnormal gene profiles in almost 50% of children with this disorder.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Children present with failure to thrive, nausea, vomiting, abdominal pain, and dyspeptic symptoms, whereas adults present with solid food dysphagia, food impaction, or chest pain. Boerhaave syndrome (see later) may also occur with this disease. Diagnosis is made by classic findings on endoscopy, such as linear furrowing, white exudates, and multiple rings (Fig. 124-6), accompanied by biopsies demonstrating eosinophilic infiltration (Table 124-2) in the absence of other conditions that can cause esophageal eosinophilia, such as GERD, achalasia, vasculitis, hypereosinophilic syndrome, Crohn disease, Ehlers-Danlos syndrome, graft versus host disease, infections, and drug hypersensitivity. The severity of the condition and its response to therapy can be assessed by both endoscopic and histologic criteria.[15]

TREATMENT AND PROGNOSIS

Treatment options for eosinophilic esophagitis include food elimination diets,[A8] proton pump inhibitors (see Table 124-1), and topical steroids.[16-18] Many patients may benefit from an empiric one, two, four- (or six-) food elimination diet that eliminates cow's milk protein (casein), soy, wheat, eggs, peanut/tree nuts, and seafood. An elemental diet also may be prescribed for severe disease. A formal allergy evaluation (Chapter 230) is required only in individuals with accompanying atopic diseases. Topical steroids (e.g., swallowed fluticasone, 880 μg twice daily; budesonide orodispersible tablets, 0.5 mg twice daily; or budesonide suspension, 1 mg twice daily) can safely sustain remission in 75% of patients, whereas up to 95% of patients may relapse when treatment is stopped.[A9,A10] Dupilumab (300 mg subcutaneously weekly for 12 weeks) is a useful option.[A11,19]

Most patients do well after an initial course of treatment. However, relapse is typical once therapy is discontinued, and chronic therapy is often needed, especially for those with prior complications such as food impaction, strictures, or a narrow-caliber esophagus.

TABLE 124-2 GUIDELINES FOR THE DIAGNOSIS OF EOSINOPHILIC ESOPHAGITIS

- Characteristic demographic and endoscopic findings
- Clinical symptoms of esophageal dysfunction
- *At least* 15 eosinophils in 1 high-power biopsy field
- Exclusion of other causes of esophageal eosinophilia

PILL-INDUCED ESOPHAGITIS

Pills (Table 124-3) can induce esophageal injury by producing a caustic acid solution (e.g., ascorbic acid and ferrous sulfate), producing a caustic alkaline solution (e.g., alendronate, button batteries), placing a hyperosmolar solution in contact with the esophageal mucosa (e.g., potassium chloride), or causing direct drug toxicity to the esophageal mucosa (e.g., tetracycline). Because prolonged contact is an essential part of the injury, predisposing factors for pill-induced injury include anatomic barriers, such as a stricture, a prominent aortic arch that compresses the esophagus, or improper ingestion of the pill because of inadequate fluid or improper positioning (i.e., lying down directly after taking the pill). The most common medications are tetracycline and its derivatives, but other commonly implicated medications include nonsteroidal anti-inflammatory drugs, bisphosphonates, ferrous sulfate, quinidine, and potassium chloride.

Patients usually complain of the acute onset of severe odynophagia. Radiographic or endoscopic findings may range from discrete ulceration to diffuse esophagitis. Treatment is generally supportive with discontinuation of the medication until the injury resolves. Although acid suppression is commonly recommended, there is no proof that this approach is beneficial. Patients should be given careful instructions to avoid lying down immediately after ingesting medication and to drink adequate fluids to prevent injury. Rarely, pill-induced injury may lead to strictures and even fistulas.

CAUSTIC INJURY

Potentially devastating caustic esophageal injuries may be caused by highly alkaline solutions, such as sodium hydroxide, or highly acidic solutions, such as sulfuric acid. The most common products that contain these substances are drain cleaners and industrial strength cleaners, but other corrosive substances include hair relaxers, oven and toilet bowl cleaners, and button batteries. Patients require emergent endoscopy to determine the degree of injury,

TABLE 124-3 MEDICATIONS COMMONLY ASSOCIATED WITH ESOPHAGITIS OR ESOPHAGEAL INJURY

ANTIBIOTICS
Tetracycline

Multivitamins
Theophylline

which helps predict long-term prognosis. No clear evidence supports routine steroids or antibiotics. Many patients will have lifelong disease marked by chronic strictures that require frequent dilation and even esophageal reconstruction. In patients with a severe initial injury, the risk for esophageal cancer is significantly increased.

ESOPHAGEAL MOTOR DISORDERS

OROPHARYNGEAL DYSFUNCTION

The cricopharyngeus and inferior pharyngeal constrictor are composed of striated muscle and innervated by upper motor neurons, the brain stem, and the cerebral cortex. Both primary myopathic and neuropathic disorders can result in dysfunction. The most common neurologic cause of oropharyngeal dysphagia is a cerebrovascular accident (Chapter 376). Other neuropathic disorders that may also affect function include myasthenia gravis (Chapter 390), brain stem tumors (Chapter 175), amyotrophic lateral sclerosis (Chapter 387), Parkinson disease (Chapter 378), Alzheimer disease (Chapter 371), postpolio syndrome (Chapter 349), Guillain-Barré syndrome (Chapter 388), and botulism (Chapter 271). Myogenic disorders that cause dysfunction include paraneoplastic antibody-mediated syndromes (Chapter 164), thyroid disease (Chapter 207), primary myopathies (Chapter 389) such as dermatomyositis and inclusion body myositis and drugs that cause myopathy such as statins and amiodarone.

Patients with oropharyngeal abnormalities experience dysphagia, often accompanied by postprandial coughing, hoarseness, and aspiration pneumonia. Treatment focuses on the underlying myopathic or neurologic cause and swallowing therapy, but prognosis is often poor owing to limited treatment options.

ACHALASIA

Achalasia, which is the prototypic esophageal motility disorder,[20] is characterized by insufficient relaxation of the lower esophageal sphincter accompanied by loss of esophageal peristalsis.

EPIDEMIOLOGY AND PATHOBIOLOGY

Achalasia can occur in patients of almost any age, from infants to nonagenarians, but it most commonly presents between 30 and 60 years of age. The prevalence is 10 per 100,000 in the United States, with all races affected and an equal distribution in men and women. The pathophysiology of achalasia most likely reflects an antibody-mediated autoimmune myenteric plexopathy in the lower esophageal sphincter and a generalized neuropathy in the esophageal body. The triggering event is unclear, but a viral cause is suggested. Injury to the lower esophageal sphincter neurons leads to a relative selective deficiency of nitric oxide. With this loss of the main functional inhibitory neurotransmitter, the sphincter loses its ability to relax. The neurochemical process that leads to aperistalsis is unclear.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The cardinal symptoms of achalasia are dysphagia to both liquids and solids, regurgitation, and chest pain. Some patients may have more subtle symptoms, including heartburn, presumably caused by esophageal stasis of acidic food content, weight loss, and aspiration pneumonia; in these settings, diagnosis is often delayed.

The diagnosis of achalasia relies on esophageal manometry and barium radiography. The classic radiographic appearance is esophageal dilation, stasis of contrast material, and a "bird's beak" appearance to the lower esophageal sphincter (Fig. 124-7). Manometry demonstrates high residual pressures of the lower esophageal sphincter and either simultaneous contractions or complete absence of peristaltic contractions (E-Fig. 124-1). Whether classification systems based on manometric findings can predict response is being studied. Endoscopy is recommended to exclude secondary causes of achalasia, such as gastroesophageal junctional cancer. Occasionally, patients present with a massively dilated esophagus and marked food retention. Radiographically, these patients develop a "sigmoid" esophagus with a radiographic picture similar to a sigmoid colon.

Achalasia may represent a paraneoplastic presentation of some malignancies, particularly small cell lung cancer (Chapter 177); in these patients, the tumor produces an antineuronal antibody (anti-Hu) that mediates the autoimmune lower esophageal sphincter plexopathy and produces a syndrome identical to primary achalasia. Some tumors, such as proximal gastric cancer, may also metastasize to or directly extend into the lower esophageal sphincter and produce an achalasia-like picture, possibly owing to extrinsic compression or tumor infiltration.

TREATMENT

Treatment options to decrease the functional obstruction at the level of the lower esophageal sphincter include the intrasphincteric injection of botulinum toxin, pneumatic dilation, surgical myotomy, and peroral endoscopic myotomy. Injection of botulinum toxin during endoscopy reduces symptoms and improves esophageal emptying in up to 90% of patients. Because symptoms typically recur within 6 to 24 months, this treatment is best for patients who are not candidates for more definitive therapies or to confirm the diagnosis of achalasia when clinical, radiographic, and manometric criteria are not conclusive.

In pneumatic dilation, a 30- to 40-mm pneumatic balloon is placed fluoroscopically to straddle the lower esophageal sphincter; the balloon is then inflated to tear the muscle fibers of the lower esophageal sphincter. In general, one pneumatic dilation will achieve 5 years of symptomatic remission in 70% of patients, and three dilations will succeed in 90% of patients. The downside of this procedure is the risk for perforation, which occurs in less than 1% of patients in experienced hands.

The third approach is a Heller myotomy, which is now typically performed laparoscopically. This long myotomy starts at least 2 cm below the lower esophageal sphincter and extends for about 6 cm upward past the sphincter; a loose fundoplication is performed to prevent gastroesophageal reflux. The 5-year success rate approaches 90%. Randomized controlled trials suggest that either pneumatic dilation or Heller myotomy will provide comparable clinical results over 2 years.[A12]

Peroral endoscopic myotomy is an alternative to laparoscopic myotomy. Results at 2 years are equal to or better than for pneumatic dilation[A13,A14] or laparoscopic Heller myotomy, and long-term follow-up data are encouraging; however, reflux is observed in approximately 50% of patients. As a result, patients should be aware of this issue when selecting between the endoscopic and laparoscopic approaches and should undergo endoscopy at 6 to 12 months after peroral endoscopic myotomy.[21]

In patients with massive dilation, esophageal dysfunction may warrant total esophagectomy because of life-threatening symptoms such as continued weight loss, recurrent aspiration pneumonia, or tracheal compression. In patients with underlying paraneoplastic malignancy, treatment of the tumor may be helpful, and botulinum toxin has been tried with anecdotal success.

PROGNOSIS

No treatment approach is curative, and all are palliative. Recurrent symptoms may be related to an incomplete myotomy, herniation or unwrapping of the fundoplication, esophageal strictures, Barrett esophagus, or just the natural history of the disease. Achalasia patients also may be predisposed to squamous cell carcinoma of the esophagus, although current evidence does not support cancer screening.

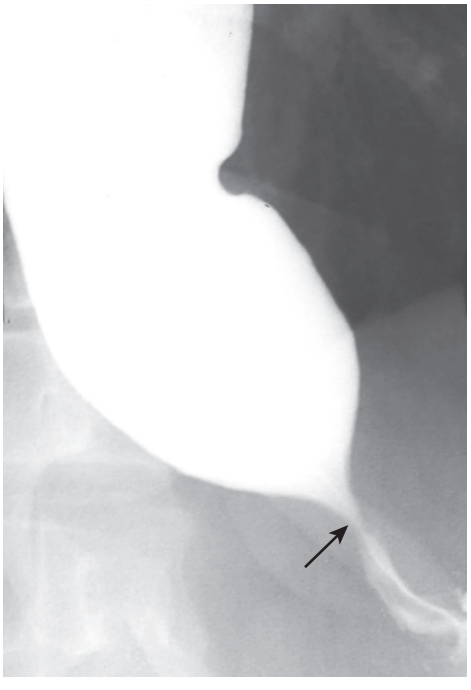

FIGURE 124-7. Esophagogram of a patient with idiopathic achalasia. Note the dilated esophagus and distal tapering result in a "bird's beak" deformity in the area of the lower esophageal sphincter *(arrow)*. (Courtesy Marc Levine, MD.)

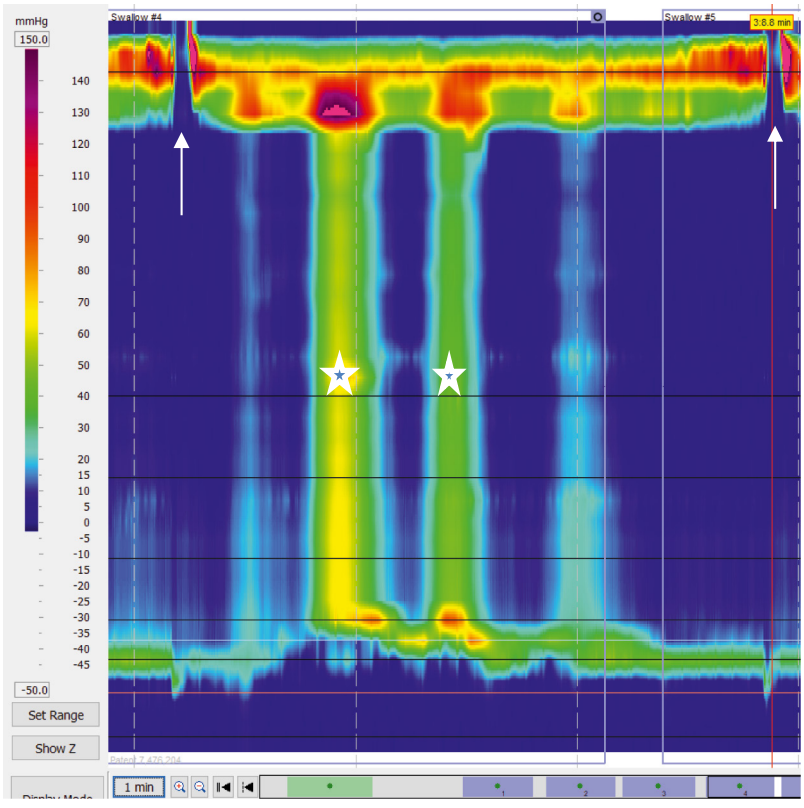

E-FIGURE 124-1. High resolution pattern of type II achalasia. Proximal high-pressure zone is upper esophageal sphincter. Lower high-pressure zone is lower esophageal sphincter. Swallows are designated by *arrows*. *Stars* represent examples of isobaric pressurizations in response to swallow. Note the lower esophageal sphincter moves proximally with swallows.

DIFFUSE ESOPHAGEAL SPASM

Diffuse esophageal spasm is found in fewer than 5% of patients who undergo manometry for symptoms of chest pain, dysphagia, or both. The pathophysiology of diffuse esophageal spasm is not well understood, but a deficiency of nitric oxide in the esophageal body may lead to a loss of control of esophageal peristalsis, high pressures, and rapid velocity contractions.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Classically, patients have symptoms of intermittent chest pain (Chapter 123), dysphagia, or both. On endoscopic ultrasound, patients may demonstrate thickening of the circular and longitudinal muscle layers. Diffuse esophageal spasm is defined manometrically by premature rapid contractions in at least 20% of all swallows, accompanied by normal peristalsis.[22] Radiographically, diffuse esophageal spasm is characterized by a "corkscrew" esophagus with multiple simultaneous contractions that obliterate the lumen (Fig. 124-8).

TREATMENT AND PROGNOSIS

Treatment of these patients is challenging, and clinical trials have not demonstrated efficacy of any therapy. Empirical therapy may be tried with agents that relax smooth muscle or augment the nitric oxide content, such as hyoscyamine (0.125 mg sublingually), calcium-channel antagonists (nifedipine, 10 mg sublingually), nitroglycerin (0.3 mg sublingually), and sildenafil (50 mg orally). Injection of botulinum toxin into the esophageal body has had equivocal results. Antidepressants, particularly low-dose tricyclics (e.g., imipramine, 10 to 50 mg before bedtime), have had some success. For patients with dysphagia, sphincter options include botulinum toxin injection and pneumatic dilation, but surgery is not indicated unless there is evidence of achalasia. Early results of peroral endoscopic myotomy are encouraging. In general, these disorders can be difficult to manage but are not life-threatening.

OTHER MOTILITY DISORDERS

Jackhammer esophagus and hypertensive peristalsis are recently described manometric diagnoses that formerly were called nutcracker esophagus. Both are characterized by high-amplitude peristaltic contractions and are of uncertain clinical significance. Antisecretory therapy with proton pump inhibitors (see Table 124-1) is often warranted.

Isolated incomplete relaxation of the lower esophageal sphincter, also known as esophagogastric junction outflow obstruction, may represent a variant of achalasia and should be treated as such in patients with dysphagia and supportive findings or functional imaging or impedance planimetry. This entity also may be seen with structural and vascular abnormalities in the vicinity of the gastroesophageal junction. Patients with manometric findings of low-amplitude contractions, failed contractions, or contractions with large breaks have weak peristalsis, which is commonly seen in patients with severe underlying GERD.

STRUCTURAL ABNORMALITIES

CRICOPHARYNGEAL BARS

A cricopharyngeal bar diagnosed by a prominent impression of the cricopharyngeus, reflects an inability to relax the upper esophageal sphincter maximally during the flow of barium, with a sustained decrease in compliance. The decrease in cross-sectional area of the upper esophageal sphincter is likely caused by fibrosis. This condition may be asymptomatic or accompanied by symptoms of oropharyngeal dysphagia to solids. Treatment of symptomatic patients is either large-caliber dilation or surgical or endoscopic myotomy; the clinical results are generally excellent.

ESOPHAGEAL DIVERTICULA

Esophageal diverticula are encountered in fewer than 1% of upper gastrointestinal radiographic studies and account for less than 5% of cases of dysphagia. Esophageal diverticula may occur in one of three locations: above the upper esophageal sphincter, in the mid-esophagus, and just above the lower esophageal sphincter.

Zenker diverticulum is a pouch that protrudes posteriorly above the upper esophageal sphincter (Fig. 124-9). This protrusion occurs through a triangular region known as Killian triangle, which is bordered above by fibers of the inferior constrictor muscle and below by the cricopharyngeal muscle. It is thought to be caused by increased hypopharyngeal pressure that results from decreased compliance and impaired opening of the upper esophageal sphincter. Small diverticula may be asymptomatic, but increasing size is associated with globus, dysphagia to solids or liquids, regurgitation of undigested food, halitosis, and aspiration. Although no treatment is needed for asymptomatic patients, open or endoscopic surgery is indicated when symptoms occur. Prognosis after surgery is excellent.

Mid-esophageal diverticula, which are focal outpouchings of the middle of the esophagus, are thought to be related to an underlying abnormality of esophageal motility. Past tuberculosis may result in such diverticula. Symptoms typically include dysphagia with or without regurgitation, and diagnosis is usually made with barium contrast radiography. Surgical diverticulectomy with myotomy or endoscopic myotomy is reserved for patients with symptoms.

Epiphrenic diverticula are herniations of mucosa and submucosa through the muscular layers of the distal 10 cm of the esophagus. They are most commonly caused by functional lower esophageal sphincter obstruction, owing to

FIGURE 124-8. Barium esophagogram showing a "corkscrew" esophagus in a patient with diffuse esophageal spasm. The patient had dysphagia, chest pain, and normal endoscopic findings. (Image courtesy of Marc Levine, MD.)

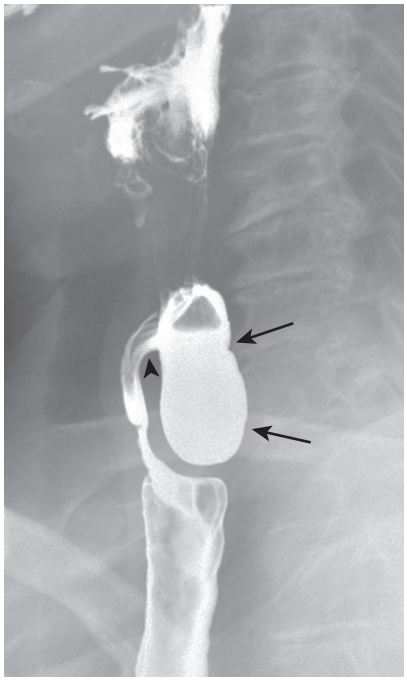

FIGURE 124-9. Barium radiograph of Zenker diverticulum *(arrows)* and cricopharyngeus *(arrowhead)*. (Courtesy Marc Levine, MD.)

underlying motility abnormalities such as achalasia or diffuse esophageal spasm, but also may be associated with mechanical obstruction, owing to a leiomyoma, prior surgery, stenosis, stricture tumor, or web. Epiphrenic diverticula may be asymptomatic or cause dysphagia, regurgitation, odynophagia, chest pain, heartburn, or aspiration. Diagnosis is typically made by barium radiography (Fig. 124-10), but endoscopy is recommended to exclude a structural cause of obstruction, and esophageal manometry is recommended to evaluate for underlying motility abnormalities. No therapy is warranted in asymptomatic patients, but symptomatic patients generally do well with surgical diverticulectomy, repair of the defect in the esophageal wall, and relief of the underlying obstruction, usually with a myotomy and partial fundoplication.

RINGS AND WEBS

Esophageal rings are concentric areas of narrowing, usually in the distal esophagus. *Schatzki ring* (Fig. 124-11) is a thin, fixed, circumferential membrane-like narrowing at the gastroesophageal junction, typically at the proximal border of a hiatal hernia. The cause may be congenital, secondary to a pleat of redundant mucosa, or related to gastroesophageal reflux. Symptoms typically occur if the ring results in a lumen that is 13 mm or less in diameter. Classic symptoms are intermittent dysphagia to solids or impaction of solid food. Diagnosis is best accomplished with barium radiography, especially for rings larger than 13 mm in diameter, which may be missed at the time of endoscopy. Treatment involves use of large-caliber dilators at least 18 mm in diameter. Long-term therapy with proton pump inhibitors (see Table 124-1) may prevent relapses. Most patients relapse after a single dilation.

Muscular rings, which are located several centimeters above the squamocolumnar junction, are composed of mucosa, submucosa, and muscle. Barium radiography and endoscopy reveal a focal constriction of variable diameter. Optimal therapy is unclear. Dilation leads to only partial or temporary relief. Other treatment modalities include injection of botulinum toxin and anticholinergic agents.

Esophageal webs are thin, eccentric, membranous areas of narrowing that may be found anywhere in the esophagus but most commonly are in the proximal region (Fig. 124-12). The pathogenesis of webs is unknown, but they are associated with a number of systemic diseases, including bullous skin disorders, chronic graft-versus-host disease, and iron deficiency anemia.

HIATAL HERNIA

A hiatal hernia involves herniation of elements of the abdominal cavity through the diaphragmatic hiatus. A sliding, or type I, hernia, in which the gastroesophageal junction is displaced above the diaphragmatic hiatus, is the most common type. Type I hiatal hernias typically are not associated with symptoms or are associated with heartburn or acid regurgitation. Treatment is the same as for GERD.

In a type II, or true, paraesophageal hernia, which is uncommon, the gastroesophageal junction is in its normal location, but the fundus and parts of the greater curvature of the stomach herniate into the mediastinum alongside the esophagus. With type III or mixed paraesophageal hernia, the gastroesophageal junction and a large part of the stomach herniate into the mediastinum. Both types of paraesophageal hernias present with symptoms of postprandial distress, such as epigastric pain, chest pain, substernal fullness, shortness of breath, nausea, or vomiting. Iron deficiency anemia may be seen with large hiatal hernias in which at least one third of the stomach is in the chest; linear gastric erosions at the top of gastric folds at the level of the diaphragm have been implicated as a cause of chronic blood loss. Asymptomatic paraesophageal hernias do not require surgery. Symptomatic paraesophageal hernias warrant surgical therapy because of the risk for strangulation, bleeding, perforation, or obstruction.

THE ESOPHAGUS IN SYSTEMIC DISEASES

SCLERODERMA

Up to 90% of patients with scleroderma (Chapter 246) have esophageal involvement, thereby making it the most common gastrointestinal abnormality in the disease.[23] The classic manometric and radiologic findings are aperistalsis of the distal two thirds of the esophagus and hypotensive or patulous lower esophageal sphincter on manometry or radiography, respectively. Only one third of scleroderma patients have these classic findings. These findings result initially because of neuropathy and later because of the myopathy. The main clinical manifestation is severe gastroesophageal reflux. Delayed gastric emptying may also occur. Marked esophageal stasis may also lead to *Candida* esophagitis. A patulous (on radiography) or hypotensive (on manometry) lower esophageal sphincter strongly supports the diagnosis. Proton pump inhibitor therapy (see Table 124-1) is the cornerstone of treatment. Lifestyle changes, including small frequent meals and avoiding nighttime meals, may reduce the gastric symptoms. Antireflux surgery can exacerbate dysphagia by creating a functional high-pressure zone in the distal esophagus and is thus usually contraindicated. Unfortunately, many patients suffer from chronic GERD and are at risk for developing Barrett esophagus and recurrent strictures.

AMYLOIDOSIS

Amyloidosis (Chapter 174) may lead to smooth muscle and autonomic nervous system dysfunction that involves the esophagus in a pattern similar to scleroderma. Patients will have both dysphagia and severe reflux because of esophageal aperistalsis and a hypotensive lower esophageal sphincter. Dysphagia may result not only from the motility changes but also from diffuse esophageal rigidity and loss of compliance owing to amyloid infiltration of the esophageal wall. Rarely, an achalasia-like pattern may develop. No treatment improves the esophageal manifestations of amyloidosis, other than treatment for the underlying disease and high-dose proton pump inhibitors given twice daily.

OTHER SYSTEMIC DISEASES

Dermatomyositis (Chapter 248) principally involves the striated muscle of the oropharynx and proximal esophagus, but sometimes the distal esophagus may lose normal peristaltic function. Symptoms can be oropharyngeal or esophageal depending on the site of greatest muscular involvement. Dysphagia may be an early presenting symptom of dermatomyositis, and the esophagus may be involved in 10 to 50% of patients. Treatment is directed at the generalized myositis because there are no specific treatments for the esophagus. Swallowing therapy may sometimes be helpful. Return of swallowing commonly lags behind recovery of other striated muscle symptoms.

Esophageal involvement in *systemic lupus erythematosus* (Chapter 245) is not as prominent as in scleroderma, dermatomyositis, or mixed connective tissue disease. Dysphagia occurs in fewer than 15% of patients and may be caused by decreased salivation from secondary Sjögren syndrome or reduced esophageal peristalsis. Other causes of esophageal symptoms in patients with systemic lupus erythematosus include GERD, esophageal ulcers, esophageal infection, and medication-induced esophagitis. *Behçet disease* (Chapter 249) causes esophageal ulcers in less than 15% of affected patients. Ulcers are typically located in the middle third of the esophagus and are often associated with ulcers in the stomach, ileum, or colon. Rare esophageal lesions include strictures, varices, and fistulas connecting with the trachea. These complications can be severe and debilitating.

Esophageal involvement in *Crohn disease* (Chapter 127) is uncommon but has been described in up to 1 to 2% of patients. Occasionally, isolated esophageal disease may occur. Ulceration is the most common manifestation, but strictures, fissures, esophagobronchial fistulas, mediastinal abscesses, and aphthoid lesions have been described. Patients typically complain of dysphagia and odynophagia. Treatment and prognosis are as for the underlying Crohn disease.

In the *Ehlers-Danlos syndrome* (Chapter 239), hiatal hernias are common, and structural esophageal defects such as giant epiphrenic diverticula, megaesophagus, and spontaneous esophageal rupture may also be seen.

SKIN DISORDERS THAT INVOLVE THE ESOPHAGUS

Lichen planus (Chapter 405) often involves the esophagus. Patients generally present in the fourth to seventh decade of life. Histologically, the lesions in up to 25 to 50% of patients show a characteristic lymphohistiocytic inflammatory infiltrate and apoptotic basal keratinocytes known as Civatte bodies. Lesions classically occur on the buccal mucosa and the tongue, but the disease may also involve other areas of the oral cavity and the esophagus, conjunctiva, nose, larynx, stomach, bladder, and anus. Most patients are asymptomatic or have only minor symptoms, but patients with severe esophageal lichen planus often develop strictures and may present with dysphagia, odynophagia, and weight loss. Strictures are typically proximal but may be variable in length and location, sometimes involving most of the esophageal body. Patients may present with esophageal lichen planus in the absence of extraesophageal disease. Endoscopic findings, which can be subtle and nonspecific, include peeling mucosa, hyperemic focal abnormalities, and submucosal plaque or papules. High-dose systemic steroids, starting with at least 40 mg prednisone and then tapering over 1 to 2 months, are often successful, but relapse is common when steroids are tapered. Topical steroids, tacrolimus, and methotrexate also have been tried. Dilation and intralesional steroids can alleviate the symptoms associated with strictures, but symptoms frequently recur in less than a year and necessitate repeat dilations. The esophageal lesions of lichen planus may have malignancy potential.

Pemphigus vulgaris (Chapter 406) patients who experience acute flares may have upper gastrointestinal symptoms (dysphagia, odynophagia, or retrosternal burning) in 80% of cases and biopsy-proven esophageal pemphigus lesions in nearly 50% of cases. Pemphigus vulgaris may rarely be isolated to the esophagus. Paraneoplastic pemphigus (Chapter 406), most commonly reported with lymphoreticular disease, also may involve the esophagus. Like lesions on the skin, esophageal lesions may be flaccid blisters or erosions, but they may also appear as red longitudinal lines along the entire esophagus. Like cutaneous and oral pemphigus, esophageal pemphigus is generally treated with corticosteroids.

In *mucous membrane pemphigoid* (cicatricial pemphigoid; Chapter 406), the esophagus is the most common site of gastrointestinal involvement, but esophageal disease occurs in less than 15% of patients. The esophageal disease can present as long as 10 years after disease onset and may be the only presentation of the disease. Patients complain of dysphagia and odynophagia. Imaging typically shows erosions, strictures, bullae, or webs. Treatment generally is as for the skin disease.

In *dystrophic epidermolysis bullosa* (Chapter 406), approximately 70 to 95% of patients develop esophageal stenosis or strictures. Strictures are especially common in children with recessive dystrophic epidermolysis bullosa, whereas fewer than 10% of patients with dominant dystrophic epidermolysis bullosa develop strictures by age 50 years.

ESOPHAGEAL INFECTIONS

HERPES SIMPLEX VIRUS

Herpes simplex virus (HSV; Chapter 345) esophagitis, which is usually caused by HSV-1, is a well-recognized disease in immunocompromised patients but may also occur in immunocompetent hosts. HSV typically presents as severe odynophagia. Endoscopy and radiology characteristically demonstrate multiple ulcers and friable mucosa, predominantly involving the distal esophagus. Mucosal biopsies demonstrate typical intranuclear inclusion bodies. Depending on the severity of the esophageal disease and the underlying health of the patient, treatment options may include intravenous acyclovir, 5 mg/kg every 8 hours for 7 days, or oral acyclovir, 400 mg five times daily for 7 days, combined with symptomatic treatment.

CANDIDIASIS

Esophageal candidiasis is common in patients with human immunodeficiency virus (HIV) infection or with impaired cellular immunity owing to hematologic malignancies, immunosuppressive therapy, or diabetes mellitus.[24] Esophageal candidiasis is also seen in immunocompetent patients who are taking corticosteroids and in individuals with marked esophageal stasis, such as patients with advanced achalasia or scleroderma. Esophageal candidiasis characteristically presents with symptoms of odynophagia, dysphagia, and chest pain. Endoscopy demonstrates scattered or coalescent yellow-white mucosal plaques (Fig. 124-13). Given the high prevalence of esophageal candidiasis in HIV patients, some recommend treating symptomatic HIV patients empirically and reserving endoscopy for refractory symptoms. Mild oropharyngeal candidiasis may be treated with topical clotrimazole (10 mg troche five times daily for 7 to 14 days) or nystatin (600,000 units four times daily for 7 to 10 days), whereas oral fluconazole (100 mg daily for 7 to 14 days) is needed for moderate to severe oropharyngeal and esophageal candidiasis.[25] Intravenous fluconazole and amphotericin B deoxycholate (Chapter 307) are appropriate options for severe esophageal candidiasis and toxemia or for patients who cannot tolerate oral therapy.

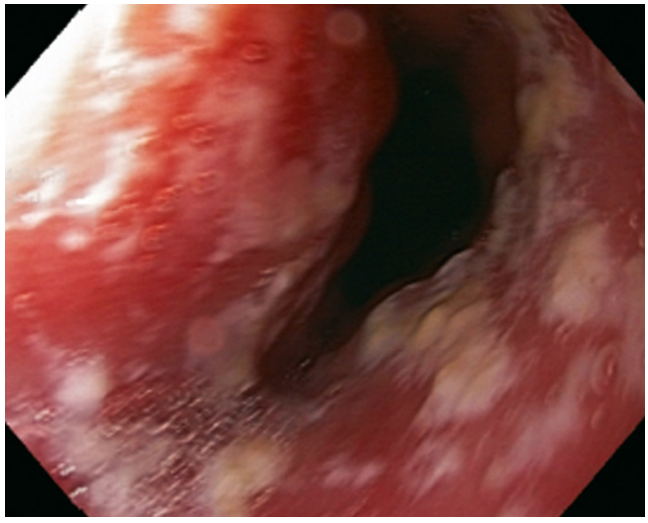

FIGURE 124-13. ***Candida*** **esophagitis.**

CYTOMEGALOVIRUS

Cytomegalovirus (CMV; Chapter 347) infection of the esophagus is almost exclusively found in immunocompromised patients. Patients infected with the HIV virus with low CD4 counts are most commonly affected, but CMV also occurs in transplant recipients on immunosuppressive therapy and in immunosuppressed patients with malignancy. Patients typically have severe odynophagia with evidence of radiographic or endoscopic esophageal ulcers. Treatment is usually with intravenous ganciclovir (5 mg/kg once or twice daily for 10 to 14 days) or foscarnet (90 mg/kg every 8 to 12 hours until healing occurs).

BACTERIAL ESOPHAGITIS

Bacterial infection of the esophagus is uncommon but can occur in immunosuppressed patients, typically those with neutropenia and malignancy. Patients present with chest pain or odynophagia, or both, and endoscopy reveals extensive erosions, usually in the distal esophagus. Biopsy and Gram stain reveal acute and chronic inflammation and bacteria, commonly gram-positive organisms, especially viridans-group streptococci, *Staphylococcus aureus, Staphylococcus epidermidis,* and *Bacillus* species. Treatment is with the appropriate antibiotics administered parenterally.

HUMAN PAPILLOMAVIRUS
